Effect of Mowing and Feeding-off Plants on the Production of Side Shoots.—Removing the principal stems from plants either by mowing or feeding-off is very beneficial to the reproductive powers of the plants, inasmuch as it reduces the amount of leaf evaporation, and thus increases the amount of water in the soil; this increase is, however, only slight, because at the same time it (mowing, &c.) raises the temperature of the soil by favouring insolation; it also allows the free access of light to the young shoots. It is therefore advisable to cut grasses, clover, &c., as early as possible, for by prolonging the growth the soil becomes dry and the light is shut out from young shoots. Cutting must not be too frequent, for frequent interruption of growth lowers the yield. Even when the ground is already dry it is better to mow the plants, because in case rain comes the leaves of unmown plants hold back the water which would be useful in the soil. Mowing potato plants in an early stage of growth lowered both weight and number of harvested potatoes.

Removing the shoots from the seed tubers increases the number of potatoes harvested; there are, however, a smaller number of large and medium tubers, and the total harvest is slightly lowered.

Removing the top joint at a not too early period from peas, beans, and vetch plants increased the number of side shoots, but lowered the yield of seed and partly of the straw. Experiments with maize plants, in which the male blossom was removed from alternate plants, so that the blossoms of the untouched plants were sufficient to fertilise all the female blossoms, showed that this operation increased the number of heads, the total harvest, the quantity of ripe corn, and in most cases the straw, whilst the number of shoots from the parent stem was in most cases diminished. D. A. L.

Effect of Variations in the Quantity of Oxygen on the Growth of Plants. By A. WIELER (*Bied. Centr.*, 1883, 715).—The object of the present investigation is to ascertain what reduction of oxygen in the atmosphere is required to arrest vegetable growth, or to diminish the rate of development. Seedlings of the following plants were employed:—*Helianthus annuus*, *Vicia Faba*, *Lupinus luteus*, *Brassica Napus*, *Curcubita Pepo*, *Coprinus lagopus*, *Mucor Mucedo*, and *Phycomyces nitens*. The first experiments showed that the quantity of oxygen capable of sustaining vegetable growth is an extremely small quantity; thus the limit for *L. luteus* is from 1·32 to 0·00001865 c.c.* of oxygen in 1500 c.c., whilst the limit for *Phycomyces* is from 1·94 to 2·90 c.c. In another series of experiments, plants grown in rarefied air are compared with those grown in atmospheric air. With *H. annuus* growth gradually increases during the diminution of pressure to 100 mm., the growth then diminishes suddenly until 5 to 10 mm. is reached, when the rate of growth is the same as in ordinary air. The maximum of vigour for *V. faba* lies between 100 and 300 mm., whilst the diminution commences at 50 mm. Under increased pressure the growth at first decreases, but subsequently increases, and then becomes more considerable than in the open air. These results help to explain the rapid growth of plants in elevated regions. D. A. L.

---

* This number is very probably a misprint.

Influence of Radiant Heat on the Growing Parts of Plants. By J. WORTMANN (*Bied. Centr.*, 1883, 685—687).—For every species of plant there is a certain range of temperature especially favourable to the growth of the part of the plant exposed to it, and between the maximum and minimum of this range is the most favourable point (the optimum). Experiment has proved that plant-growth depends essentially on the degree of temperature to which a plant is exposed. Van Tieghem has therefore suggested that if the growing part of a plant is exposed to unequal temperatures on different sides, the side exposed to the most favourable temperature would grow quicker than the other, and thus cause curvature with the convexity towards the most favourable source of heat. The author has experimented in this direction with *Phycomyces nitens*, *Lepidium sativum*, and *Zea Mays*, and finds that his observations do not agree with the above hypothesis, inasmuch as the parts of plants capable of curvature bend sometimes towards and sometimes from the source of heat, irrespective of increased or retarded growth resulting from either favourable or unfavourable heating; thus maize always bends towards the source of heat, even when the other side is exposed to the optimum temperature. D. A. L.

Correlative Growths in the Vegetable Kingdom. By J. v. SACHS (*Bied. Centr.*, 1883, 714).—The author applies the term "correlation of growth" to the influence a growing organ exerts on the growth of another organ in the same plant. Many illustrations are given. For example, cutting off the leaf-shoots of a potato plant prevents the formation of underground tubers, whilst removing the underground tubers causes the formation of tubers on the leaf stem above ground. When the radiating top of *Abies excelsa* is removed, lateral branches develop, become vertical, and finally assume the form of radiating tops. This the author explains by the assumption that the organs of the plant act as competitors for the common store of nutritious matter, each homogeneous organ, so to speak, competing for its own special food, its removal, therefore, necessitating a more vigorous attack on the nutritious matter in order to effect its regeneration. Another form of correlation depends on the interdependence of different organs, that is, when the increased or diminished development of an organ influences the development of another organ connected with it functionally as a whole. For instance, in ordinary land plants the development of leaf surface is accompanied by production of chlorophyll, rising of sap, and consequently formation of wood and extension of roots, whilst in submerged water plants capable of absorbing nutriment with their entire surface transpiration is not required, and so the formation of wood and extension of root are found wanting. Other examples are given. D. A. L.

Influence of the Amount of Soil on the Development of Roots of Various Plants. By HELLRIEGEL (*Bied. Centr.*, 1883, 756—775).—The proper structure of the roots was first observed by planting seeds in boxes full of sawdust. After growing for six or eight weeks the plants were removed, the roots washed, and their form noted. In the case of the pea, the original tap root throws out branches which grow faster than the tap root, and in time surpass it in length and abundance of secondary roots. Beans begin in the same manner, but the first side roots are stronger and stiffer than those of the pea, and do not grow to such a length. They increase, however, regularly throughout, giving the whole root the form of an inverted cone, the original tap root being the longest. The root of the lupine is developed on an entirely different plan, assuming in time the form of an upright cone, the upper part of the tap root being free from branches, which are almost confined to the lower half. During the earlier stages of growth the roots of all three grow very rapidly, but their relative growth diminishes with the age of the plant. In the case of oats, the total length of root branches was found to average 40 metres per plant. Diminution of the volume of the soil was found to damage lupines earliest, then buckwheat, peas, barley, clover, and beans in descending order. When the quantity of soil is too small for the proper growth of the roots, the crops are damaged in proportion to the diminution in the soil. The same result occurs when the plants are sown too closely together—they do not thrive so well, and their time of vegetation is shorter. In the case of barley, the author found that one plant per kilo. of soil was about the right proportion. The depth at which the seeds were planted (2—6 cm.) made very little difference in the growth of the roots. J. K. C.

Effect of Altitude on Plant Growth. By A. ANGOT (*Bied. Centr.*, 1883, 713).—The author has observed that the harvest period of winter rye in France is delayed four days for every increase of 100 meters in altitude. D. A. L.

Studies on Evaporation. By A. SORAUER (*Bied. Centr.*, 1883, 687—699; comp. Abstr., 1881, 1059).—Previous researches have shown that the water which is evaporated consists both of that produced within the plant by oxidation and that which has served simply as a carrier of nutritious matter and has passed through the organism undecomposed. It has also been proved that the greater the amount of new substance added, the more carbonic anhydride and water is given up by the plant. Hence, in the author's opinion, the amount of evaporation should indicate the amount of work done by a plant, and vary therefore according to the size of the working parts of the plant. Making use of the data supplied in this manner, the author now finds that with plants of the same species, and grown under like conditions, those having less leaf-surface work harder to produce a definite amount of substance than those having a greater leaf surface, and therefore the transpiration per square centimeter of leaf is smaller the greater the available leaf surface of the individual plant. Thus in some experiments with three gourd plants he found that diminishing the leaf surface by removal of leaves from one plant on two occasions did not alter the amount of evaporation in the least, and even when half the leaves were removed from another plant, a reduction in the amount of evaporation ensued at first, but after eleven days the evaporation was equal to that of an untouched plant. Thus by removing some of the leaves of a plant, the remaining leaves do relatively more work and develop a higher relative evaporation coefficient than those of an untouched plant. This extra activity is derived from the roots, and therefore the growth above ground is going on at the expense of the subterranean growth, and the result of this diminished root growth is made evident in subsequent development of the plant, *e.g.*, in the size of the organs above ground, &c.

D. A. L.

Respiration and Transpiration of Fungi. By G. Bonnier and L. Mangin (*Bied. Centr.*, 1883, 712).—All the present experiments with fungi prove that the volume of oxygen absorbed during respiration is greater than the volume of carbonic anhydride produced, and in various kinds of fungi the proportion of the absorbed oxygen to the volume of carbonic anhydride fluctuated between 0·55 and 0·81. When the respiration takes place in a confined volume of air, the oxygen is soon entirely consumed, whilst on account of internal respiration large quantities of carbonic anhydride are continually evolved. Respiration increases regularly with the temperature, while the proportion of oxygen to carbonic anhydride does not change perceptibly for one and the same species. The intensity of respiration increases with the humidity of the air. Diffused light, on the other hand, lowers it, the reduction in many cases amounting to two-thirds of the total quantity of carbonic anhydride. Respiration is, however, greater under the influence of the more refrangible rays than it is under the influence of the less refrangible rays.

Evaporation is greater in diffused light than in darkness, the difference amounting in some cases to one-half of the weight of the water evaporated.

D. A. L.

Function of Tannin in Plants. By E. Kutscher (*Bied. Centr.*, 1883, 713).—Investigations were made with *Vicia faba*, *Helianthus tuberosus* and *annuus*, *Ricinus sanguineus*, and *Phaseolus multiflorus*, plants well adapted for the purpose, as they were found to be typical examples of the different locations of tannin; inasmuch as it is distributed throughout the plant in the *Vicia* and *Helianthus*, whilst it is only local and inactive in the *Ricinus* and *Phaseolus* plants. In the last two species, tannin is not found in the top of the plants, nor in the cell-walls, nor in the general sap during the period of vegetation; moreover, it is never equally distributed throughout the tissue-complex, but is confined in separate secluded cells where it, at the most, changes to a red colouring matter without being used in the general development, whilst with the *Vicia* and *Helianthus* tannin is found in all the tissues soon after germination, but disappears with the formation of organs. *Vicia* tannin is iron-green, *Ricinus* iron-blue. Tannin apparently takes part in the formation of and primary differentiation of the tissues, but does not take part in the further growth of the cell-walls; the most feasible use attributed to this substance is in aiding respiration.

D. A. L.

Effect of Drying on the Germination of Seeds. By P. v. TIEGHEM and G. BONNIER (*Bied. Centr.*, 1883, 715).—It is well known that dried seeds can germinate in a perfectly normal manner, and that in such cases the temperature and length of exposure are of the utmost importance. For example, two lots of *Vicia faba* seed were exposed respectively for 24 hours to temperatures of 35° and 85°; both lots were now treated in the same manner, and after three days the 35° lot had germinated, whilst the other lot had not. After eight days, all had germinated; those from the seed exposed to the lower temperature were stronger, and continued developing; whilst those of the 85° portion soon stopped in their germination. Cereal seeds were now dried until they had a constant weight at 100° (*a*) and at 35° (*b*); of series (*a*) none germinated; series (*b*) germinated as follows:—Rye, 100 per cent.; oats, 90; barley, 83; and maize 20 per cent. Rye-grain, even after exposure for a short time to 100°, showed signs of vitality, and after its *drying* (for six days) at 80° and then setting for germination, in four days all the grains had sprouted. The deadly temperature for rye-grain is therefore considerably higher than the coagulating temperature of albumin. D. A. L.

Presence of Mannitol in the Anana. By L. LINDET (*Bull. Soc. Chim.*, **40**, 65—66).—In the course of the analysis of ananas from Pernambuco and Brazil, the author isolated crystals of mannitol; the quantity obtained was equal to more than 1 per cent. of the fresh fruit. The identity of the crystals with mannitol was established by combustion, crystalline form, solubility, and absence of rotatory and cupric oxide reducing power. V. H. V.

Sulphuring of Vines. By A. BASAROW (*Bied. Centr.*, 1883, 700).—The author is not satisfied with the explanations already offered as to the manner in which sulphur acts on the vines. He therefore made the air from a sulphured vine pass through a solution of caustic soda, and on subsequent examination he detected sulphurous acid, and determined it in the soda-solution, showing that oxidation of the sulphur takes place. D. A. L.

Nature of Hop Mildew and Means of Counteracting it. By A. SCHWARTZ (*Bied. Centr.*, 1883, 718—719).—Mildew is the result of an unsound state of the hop-plant caused by climatic influences, cold winds, severe frosts, sudden changes of temperature, and excessive humidity, whereby the plant is weakened, its growth hindered, and it therefore becomes an easy prey to the insects. The hop louse, *Phrodon humili*, lays its eggs either in the ground in the neighbourhood of hop gardens or on the stems and leaf-stalks of hop-plants, choosing by preference the sickly plants as noted above. Plants sheltered by trees or hills, or otherwise protected from the changes of weather, are exempt from these visitations. Proximity to the sea is destructive, to a certain extent, to these insects. In wet seasons, plants grown on rich soils are more subject to mildew than those produced on poor and therefore drier soils. Moreover, plants set late can resist the attack better than those sown earlier, inasmuch as they are less frequently exposed to fluctuations of temperature. Mildew can be prevented by washing with soft soap and water, provided the washing is commenced in time, regularly and systematically continued until the cleansing is complete, and carefully watched.

Further researches are required to study the habits, &c., of these and other leaf lice. D. A. L.

Composition of Saxon Barley. By M. Märcker (*Bied. Centr.*, 1883, 698—700).—The author has compared the results obtained from the examination of several samples of Saxon barley with results obtained from other kinds of barley, in the following manner:—

Constituent.	Mean of results, per cent.		
	For Saxony barley. By the Author.	For the composition of barley.	
		By J. Kahn.	By E. Wolff.
Moisture	15·0	13·8	14·3
Albuminoïds	8·4	11·2	10·0
Fat	1·6	2·1	2·5
Non-nitrogenous extractive matter	66·8	65·8	63·9
Fibre	4·6	5·2	7·1
Ash	3·6	2·2	2·2

It will be observed that in the Saxon barley the percentage of albuminoïds and fibre is low, whilst the amount of non-nitrogenous extractive matter is large; and it is these qualities which make the barley of such high value. With regard to the low percentage of albuminoïds, the author makes no notes of manuring, mode of cultivation, or kinds of barley analysed; if the greater part analysed consisted of Chevalier barley, then the results would necessarily be low, for this variety of barley only contains on an average 8·19 per cent. of albuminoïds. D. A. L.

Feeding-stuffs. By A. Voelcker (*Bied. Centr.*, 1883, 711).—The author has obtained the following results in various analyses:—

	Locust beans.		Dari seeds.	Millet.		Fine Russian linseed cake.
	Shell and seed.	Seed.		Crushed.	Not crushed.	
Moisture	14·73	14·11	12·55	12·85	13·19	11·13
Fat	0·62	2·03	2·93	3·91	3·83	10·73
Nitrogenous matter	5·62	16·94	10·31	11·25	9·56	36 62
Woody fibre	5·27	8·81	1·63	7·73	12·51	7·91
Extractive matter	30·99	54·50	70·43	60·25	57·06	28·22
Ash	2·76	3·61	2·15	4·01	3·85	5·39
Sugar	40·01	—	—	—	—	—

The shells of the locust-bean form a condiment; they must not be given in too large a quantity on account of their very sweet taste and poorness in nitrogenous matter. Locust-beans (corn) are very hard, but swell up in water; when ground they constitute an easily digestible and nutritious food. Dari seeds (a kind of sorghum) and millet on account of their comparative poorness in nitrogen are suitable for mixing with highly nitrogenous foods for feeding purposes. Green rye ensilage had the following composition:—

	Moisture.	Lactic acid.	Nitrogenous matter.	Extractive matter.	Woody fibre.	Ash.
Per cent. ..	72·50	0·80	1·99 (0·31 N)	12·86	9·72	2·13

Sheep and cattle ate it readily, and cows gave milk abundantly after eating it. D. A. L.

Palm-cake and Palm-meal. By Holdefleiss (*Bied. Centr.*, 1883, 709).—The first of these substances is the residue after pressing out the oil; the second is left after the chemical extraction of the oil. Analysis of these substances yielded the following results per cent.:—

	Moisture.	Albuminoids.	Fat.	Extractive matter free from nitrogen.	Woody fibre.	Ash.
Cake.	10·69	16·66	7·43	44·76	16·96	3·50
Meal.	12·48	16·66	2·72	40·53	22·79	4·82

D. A. L.

Amount of Fat and Albuminoïds in Feeding-stuffs. By P. Wagner (*Bied. Centr.*, 1883, 710).—161 samples of palm-cake were analysed with the result that—

	6	7	39	32	16 p. c. of samples
contain less than	8	8—9	9—12	12—15	over 15 p. c. of fat;

of 87 samples of rice-meal 17 per cent. contained 10 per cent. of fat; 38, 10—12; 22, 12—14; 23, over 14; whilst 18 per cent. of the samples contained 10 per cent. of albuminoids; 46, 10—12; and 36, 12 to 14.

Out of 49 samples of decorticated earth-nut cake 31 per cent. contained 9 per cent. of fat; 24, 9 to 11; and 45 over 11; and of albuminoïds 39, 44 per cent.; 35, 44 to 46; 26 over 46. Undecorticated earth-nut, mean of 2, 8·4 per cent. fat; 37·23 per cent. albuminoids. Wheat-bran, 24 samples. Of fat, 8 contained 3·5; 54, 3·0 to 4·5; 38 over 4·5 per cent.; whilst of albuminoids 42 per cent. contained 13 per cent.; 50, 13 to 15; 8, 8 to 15 per cent. The mean of six analyses of rape-cake is as follows:—10·71 per cent. fat, 28·73 per cent. albuminoids, whilst with cotton-cake the mean of six analyses gives 13·7 per cent. fat, 30·90 per cent. albuminoids: sesame-cake 17·45 per cent. of fat; 31·59 per cent. albuminoïds. D. A. L.

Old Sugar-beet Seeds as Cattle Food. By Simon Legrand (*Bied. Centr.*, 1883, 709).—Old and sterile sugar-beet seeds were ground and mixed with diffusion residue to a homogeneous mass; 3 kilos. of this meal a day per head were given to fattening bullocks as a supplementary food, whilst another lot of cattle had instead 3 kilos. of linseed-cake daily per head. The beet-seed meal was always eaten with great relish, and both lots of animals were in equally good condition. D. A. L.

Forests as a Protection against Hailstorms. By L. GLASER (*Bied. Centr.*, 1883, 723—725).—This is a selection of short reports from various neighbourhoods in Germany, Switzerland, and Italy, showing that hailstorms do not occur in the vicinity of pine forests. Instances are given of localities which when well wooded were absolutely free from hailstorms, but having been stripped of their forests are now often subject to such visitations. J. K. C.

Different Soils Rich in Humus and their Behaviour with Water. By A. EMMERLING and G. LOGES (*Bied. Centr.*, 1883, 655—657).—Three soils have been examined. 1. Heath-turf from dry "grey" sand-soil. 2. Beech humus also form dry "grey" sand-soil. 3. Heath-turf from the wet Jlow moor; they contained respectively 39·73, 33·24, and 75·40 per cent. of moisture, and the air-dried substances yielded the following numbers on analysis:—

		1.	2.	3.
Per cent.	Water	3·25	1·75	11·56
"	Inorganic matter	67·58	83·39	8·47
"	Humus	29·17	14·86	79·97
"	Nitrogen	0·39	0·53	1·11
In 100,000 parts of air-dried substance, soluble in cold 12 per cent. hydrochloric acid	Phosphoric acid	45·20	35·80	75·30
	Potash	32·10	38·60	34·90
	Lime	68·70	34·70	115·00
	Magnesia	30·40	24·40	181·10
	Sulphuric acid	41·90	19·00	287·80

1500 grams of each soil was treated for 14 days with 4½ litres of water and filtered; in one case forthwith, and in another lot after the samples had been moistened daily for two months, they then contained respectively 21·40, 8·60, and 32·40 per cent. of moisture. The solutions yielded on analysis the following numbers in parts per 100,000 of air-dry soil:—

Constituents.	1.		2.		3.		Remarks.
	At start.	After 8 weeks.	At start.	After 8 weeks.	At start.	After 8 weeks	
Humus	19·30	22·50	100·60	83 00	158·00	149·30	In Soils 1 and 2, the proportion of lime is small. The quantity of soluble phosphoric acid is large in Soil 2. In Soil 3, the large quantities of magnesium and sulphuric acid are remarkable.
Nitrogen	1·89	1·14	3·90	4·22	3 66	4·07	
Ammonia	0·19	0·31	0·49	1 22	0·65	0·95	
Nitric acid	—	—	—	—	—	—	
Phosphoric acid	0·53	0·40	3·61	4·43	—	0·39	
Potash	1·00	1·88	2·93	3·03	3 22	5·14	
Lime	1·50	1·42	2·00	1·50	4 80	3·24	
Magnesia......	—	1·31	—	1·10	—	4·15	
Sulphuric acid .	1·16	2·62	1·66	1·05	4·70	5·98	
Ferrous oxide ..	0·43	—	3·60	4·30	2·20	—	
Silica	1·05	4·00	2·30	5·40	2 20	3·64	
Humus soluble in water at 14—18° .	66·0	78·0	678·0	558·0	197·0	187·0	In parts 100,000 of pure humus.
Soluble nitrogen	0·39	0·39	0·73	0·79	0·33	0·37	In parts per 100 of total nitrogen.

The great solubility of beech humus arises from the large amount of undecomposed vegetable refuse it contains, which yields extractive matter to the water. The fertility of these soils seems in some way connected with the solubility of the humus. D. A. L.

Absorptive Power of Different kinds of Soils for Water. By P. Pichard (*Bied. Centr.*, 1883, 728—729).—The soils investigated were clay, silica, and calcium carbonate, in varying degrees of fineness. The author shows that land which has been covered with water will remain saturated for fifty days when it contains 30 per cent. of clay or 10 per cent. of clay and 60 per cent. fine silica. J. K. C.

Chemical Changes in Soil and Drainage Water. By F. Hoppe-Seyler (*Bied. Centr.*, 1883, 725—727).—Samples of black mud from sewers, drains, ditches, wells, ponds, &c., were obtained and employed in this investigation. Note was taken of their mechanical composition, of the action of various reagents upon them, and of their behaviour under different conditions. In their external properties, the samples of mud of different origin were all much alike, separating into a grey upper and a black under layer. The former contains numerous organisms, and the latter consists chiefly of shells of diatomaceæ. At the ordinary temperature, gas bubbles are from time to time evolved from the mud; these contain carbonic anhydride and marsh-gas, and in the absence of ferrous carbonate also sulphuretted hydrogen. A strong fermentation is continually going on, whereby even the cellulose present is gradually converted into carbonic anhydride, marsh-gas, and hydrogen.

Nitrous and nitric acids are entirely absent in the under layers, and in these, nitrates are speedily converted into ammonium carbonate.

As regards the hygienic condition of a soil, the above results give only negative information. The evolution of carbonic anhydride from a soil cannot be taken as a measure of the quantity of animal matter present, nor can the amount of nitrates and nitrites in the drainage water give any idea of the quantity of impurity, as the existence of all these substances depends on several other variable factors.

J. K. C.

Contributions to Systematic Manuring. By P. Wagner and others (*Bied. Centr.*, 1883, 729—744).—Experiments conducted with the greatest care for five years have, says the author, led to a method as trustworthy as the estimation of phosphoric acid by ammonium molybdate. The first trials were made on a plot of sandy soil divided into 40 lots by means of brick walls sunk 18 inches into the ground. The soil was carefully mixed and made as homogeneous as possible for a depth of 18 inches, and the manure introduced by mixing with the upper layers. Potatoes and barley were the subject of the first series of experiments, but the results obtained were not satisfactory, as several disturbing factors still remained to be eliminated, such as position of the plots, moisture of the soil, &c. In the next series of experiments the dividing walls were made impervious to water by means of cement, and the soil removed to a certain depth from each plot, and replaced by well mixed earth. Barley was also planted round each plot to give similar conditions of light and shade. The results gained were better, but still not satisfactory, and further modifications were introduced, although also without success. The experiments on open land also failed from like causes, and the author holds all results obtained from manuring experiments on this basis to be untrustworthy. Recourse was therefore had to zinc boxes, sunk into an artificial soil, and filled very carefully with the same quantities of sand and earth. The conditions of the soil in the boxes could then be regulated so as to be as nearly as possible alike. The boxes were so arranged that the soil in them was always saturated with water up to a certain height. The same number of seeds were planted in each box, and each experiment repeated at least six times. The results were most satisfactory, the figures obtained agreeing so closely that the mean result could almost be looked upon as free from error.

Careful experiments were made by this method to ascertain the requisite quantity of manure to be used for each kind of seed, and attention was also paid to the accompanying constituents of the manure, and to its coarser or finer condition.

In conclusion the author insists on the above methods as necessary to the carrying out of a tolerably exact manuring experiment, the quantity of moisture in the soil being a factor which must before everything be the same throughout, and the other conditions determining growth must exist in their proper relative proportion.

J. K. C.

Four-year Rotation Experiments. By A. Voelcker (*Bied. Centr.*, 1883, 668—671).—In the present series, the crops grown were wheat, barley, clover, and turnips. Wheat was grown on *plot* 1 after clover consumed on the field by sheep, which received in addition 350 kilos. of decorticated cotton-cake per acre; on *plot* 2, after clover consumed on the field, along with 330 kilos. of maize meal per acre; on *plot* 3, after clover consumed on the field without other food, but receiving as manure potash, phosphoric acid, nitrogen, &c., in quantities equal to that in 305 kilos. of cotton-cake per acre; on *plot* 4 same as plot 3, but receiving, in artificial manures, plant food equivalent in quantity to that of 330 kilos. maize meal per acre. The largest quantity of wheat was obtained on plot 4; plots 1 and 2 were nearly equal; whilst plot 3 yielded the least.

With barley after turnips consumed on the field without artificial manuring, the best yield was obtained on the cotton-cake plot, the maize meal and unmanured plot being nearly equal, whilst a top dressing of sodium nitrate on the other plot, lowered the yield of corn but raised the quantity of straw. The clover was fed off by sheep, some getting cotton-cake and others getting maize meal in addition. The live weight of the sheep increased to the largest extent with maize meal; the cotton-cake also gave a large increase, whilst the increase from the other plots was small. Sweedish turnips yielded best with complete mineral manures and sodium nitrate.

D. A. L.

Irrigation by Means of Danube Water. By J. F. Wolfbauer (*Bied. Centr.*, 1883, 721—723).—10,000 parts of Danube water contain a minimum quantity of 1·294 parts dissolved substances in summer, and a maximum of 2·104 parts in the winter, the maximum and minimum of suspended matter being 3·383 in summer and 0·096 in winter. According to the irrigation project, 18,000 cm. of water per hectare are to be run over a field in the space of 180 days; the soil will therefore receive per hectare 2500 kg. of suspended and 2800 kg. dissolved matter, containing altogether 62 kg. of potash, 46 kg. sodium nitrate, and 4 kg. phosphoric acid. This quantity of potash is, according to the author, sufficient for the production of 2000 kg. of hay, but in order to produce 4000 kg., will require to be supplemented by phosphoric acid in the form of artificial manure, the amount contained in the above quantity of Danube water being insufficient.

J. K. C.

Manuring Experiments with Potatoes, Beet, and Maize. By A. Nautier (*Bied. Centr.*, 1883, 662—666).—The soil on which the following experiments were made contained 29·4 per cent. of stones above 1 mm. in diameter. The air-dried fine mould contained per cent.:—

OH_2.	N.	P_2O_5.	Humus (containing C).	K_2O.	CaO.
6·93	0·20	0·25	1·06 (0·64)	0·10	5·97

It is 0·15 m. thick, and therefore contains about 2800 kilos. of phosphoric acid and 2260 kilos. of nitrogen per hectare. The season was bad, there being 411 mm. of rain between May and September.

Some experiments on various kinds of potatoes showed that the best yield, both of tubers and starch, was obtained with Champions, Merveille d'Amérique the next, Early Rose next, then Snowflake, the worst being Saucisse, a French variety. Experiments with potatoes and beet show that on such a soil as the above phosphatic manures are the only ones which cover their cost by increase in crop; moreover, the precipitated phosphate and the superphosphate are of equal manurial value. Nitrogenous manures may be applied in small quantities in fine weather. In experiments on maize for fodder, it was found that stable manure was the only one of any actual value for that plant.

D. A. L.

Manuring Experiments at Peterhof. By W. KNIERIEM (*Bied. Centr.*, 1883, 744—749).—Experiments were made with two different soils to ascertain the kind of plant nourishment required. The amount of humus contained in both was large. Varying combinations of potash, phosphates and nitrogen manures were used with each soil, and the crop consisted of oats. In one case, where the soil was very rich in nitrogen, a mixture of potash and phosphates answered best, and without the latter no good yields at all were obtained. The other soil appeared to be in want of all three kinds of manure, as each sort separately gave better results than on the unmanured plots; a nitrogen manure was found to increase the amount of straw, and phosphates gave a larger yield of corn. The quantity of meal in the corn was apparently decreased by the nitrogen manures, whilst the converse took place with the phosphates; and the latter worked equally well whether given in the form of superphosphate or precipitated calcium phosphate.

J. K. C.

Manuring Experiments. By v. SCHWERIN (*Bied. Centr.*, 1883, 665—667).—In some experiments made in Löwitz, nitrogenous manures were found efficient on light and medium rye land, and on light warm barley land; whilst phosphatic manures proved valuable on heavy loamy wheat land and on low-lying cold oat land. Flesh meal phosphoric acid was found to be equal in manurial value to superphosphate phosphoric acid on wheat land, and to surpass it on rye land.

D. A. L.

Silesian Farm without Cattle. By FISCHER (*Bied. Centr.*, 1883, 671—673).—Since 1871 the author has conducted his farm without cattle, with the exception of a few milking cows, because there is a good demand for fodder and straw in his district. Manures of commerce have, therefore, been employed instead of farmyard manure. The author does not consider this course advisable, unless such special opportunities for the disposal of fodder and straw are offered. Rape seed requires very strong manures, and therefore this crop was grown on those lands which could be manured with the existing farm manure, which consisted chiefly of cuttings from turnips. In his opinion bone meal is the most important manure after farmyard manure. It has been especially favourable to clover in his district. Potassium salts have yielded very variable results: in one manure experiment with potatoes, potassium salts gave even better results than guano. He uses phosphoric manures for cereals, or where large quantities are desired, and for green crops nitrogenous, and, when required, potash manures. The author is well pleased with his results, for his farm produce has been steadily increasing since the banishment of cattle.

D. A. L.

Artificial Manures for Vineyards. By J. A. Nippgen (*Bied. Centr.*, 1883, 708).—The usual manuring for vineyards consists of 400 centners stable manure per morgen every three years. Instead of this the author has employed 300 centners of stable manure and 4 centners of a mixture containing 9—10 per cent. P_2O_5, 10 per cent. K_2O, and 2 per cent. N (as ammonium salt), along with 4 centners of kainite, every two years on old vineyards or sickly plants. The results have been very favourable. D. A. L.

Cost of Production of Stable Manure. By A. Dettweiler (*Bied. Centr.*, 1883, 749—750).—The calculation was made in the case of four herds of cows: After allowing for cost of keep, attention, and depreciation in value, and subtracting the amount realised by the sale of the milk, a result was obtained as to the prime cost of the manure produced, which varied considerably in each case. The cost of the 117 lbs. of nitrogen contained in the year's yield of manure from one cow was estimated variously from nothing to 70 shillings.

J. K. C.

Wool-dust. By J. Nessler (*Bied. Centr.*, 1883, 705).—The author has examined 16 samples of refuse from woollen manufactories, and has determined the amount of fibre, dust, and total nitrogen. The amount of fibre varies from 50 to 7 per cent., the dust from 93 to 50 per cent., the quantity of total nitrogen from 1·08 to 9·68 per cent. From the results obtained, it is shown that the quantity of nitrogen increases with the amount of fibre. D. A. L.

Manuring Beetroot with Chili Saltpetre. (*Bied. Centr.*, 1883, 786.)—At a meeting of beet-sugar manufacturers the conclusion was arrived at that Chili saltpetre could be employed with twice its weight of phosphoric acid without harm, but also without much advantage, whilst by itself it was harmful at any time. J. K. C.

Manuring with Bone-meal. By L. Koch (*Bied. Centr.*, 1883, 709).—The effect of the manure on the harvest was not generally evident. Heavy manuring frequently produced smaller yields than light manuring. "Magnum Bonum" and "Champion" potatoes yielded well. By the use of either large seed, one tuber per hole, or small seed, four tubers per hole, the quantity produced was on an average the same, but the potatoes from the large seed were of better appearance. D. A. L.

Gypsum for Manure. By J. Nessler (*Bied. Centr.*, 1883, 705). —The author has examined gypsum from various localities with regard to the fineness and percentage of calcium sulphate. Twelve specimens were examined, that from Trüb, in Hornstein, being the finest; whilst the richest in calcium sulphate was from Kray, in Achern. D. A. L.

Analytical Chemistry.

Employment of Boric Acid and Hæmatin in Alkalimetry. By A. GUYARD (*Bull. Soc. Chim.* [2], **40**, 422—423).—The author recommends boric acid for the preparation of a standard acid solution in alkalimetry. A solution of commercial hæmatin, the colouring matter of Campeachy wood, is used at the indicator. W. C. W.

Value of Lenz's Method for the Purification of Hydrogen Sulphide. By R. OTTO (*Ber.*, **16**, 2947—2954).—The author having doubts as to the possibility of hydrogen arsenide being sufficiently basic in its properties to combine with hydrochloric acid, repeated the process by which Lenz (this vol., p. 215) asserted he had freed hydrogen sulphide from traces of arsenic. Hydrogen sulphide, evolved from commercial sulphide of iron and commercial hydrochloric acid, both known to contain arsenic, was passed through the water and hydrochloric acid solutions at 60—70°, as required in Lenz's process, then through concentrated caustic soda, and finally through pure nitric acid. On testing these in a large number of trials arsenic was always found in the nitric acid, but not in the hydrochloric acid solutions; and the author supposes that the hydrochloric acid, employed for washing the gases by Lenz, may have contained some foreign substance capable of absorbing hydrogen arsenide, possibly chlorine. A. B.

Preparation of Concentrated Nitromolybdic Acid Solution. By A. GUYARD (*Bull. Soc. Chim.* [2], **40**, 423—425).—A saturated solution of ammonium molybdate is poured into 20 c.c. of dilute nitric acid (prepared by mixing equal volumes of strong acid and water) until a permanent precipitate begins to form. The acid must be kept perfectly cold during the process. The author considers it advisable not to use more than 20 c.c. of dilute acid for each operation. W. C. W.

Determination of Ammonia as Nitrogen in Manures. By W. MASSALSKI (*Bull. Soc. Chim.*, **40**, 18—21).—The researches of Knop, Mehu, and others have established that ammonium salts when heated with sodium hypobromite, in presence of excess of soda and of glucose, evolve all their nitrogen as such. The presence of the glucose does not, as usually supposed, reduce any nitrates which may be produced, but it prevents their formation. In this paper an apparatus is described for the determination of nitrogen in manures containing ammoniacal compounds, and the results were found to agree with those obtained by the soda-lime process. However, the application of the method proposed is rather restricted, for powdered horn, meal, or fish guano only give up from one-quarter to one-tenth of their nitrogen to sodium hypobromite. Ordinary guano gives up about four-fifths of its nitrogen, and it is suggested that it is desirable to ascertain by experiment whether the whole of the nitrogen of guano can be considered to be ammoniacal, or part ammoniacal and part so-called organic nitrogen. V. H. V.

Estimation of the Total Nitrogen in Manure. By E. Dreyfus (*Bull. Soc. Chim.* [2], 40, 267—271).—When manure contains nitrogen in the different forms of nitrates, ammonia, soluble and insoluble organic matter, the total nitrogen is best estimated by the following process, which yields very exact results. 1 gram of the manure is heated with sulphuric acid in a small glass vessel until the nitric acid is expelled, and fumes of sulphuric acid begin to come off. When the solution is cold, sufficient calcium carbonate is added to form a perfectly dry mixture. The nitrogen in the mixture is determined in the usual way by means of soda-lime; this gives the total organic nitrogen plus the ammonia. The nitrogen present as nitrate is determined in another portion of the sample by Schloesing's method. Corrections for temperature and pressure may be avoided by comparing the volume of gas obtained with that evolved from a normal solution of sodium nitrate (66 grams per litre).

To prepare soda-lime, 3 parts of quicklime are slaked with 3 parts of water containing 1½ of caustic soda, and ⅓ of a part of pure sugar. On heating the soda-lime, the sugar is decomposed, and any traces of nitrate contained in the soda are destroyed. W. C. W.

A Cause of the Differences noticed in the Estimation of Superphosphates. By M. Maercker (*Bied. Centr.*, 1883, 751—752).—The author finds that the amount of soluble phosphoric acid in superphosphates decreases somewhat rapidly when the latter is packed in tin canisters, owing to the formation of insoluble phosphates of iron and tin. This may reasonably be supposed to be the cause of the differences in the analyses of superphosphates, some samples having probably been packed in these vessels, and thereby undergone change, while the original stock has remained unaltered. J. K. C.

Gladding's Process for the Estimation of Retrograde Phosphates. By Millot (*Bull. Soc. Chim.*, 40, 101—104).—In order to obtain an accurate estimation of the retrograde phosphate, it is necessary to use a reagent which will dissolve it without attacking that portion of the original phosphate which has escaped the action of the sulphuric acid. For this purpose Gladding has proposed a slightly ammoniacal solution of ammonium citrate of density 1·07; the superphosphate is heated for about an hour at the temperature of 70°. In France a similar process is in vogue; the superphosphate is placed in contact for 12 to 15 hours with a very concentrated and ammoniacal solution of ammonium citrate. In this paper analyses by these two processes are cited, and the results obtained are found to be comparable in the case of aluminium and ferric phosphates.

V. H. V.

Separation of Alumina, Ferric Oxide, and Titanic Oxide. By E. COHLN (*Jahrb. f. Min.*, 1884, 1, Mem., 186—187).—The author recommends the following as the most exact method of separating alumina, ferric oxide, and titanic oxide. The precipitate of the three hydroxides produced by ammonia is dissolved in hydrochloric acid. The alumina is separated by sodium hydroxide, and the acid solution of ferric oxide and titanic oxide is reduced with sulphurous acid in the cold (on heating, a portion of the titanic oxide is precipitated). Tartaric acid is added until ammonia gives no precipitate. The FeO is precipitated by ammonium sulphide. The TiO_2 obtained from the filtrate by evaporating and fusing, must be taken up by acid potassium sulphate and precipitated from the dilute solution by boiling in order to obtain it pure. B. H. B.

Detection of Manganese in Commercial Zinc-dross and in Calamine. Detection of Bismuth in Lead. By A. GUYARD (*Bull. Soc. Chim.* [2], 40, 420—421).—The zinc-dross or calamine is dissolved in sulphuric acid and the solution subjected to electrolysis, platinum electrodes being employed. If manganese is present, the positive pole is surrounded by a purple coloration due to permanganic acid.

To detect bismuth in metallic lead, make a piece of the lead into the positive electrode in the electrolysis of a solution of pure zinc sulphate. Dissolve the deposit on the negative electrode in dilute sulphuric acid, and if a dark residue remains, test it for bismuth.

W. C. W.

Use of Air Saturated with Bromine in the Precipitation of Manganese. By A. WOLFF (*Zeitschr. Anal. Chem.*, 22, 520—522).—A current of air is made to pass through a wash-bottle containing water and bromine, it thus becomes saturated with the vapour of bromine, and is then passed into the strongly ammoniacal solution of manganese acetate. The current is continued until the brown flakes of the hydrated manganese peroxide have separated, the precipitation being usually complete in 20 minutes. The bromine wash-bottle is then replaced by one containing ammonia, through which the current of air is continued for another 15 minutes. The solution is then ready for filtration, and if ammonium instead of sodium acetate has been employed for separating the iron, the precipitate may be at once ignited and weighed as Mn_3O_4. P. F. F.

Estimation of Chromic Oxide by Titration. By B. PAWOLLECK (*Ber.*, 16, 3008—3009).—This method depends on the fact that chromic oxide is readily oxidised by nitric acid and potassium chlorate, whilst cold dilute nitric acid has no oxidising action on a ferrous salt, and is of use in the estimation of commercial chromic salts and chromic hydroxides. The process is as follows. The weighed substance containing from 0·3 to 0·5 gram Cr_2O_3 is dissolved in a flask containing 25 c.c. nitric acid, sp. gr. 1·4, and slowly with gentle boiling crystals of potassium chlorate (about 2 grams for the abovementioned quantity of oxide) are added until the liquid has the pure reddish-yellow colour of a chromic acid solution: with practice this is easily recognised. The solution is boiled until the decomposition products of the chlorate are driven off, cooled, diluted to about 350 c.c. with water, and titrated in the ordinary way with ferrous ammonium sulphate solution. If the substance for analysis is already in solution, concentration is necessary before oxidation. The method may also be used for ignited or insoluble chromic oxide, but complete oxidation is more difficult. The process has been carefully investigated and verified by comparison with the ordinary method of oxidation by fusion with alkaline carbonates, and has been found much quicker and equally accurate. A. B.

Determination of Small Proportions of Alcohol in Viscous Liquids. By E. BORGMANN (*Zeitschr. Anal. Chem.*, 22, 534—535).—100—200 grams of the liquid are distilled in a current of steam until about 100 c.c. of distillate has collected. The distillate is then redistilled in the ordinary way, the first two-thirds which pass over being collected and used for the determination of sp. gr. P. F. F.

Halymetric Determination of Alcohol in Beer. By KLEINERT (*Zeitschr. Anal. Chem.*, 22, 505—512).—The author finds that shaking beer for the prescribed 15 minutes does not render its weight constant by the elimination of the dissolved carbonic anhydride, but that on continuing the agitation a further loss takes place. Moreover, different varieties of beer require different periods of agitation. The determination of the carbonic anhydride is thus liable to serious error, as are also those of the alcohol and extract, which depend on this determination. The same uncertainty also exists as to the length of time for which the beer should be shaken up with the salt in order that saturation may take place. P. F. F.

Ratio of Glycerol to Alcohol in Beer. By E. BORGMANN (*Zeitschr. Anal. Chem.*, 22, 532—534).—The author has previously investigated the ratio of glycerol to alcohol in wine (Abstr., 1883, 518). The ratios found for different kinds of beer were—

	Alcohol.	Glycerine.
Maximum	100	5·497
Minimum	100	4·140
Mean	100	4·803

The ratio thus varies within very narrow limits, and this result is of particular importance, as an artificial admixture, either of spirit or glycerol, can be inferred if the above ratio is appreciably disturbed. The samples of English beer examined, although of much greater alcoholic strength than the others, exhibited the same ratio.

P. F. F.

Determination of Acetic Acid in Wine by Distillation with Steam. By B. LANDMANN (*Zeitschr. Anal. Chem.*, 22, 516—519).—50 c.c. of wine, to which a few grains of tannin have been added, are placed in a small flask. A rapid current of steam is conducted through the wine, which is also heated to boiling, and the escaping vapours are passed through a condenser and collected in a graduated flask. The distillation is carried on until 200 c.c. of liquid are collected in the receiver. The distillate is titrated as acetic acid.

P. F. F.

Reaction of Ashes from Wine. By CHIAPPE (*Bied. Centr.*, 1883, 790).—The alkaline reaction of wine ashes cannot be taken as an indication of the absence of free sulphuric acid in the wine. The ash will be alkaline if the sulphuric acid is not sufficient to combine with the whole of the bases, and even sulphates when incinerated will often be reduced to alkaline sulphides, which give an alkaline reaction.

J. K. C.

Determination of Sugar in Beetroot. By K. STAMMER and E. SOSTMANN (*Bied. Centr.*, 1883, 779—782).—According to Stammer the different methods of extracting sugar from beet do not yield concordant results on polarisation. To obviate this difficulty, he digests the crushed root with 92 per cent. alcohol for an hour, makes up to a certain quantity, and finds that the liquid so obtained gives exact results. As the method, however, is tedious, he prefers to grind the root up in a mill until it becomes an impalpable pulp, and then shake up with cold 92 per cent. alcohol, which extracts the whole of the sugar.

Sostmann digests beet pulp with 80 per cent. alcohol, treats with lead acetate, filters, and determines the sugar by polarisation in the filtrate, making the correction suggested by Degener. J. K. C.

Examination of Spices. By E. BORGMANN (*Zeitschr. Anal. Chem.*, **22**, 535—537).—The author has determined the alcoholic extract and ash in a number of samples of various condiments—white and black pepper, cinnamon, cloves, mace, and allspice.

P. F. F.

Technical Chemistry.

Sanitation of Large Towns and Value of the Refuse Matter from them. By A. MÜLLER (*Chem. Centr.*, 1883, 706—708).—The author enumerates the various points to be observed in order to effect the sanitation of towns, and some of the methods at present employed for the disposal of sewage and otherwise rendering it harmless. The "water carriage systems," the separating system, the earth system, &c., are referred to. In order to utilise sewage for agricultural purposes, it must be treated on a manufacturing scale, concentrated so as to be stored, easily conveyed from place to place, and rendered useful as manure. Two methods of concentration are alluded to: Liernur and Podewil's process of evaporation in a vacuum, and Buhl and Keller's process of precipitation, pressing, and distillation. The cost is lower the more concentrated and pure the refuse matter, and the more readily the material is conveyed to the works. Swedish air closets fill the first of these conditions, and Liernur's pneumatic process the second, wherein the material is conducted through pneumatic pipes by means of steam power.

No use other than manurial has been found as yet for sewage. The incineration system, where all the organic matter is burnt, although good in some cases, can never be taken into consideration for general application. D. A. L.

Notes on the Soda Industry. By SCHEURER-KESTNER (*Bull. Soc. Chim.*, **40**, 75—83).—The memoir contains the results of the investigations of Chance, Brock, and Hurter on the sulphur regeneration process of Schæffner and Helbig, together with some critical remarks offered by the author.

Part I. In *Chance's investigations*, conducted on a large scale, the resultant hydrogen sulphide was not decomposed by sulphurous acid in a concentrated calcium chloride solution to form sulphur; but it was collected in gasometers, and finally burnt to produce sulphuric acid. The soda waste is introduced by a shaft into a cylindrical reservoir, furnished with an agitator, and the temperature is then raised to 50°; the gas evolved passes through a layer of water, and then a series of vertical pipes, into a gasometer. To prevent loss and smell. the water of the gasometer is covered with a layer of an oil known to the trade by the name of *blue* or *dead* oil. In the second or carbonating process, the admixture of calcium chloride and magnesia is transferred to a vertical cylinder analogous to that used in Weldon's manganese recovery process, warmed either externally or internally by steam and carbonic anhydride passed in. The former method is more economical, but the latter more practical. The calcium carbonate formed can be separated from the magnesium chloride by filtration through filter-presses.

As regards the pecuniary gain, Chance has calculated a profit of £66 for a quantity of waste corresponding with 300 tons sodium sulphate. But it is pointed out that as the price of pyrites will soon be lowered, this profit will be considerably diminished. As regards the decomposition of hydrogen sulphide by sulphurous acid, Chance was unable to prevent the formation of sulphuric and the polythionic acids. Analyses of the regenerated calcium carbonate are appended below:—

Calcium carbonate..........	71—79	per cent.
Calcium sulphate	3·9—4·6	„
Calcium chloride	0·25—1·51	„
Magnesium carbonate	0—1·77	„
Magnesia..................	1·67—3·2	„
Carbon....................	3·0—5·8	„
Silica.....................	0·3—3·30	„
Ferric oxide	1·0—2·3	„
Alumina	0·76—0·96	„
Soda......................	0·70—1·75	

In conclusion, the author remarks that the only hope of the competition of the Leblanc with the ammonia-soda process rests not on the regeneration of sulphur, but rather on the production and rise in price of the hydrochloric acid.

Part II. *Employment of Chalk Mud.*—Brock has employed the chalk mud from the Schæffner-Helbig process for the production of crude soda. The following mixture was introduced into the revolving furnace:—

Sodium sulphate................	100 parts
Chalk mud.....................	200 „
Coal..........................	40·3 „

The crude soda obtained possessed the following composition:—

	Per cent.	
Sodium oxide................	21·3	
Sodium sulphate	1·2	or 25Na_2O
Sodium chloride	2·88	
Sodium sulphide	0·55	

The amount of chloride is very large, and probably arises from an imperfect washing of the chalk mud. The operation lasted 2¾ hours; whilst only 2 hours are required with dry chalk.

Part III. Hurter has investigated the same subject, employing various mixtures of chalk mud, sodium sulphate, and coal, and obtained crude soda containing 24 per cent. sodium oxide, and 3·88—4·08 sodium chloride (or 25 Na_2O). Mactear considers that a more perfect washing of the chalk mud could be effected by warm water, and remarks that the soda manufacturers cannot rely on large profits from the sale of sulphur. The sole gain of the Schæffner and Helbig process will rest on the production of sulphuric acid. V. H. V.

Manufacture of Sevres Blue. By C. Lauth (*Bull. Soc. Chim.*, **39**, 435—443).—In this paper a full description is given of the manufacture of the so-called refractory blue of Sevres, and of the various accidents attending its firing.

The colour consists of a fritted mixture of 15 parts cobaltic oxide and 85 parts of pegmatite; it forms a blackish-grey mass. It is applied on the enamelled and kilned porcelain by working it up with turpentine, oxidised by the air, and thus rendered viscous. After application, the porcelain is dried at a gentle heat to expel the turpentine, and finally it is muffled at a red heat to completely destroy any turpentine present.

The process is frequently unsuccessful, however, and the failure is due to three causes, known by the names of (i) crazing (grésillements); (ii) displacements (déplacement), and metallisation. In the first case, the enamel, instead of being smooth, is rough and crinkled, being covered with blebs; in the second the colour is not uniformly distributed, but accumulated in places; and on the third the surface of the enamel presents black mirror-like spots. Of these accidents the first is practically irremediable, and on investigation was found to arise from the introduction within the kiln of organic substances, especially hydrocarbons, which exert a reducing action on the colour. In practice, it is due to an imperfect circulation of the products of combustion within the kiln, whereby the porcelain is exposed to this action. The second accident, which is far less frequent, is caused by an imperfect volatilisation and decomposition of the turpentine; vapours of heavy hydrocarbons are evolved, which condense on the red-hot porcelain within the kiln. Finally, the third accident or metallisation is due to an insufficient burning of the porcelain; it can be rectified by raising the temperature.

V. H. V.

Purification of Alcohols. By L. NAUDIN (*Bull. Soc. Chim.* [2], **39**, 626—646).—This paper contains an account of an industrial method of the purification of alcohol and alcoholic and saccharine liquors, by means of the copper-zinc couple, and subsequently by electrolysis. The crude alcohol is pumped into a vertical cylinder, across which are serpentine-shaped bars of zinc, on which copper has been deposited; the alcohol remains in this vessel for two days. It is then either distilled or submitted to a powerful electric current from a Siemens dynamoelectric machine.

In conclusion, a table is given to show the pecuniary profit of this process of purification as against the former method of frequent rectifications.

V. H. V.

Analyses of Wine. By J. MORITZ (*Zeitschr. Anal. Chem.*, **22**, 513—515).—The author has analysed a number of German wines

Description.	Acidity ($C_4H_6O_6$). Per cent.	Extract. Per cent. Direct.	Extract. Per cent. Calculated from Hager's table.	Mineral matters. Per cent.	Alcohol. Per cent. by volume.	Phosphoric acid. Per cent.	Glycerol.	Specific gravity.	Polarisation.
Neuberg,[1] 1878	0·52	2·3	2·3	0·21	9·8	0·018	0·899	0·9980 (18·5°)	± 0
Lindlesberg, 1878	0·67	2·05	2·33	0·21	9·4	0·020	—	0·9974 (17°)	± 0

Maximum......	13·2	2·90	0·999
Minimum......	8·0	1·69	0·990
Mean......	10·88	2·23	0·995

J. K. C.

Analyses of Wines from Palestine, &c. By A. Stutzer (*Bied. Centr.*, 1883, 790).—The following are the maxima and minima percentages of some of the constituents:—Alcohol, 15·34 and 9·27; glycerol, 2·0 and 0·29; sugar, 9·82 and 0·10; and ash, 1·164 and 0·126 per cent. J. K. C.

Influence of "Plastering" on the Composition of Wine. By L. Magnier de la Source (*Compt. rend.*, **98**, 110—113).—Plastering modifies the chemical characters of the colouring-matter of the wine, and not only does the calcium sulphate decompose the potassium hydrogen tartrate with formation of calcium tartrate, potassium sulphate, and free tartaric acid, but it also decomposes the neutral organic compounds of potassium which exist in the juice of the grape. The proportion of calcium in the wine is not sensibly increased.

C. H. B.

Souring of Wine. By P. Carles (*Bied. Centr.*, 1883, 790).—The author remarks on the changes undergone by wine in this process. A diminution takes place in the amount of extract and gum; sugar and other substances which reduce Fehling's solution, but are not thrown down by lead acetate, disappear completely. The glycerol decreases in quantity, as does also the cream of tartar, while the free tartaric acid disappears altogether, and the barium slowly decomposes into ulmic bodies. On the other hand, the potash increases in quantity, owing to the decomposition of the deposit of cream of tartar. When the sickness has not gone too far, it may be remedied by the addition of new wine rich in tartaric and tannic acids.

J. K. C.

Influence of Temperature on the Fermentation of Must. By H. MÜLLER (*Bied. Centr.*, 1883, 783—785).—The higher the temperature, the sooner the fermentation is finished; at low temperatures, a moderate fermentation takes place, which becomes more violent as the liquid becomes warmer, and reaches a maximum at 27°. By the employment of high temperatures, a must rich in sugar can be converted into a wine only feebly alcoholic, sweet, and yet having lasting properties. Medium musts are best fermented at from 20° to 24°, and this temperature is reached when the fermentation begins at 15°.

J. K. C.

Removal of Juice from Sugar-beet. By A. KLEWITZ and G. KRIEGER (*Bied. Centr.*, 1883, 731).—The authors have constructed a diffusion apparatus for removing the juice from sugar-beet with a smaller quantity of water. The apparatus consists of several compartments, separated by metal sieves, the water employed is poured in the first of a series charged with beet, and then passes through all subsequent compartments, gradually becoming richer in extract. The exhausted material is also passed through the series; the first only being replenished with fresh matter for extraction. D. A. L.

Valuation of Gelatin. By F. PROLLIUS (*Dingl. polyt. J.*, **249**, 425).—The author has determined the amount of ash, water, and insoluble matter (residue insoluble in hot water) in various kinds of gelatin. To ascertain the gelatinising property 1 part of the sample was dissolved in 90 parts of water, filtered, and the degree of viscosity determined.

	Ash.	Water.	Insoluble.	Time required for the solution to run out.
	p.c.	p.c.	p.c.	seconds.
Astracan from Schmidt and Dihlmann, Stuttgart	0·20	16·0	2·8	507
Ditto, from a collection	0·37	18·0	0·7	485
Ditto, fine iridescent Russian quality, Tübingen collection	1·20	17·0	1·0	500
Ditto, Russian, from Gehe of Dresden	0·80	19·0	3·0	491
Ditto, in laminæ, from Gehe	0·50	19·0	0·4	480
Ditto, in threads, known as Hamburg threads	0·40	17·0	1·3	477
Hamburg isinglass	1·30	19·0	2·3	470
Another quality	0·13	19·0	5·2	—
Rolled northern fish bladder	3·20	1·5	10·8	467
Icelandish bladder	0·60	17·0	21·6	463
Indian isinglass	0·78	18·0	8·6	437
Yellow, quality unknown	2·30	17·0	15·6	360

To judge of the purity of isinglass, it is also recommended to subject the sample to microscopic examination. D. B.

Composition of Roasted Chicory. By A. PETERMANN (*Bied. Centr.*, 1883, 843—845).—The following are analyses of pure chicory, one sample being coarse, the other fine:—

	Coarse grains.	Fine powder.	
Water (100—105°)	16·28	16·96	57·96 per cent. soluble in hot water.
Glucose	26·12	23·76	
Dextrin, inulin	9·63	9·31	
Albuminoids	3·23	3·66	
Colouring matter and bitter extractive	16·40	17·59	
Ash	2·58	2·55	
Albuminoids	3·15	2·98	26·14 per cent. insoluble.
Fat	5·71	3·92	
Cellulose	12·32	13·37	
Ash	4·58	5·87	

The ash was somewhat higher than usual, but was quite white; as the ash of pure samples varies much, owing to the imperfections of manufacture, it is quite inadmissible to judge of the purity of a sample of chicory by its ash. E. W. P.

Soap Varnishes. By E. ANDRES (*Pharm. J. Trans.* [3], **14**, 169).—These varnishes are valuable on account of their cheapness, their resistance to water, and their elasticity. Such a varnish can be made by dissolving tallow-soap in boiling water, filtering hot through cloth, and precipitating with a boiling solution of alum; the precipitated stearate of alumina is washed and dried, heated on a water-bath until transparent, and then stirred into turpentine; this mixture is heated nearly to boiling until it forms a thick varnish, which can be thinned with turpentine. A waterproof varnish for cloth or paper is made by dissolving iron or aluminium stearate in carbon bisulphide or benzene. Varnish for gilding is prepared from resin soap, which is made by stirring and boiling for two or three hours 100 parts of powdered resin with 50 parts of soda, dissolved in 100 of water until the mixture is clear. The soap is mixed with 100 parts of water and 15 parts of steeped glue, and heated until the whole is dissolved. This is a quick drying varnish, but can be made slow drying by adding 10 to 20 parts of glycerol 28° B. The resin soap, mixed with 5 per cent. ammonia, forms a cheap and durable vehicle for paints.

General and Physical Chemistry.

Spectra of Silicon Fluoride and Hydride. By K. WESENDONCK (*Wied. Ann.*, 21, 427—437).—As the author observed in a bought Geissler tube containing silicon fluoride the spectrum of carbonic oxide, he examined the result with especial reference to the spectra of silicon compounds, and the cause of the presence of that of carbonic oxide. Silicon fluoride was prepared in the usual way in an apparatus made entirely of glass, and fitted with stopcocks; this was connected with a Geissler's tube. The apparatus was first exhausted, then the acid allowed to come in contact with a mixture of pure glass and fluorspar, and the apparatus again frequently exhausted until the gas present was in all probability pure. However, with all this care the spectrum of carbonic oxide was always visible, and mixed with that of silicon fluoride. At comparatively high pressures, when the discharge gave a continuous cylinder of light, there was observed a more or less continuous carbonic oxide spectrum with the characteristic eight blue bands of silicon tetrafluoride; with decrease of pressure, the spectrum varied precisely in the same manner as that of carbonic oxide, the eight blue bands became clearer, and bands in the violet appeared. With the introduction of a Leyden jar in the circuit, Swan's carbon spectrum became visible. In another form of apparatus in which the stopcocks and all lubricating material was avoided, the same phenomenon was observed. As the cause was proved not to be due to the action of the gas on the electrode, its probable explanation lies in the great avidity of silicon tetrafluoride for water. If by the contact of the gas with water a little oxygen were set free, the latter would possibly oxidise immediately any trace of carbon containing substances, such as dust, which might be present.

The spectrum of a mixture of silicon hydride and hydrogen (formed by Wöhler's process) gave in narrow tubes only the spectra of carbonic oxide and hydrogen; in broad tubes under high pressure a number of lines which were observed in the silicon fluoride spectrum were visible, although the characteristic blue bands were absent; possibly the latter are peculiar to silicon fluoride. V. H. V.

Fluorescence of Calcspar. By E. LOMMEL (*Wied. Ann.*, 21, 422—427).—A red-brown fluorescence of calcspar can best be observed when parallel light rays, rendered convergent by a lens, are made to pass through a cube of calcspar: it is rendered more marked if the light has previously filtered through blue cobalt glass or green glass. The phenomenon is unaltered whether the bundle of rays passes through the crystal normally or parallel to the axis, or when it is not polarised, or polarised in any direction. The emitted spectrum extends from 35 to 65 (Bunsen's scale), and is most marked about 44. The light emitted by calcspar in the phosphoroscope has the same colour tone and the same spectrum, and differs from that observed in direct radiation only in intensity. It is evident that in both cases the same phenomenon is dealt with, and thus the question is opened whether Becquerel's nomenclature of phosphoresence of long and of short duration, respectively fluorescence or phosphorescence so-called, does not best represent the relation between these two modifications.

The word phosphorescence is generally used for radiation of light visible only in a darkened position, but the conception implied in this expression is far too wide for the phenomenon. The word fluorescence generally means the self-illumination of a body during the radiation of light upon it, although there is nothing in the word which implies a permanencé of illumination after the radiation has ceased. It is here proposed to retain the word *fluorescence*, and to substitute for phosphorescence the phrase *phosphorescence of illumination*. As in the latter case the self-illumination continues for an hour or more after the source of light is removed, but in the former only a fraction of a second, the phenomena are sufficiently distinct for distinction of nomenclature.

In order to determine the kind of rays most efficacious for causing the fluorescence of calcspar, a cube of it was placed in various parts of the spectrum; it was observed that the green rays between E and *b* were most effectual. It follows, then, that the maximum of absorption of calcspar lies between the same limits. This result is possibly connected with the phenomenon of double refraction and dispersion of calcspar. In a former memoir the author has shown that this latter is conditioned by two peculiar vibrations of its molecules; the wave-length of the one normal to the axis = $\lambda_0 = 0{\cdot}1301\mu$, that of the other parallel to the axis $\lambda'_0 = 0{\cdot}0874\mu$. But integral multiples of these numbers, $4\lambda_0 = 0{\cdot}5204\mu$ and $6\lambda_0 = 0{\cdot}5244\mu$, approximately correspond to the wave-lengths for E ($\lambda = 0{\cdot}5269\mu$ and *b* ($\lambda = 0{\cdot}5183\mu$). Hence it follows from this theory that substances can absorb not only rays whose wave-lengths are equal to those of their own vibrations, but also rays whose wave-lengths are multiples or sub-multiples of them (indirect absorption). V. H. V.

Electromotive Force in Terms of Chemical Energy. By S. Czapski (*Wied. Ann.*, 21, 209—243).—Thomsen and Helmholtz have expanded the Joule-Lenz law regarding the development of heat during electrolysis thus: the electromotive force of a galvanic cell (without polarisation) can be expressed in terms of the electrothermic energy of chemical processes caused by the passage of the current. The researches of Bosscha, Braun, Wright, and others have tended rather to disprove the validity of this law. Recently Helmholtz has inferred from experiments that the value of the thermic energy of the chemical processes, not transformed into electric energy, is related to the change of electromotive force induced by change of temperature. The experiments described in the present memoir point to the conclusion that those galvanic cells which *do not convert all their chemical energy into electric work, show decreasing electromotive force with rise of temperature, and conversely those which work at the cost of their own heat capacity, show increase of electromotive force with rise of tempe-*

rature. In the experiments, the following conditions were observed as far as possible: 1st, the E.M.F. of the cell to be examined was compared with that of a constant normal cell whose E.M.F. had been determined in absolute units; 2nd, the examined cell was sufficiently constant, free from polarisation changes, and so composed that its electrolytic processes were reversible and defined; its temperature was kept constant. The standard cell was of the composition Zn | $ZnCl_2$ | Hg_2Cl_2 | Hg; its E.M.F., as also that of the examined cell, was estimated by the Bois-Reymond compensation method.

The following combinations were examined:
Zn | $ZnCl_2$ solution | AgCl | Ag; Zn | $FeCl_2$ solution | AgCl | Ag; Zn | $ZnBr_2$ | Hg_2Br_2 | Hg, and Cd | $CdCl_2$ | Hg_3Cl_2 | Hg.

The results collected from the paper illustrate the proposition enunciated above, although they must be considered only as preliminary and approximate; for the heats developed or absorbed in the various chemical changes have not been fully investigated.

Of the table below in the first column is placed the temperature, in the second the E.M.F. in volts compared with the standard element, in the third the work done by the current in calories, in the fourth the chemical heat in calories, in the fifth the difference between the two last values, and in the sixth the value calculated from the formula $Q = \theta \frac{dp}{d\theta J} E$, in which Q = quantity of heat, *p* difference of potential, E electric quantity, J Joule's equivalent.

Cell.	Zn $\mid$ $ZnCl_2$ sol. $\mid$ AgCl $\mid$ Ag.

Electric Properties of Flames. By J. Kollert (*Wied. Ann.*, 21, 244—273).—This investigation is a continuation of Hankel's researches on the electric properties of the Bunsen and alcohol flames. The method of experiment was as follows:—

A spiral of platinum was placed in the flame symmetrically with its axis, and connected with one pole of a Hankel's electrometer, the other pole being in connection with the burner; the electrometer was also connected by a commutator with the poles of a zinc-copper pile conducting to earth.

The principal results of the investigation are as follows:—

(I.) The difference of potential is dependent on the material and the temperature of the mouth of the burner; an electropotential series of the materials of which the burners are constructed can be arranged, of which iron is the most negative.

(II.) The difference of potential is also conditioned by the position of the spiral; the point at which the greatest electromotive force is produced coincides probably with that of maximum temperature. This latter result probably represents the sum of several conflicting causes: firstly, by the rise of temperature the platinum is positively electrified; secondly, by contact with the hydrogen and carbonic oxide gas it is negatively electrified; and thirdly, in the cooler parts of the flame it is positively electrified by contact with steam and carbonic anhydride. As regards the second of these points, the experiments of Deville tend to show that the higher the temperature, the greater proportion of free hydrogen and carbonic oxide present; whilst Grove has shown that platinum is negatively electrified when in contact with these gases.

(III.) The results obtained by the author agree with those of Elster and Geitl; the former finds for the E.M.F. of a platinum spiral in a Bunsen flame = 1·95 Daniell, in an alcohol flame = 1·43 Daniell; while the latter obtained the values 1·92 and 1·44 Daniell respectively. V. H. V.

A New Method of Generating Electricity. By J. A. Kendall (*Chem. News*, **49**, 49—51).—The author has observed that hydrogen passing through a red-hot platinum plate can serve as an element of a galvanic combination. Various methods of applying this discovery have been adopted, and one of the best apparatus consists of two platinum tubes of different sizes closed at one end, made from metal $\frac{1}{100}$ inch thick; the smaller tube can be connected with a hydrogen supply, and arranged at any desired height in the centre of the large tube, the intervening space between the two tubes being filled with a suitable medium. When this arrangement is heated in the oxidising flame, the internal and external metallic portions being connected with a galvanometer by means of conducting wires, no deflection is produced until hydrogen is supplied to the inner tube. The production of electricity increases with the temperature, and is proportional to the extent of surface heated; most powerful effects are observed when the metallic coating is in a finely divided form; whilst the best results have been obtained when the inner metal is much thicker than the outer coating, in fact, the cell is quite spoilt when the reverse is the case, owing to the accumulation of hydrogen on the inner plate. The E.M.F. of the new cells varies with the media employed: for example, a platinum tube cell with calcium borate at nearly a white heat, E.M.F. = 0·36 Daniell, whilst a similar cell with a Berlin porcelain tube at nearly white heat = 0·7 Daniell. The current is arrested if there is not complete combustion in the source of heat applied to the cell, in fact, a reducing flame causes a reversal of the direction of the current. The platinum-hydrogen acts as a zinc element in an ordinary galvanic cell.

The following substances have been employed more or less successfully as media, glacial phosphoric acid, sulphuric acid (at boiling point only slight current), alkaline and alkaline earthy haloid salts, glass, and vitrified earthenware and porcelain. The use of the latter substances allowed the introduction of metals which for obvious reasons could not be employed with the above metallic salts. The following metals have been employed up to the present time:—Platinum, palladium, gold, iron, nickel, molybdenum, copper, and silver. Actual contact between the metals and media is essential, and therefore with glass the metal is placed inside a glass tube which is then fused on the metal (in the case of oxidisable metals a current of coal-gas is passed during the fusion), and while the glass is still soft, the exterior is covered with metal. For the finely divided metallic elements spongy platinum, or an alcoholic solution of platinum chloride, is painted on the glass which is then ignited, and a film of platinum is left on the glass, the conducting wire is put round in the form of a spiral, with other metals the oxide is put in the tube, and is subsequently reduced by hydrogen. Sulphates, carbonates, nitrates, and glass containing metallic oxides reducible by hydrogen are unsuitable as media for the present purpose.

The hydrogen is transmitted not only through the inner tube, but also through the intervening medium and external metallic cover. The amount of gas transmitted varies greatly with the nature of the media and the nature of the metallic layer; thus with the two, $\frac{1}{100}$ inch thick platinum tubes, with a favourable medium, and 3·3 square inches of inner tube in contact with it, at nearly a white heat, 0·7 c.c. of hydrogen passed through per minute; with finely divided metal and soft glass medium, the hydrogen transmitted at a full red heat may be as high as 0·6 c.c. per square inch per minute, with Berlin porcelain it is only 0·2 c.c. per square inch per minute at white heat, and is less at red heat.

Gaseous mixtures containing free hydrogen give rise to currents, whilst carbonic oxide produces no electrical disturbance with iron or platinum. The galvanometer employed was one adapted for rather strong currents with small resistance; it was graduated by means of a voltameter, and some of the deflections were of the following values in c.c. hydrogen per minute:—10°, 0·07; 20°, 0·21; 30°, 0·60; 40°, 1·35. Some cells may be constructed by nearly covering pieces of metallic (platinum, nickel, iron, copper) wire or rod with fused glass, the external coating being foil. On heating these in the oxidising flame, a current is produced which is due to the withdrawal of hydrogen from the inner core; when this current diminishes, the application of a flame containing free hydrogen immediately gives rise to a strong current in the reverse direction accompanied by the reabsorption of hydrogen by the internal metal wire; a similar effect is produced if a platinum plate is suspended in a platinum tube containing fused glass (magnesium and calcium borates), when alternate electric currents may be produced by simply altering the nature of the flame. These effects can be repeated as often as required. The initial deflection produced by the "normal" or "reverse" current is 18° to 20°; this falls within 10 to 15 minutes to nearly zero. When iron wire is completely covered with glass (except the conducting wire which is not heated), the oxidising flame deflection may gradually be brought actually to zero. Experiments have been made in which the inner platinum tube is connected with a Sprengel pump and immersed in fused glass in a platinum cell heated in the oxidising flame; under these circumstances a good vacuum could be pumped, and there is no deflection of the galvanometer, but as soon as a reducing flame is employed there is a steady deflection of 15°, and bubbles of hydrogen come down the fall tube of the pump, and in 15 minutes 1·33 c.c. were collected. Hydrogen could not be made to pass through a glass or porcelain tube either by means of oxygen or vacuum alone. When glass is fused in a platinum crucible over a gas flame, hydrogen can be seen forming and rising from the sides, especially from the hottest part, if the glass is allowed to become viscid by cooling, and the gas flame again applied, tubes like those mentioned above may be burst by the bubble of hydrogen formed on the inside of the tube. It is noteworthy that fused vitreous matters do not conduct electricity of low tension unless hydrogen is present. D. A. L.

Weight Voltameter for Measuring Electric Currents. By L. N. LEDINGHAM (*Chem. News*, **49**, 85).

Electrolysis of Dilute Sulphuric Acid and Hydrated Salts. By J. H. GLADSTONE and A. TRIBE (*Chem. News*, **49**, 61).—Frankland (Abstr., 1883, 839) suggests that in charging and discharging storage batteries one of the changes which occurs is the electrolysis of hexabasic sulphuric acid in accordance with the views of Bourgoin. The authors have made some experiments with 4·2 per cent sulphuric acid; the apparatus employed consisted of a U-tube having a stopcock in the centre of the horizontal part. The hole in the stopcock was packed with asbestos in such a manner as to prevent both the mechanical admixture of the liquids in the two limbs, and also electrical endosmose. In experiments with currents of different densities it was observed that the increase of sulphuric acid in the positive compartment per equivalent of hydrogen set free decreased with the lowering of the current density. In other experiments with sulphate of copper in one limb and sulphuric acid in the other, it was found that the acid accumulated was largely in excess of the copper deposited, this being due to *the unequal transference of the ions.* From these results and from those of some previous investigators, the authors conclude that the electrolytic method is incapable of determining whether H_2SO_4, or a hydrate thereof, gives rise to the current, and moreover from other experiments with copper and zinc sulphates, in which both limbs of the U-tube were filled with the same solution, they show that neither the composition nor even presence of a hydrated salt in aqueous solution can be determined by this method.

Absorption of an Iodine-compound by Aluminium. By G. GORE (*Chem. News*, 49, 1—2).—When sheet aluminium is immersed in a colourless aqueous solution of iodic acid either alone or together with a piece of sheet platinum so as to form a voltaic couple, the liquid becomes discoloured, there is a copious evolution of gas from the aluminium, and the current produced, if utilised, causes a considerable deposition of silver from a plating solution. After three hours, the aluminium is considerably corroded, and even after repeated washing with cold and boiling water retains iodine, which cannot be extracted with carbon bisulphide.

In a quantitative experiment, a piece of aluminium two inches square and weighing 15·752 grains, was immersed in a solution of 25·749 grains of iodic acid in 5 ozs. of water, at a temperature of 16°. After three hours, 14·685 grains of metal remained undissolved, and 2·340 grains, apparently iodine, were absorbed by it. Only very slight absorption of iodine takes place when solutions of potassium iodide or iodate are electrolysed, using aluminium electrodes, or when sheet aluminium is immersed in aqueous hydriodic acid containing dissolved iodine. Whilst there is no absorption when a solution of sulphuric acid and iodide is electrolysed as above, neither is there absorption when aluminium is immersed in a cold saturated aqueous solution of iodine, nor in dilute hydrochloric acid containing iodine, nor in dilute sulphuric acid and potassium iodide. It is, therefore, inferred that the absorption only takes place with the nascent substance at the corroding surface of the aluminium.

The aluminium plates after action appear, under the microscope, to be partly disintegrated into thin layers. D. A. L.

Pyroelectric Properties of Boracite. By K. MACK (*Wied. Ann.*, 21, 410—421).—The optical, thermic, and pyroelectric properties of boracite have been the subjects of a series of investigations by Hauy, Hankel (Abstr., 1883, 412, 546, 950), Mallard, Baumhauer, and others. This research is based upon an observation of Kundt that Lichtenberg's figures can be used for an examination of the pyroelectric properties of crystals.

The method of observation consisted in heating the crystal to be examined in an air-bath, removing it by a pair of pincers previously heated in the same bath. The crystal is then passed through an alcohol flame and placed on a slip of wood or paper, where it is dusted thoroughly with the ordinary mixture of sulphur and red lead. On cooling, the particles of these substances arrange themselves in definite lines, thus marking out the field of positive and negative electricity. The crystals examined were cubical, rhombic, dodecahedral, and tetrahedral, obtained from Stassfurt and Luneberg.

The general results of the investigation may be summed up as follows:—

(1.) The difference of potential, whether positive or negative, does not extend over the whole surface of a crystal, but follows certain definite lines.

(2.) If upon a crystal, in which either the rhombic or dodedecahedral form is dominant, there be conceived to be marked out a smaller, perfect rhombic dodecahedron, so that its principal crystallographic axes coincide with those of one or other of the above crystals, and there be projected from the common middle point, the angle of the latter dodecahedron upon the surface of the crystal, then a system of lines is obtained, coinciding with the lines of the electro-positive or -negative potential differences. Those lines which connect the middle points of smooth and glistening tetrahedral surfaces are coloured yellow, but those which lie symmetrically to any principal symmetrical plans of the regular system are red. This system of lines coincides with the optical system of lines of double refraction which have been described by Klein and Baum-hauer.

It would appear then that there is an intimate connection between the optical and pyroelectric properties of boracite. The former are probably conditioned by a state of tension of crystal, and the experiments of T. and P. Currie would seem to point to the same conditioning of the pyroelectricities. V. H. V.

Production of Low Temperatures by the Use of Liquefied Gases. By CAILLETET (*Ann. Chim. Phys.* [5], 29, 153—164).—To remedy the inconveniences previously attending the use of Thilorier's apparatus for condensing gases, the author has devised certain improvements in the arrangements and fittings of the apparatus, by which the liquefaction of ethylene and other gases can now be effected without difficulty, although the pressure required may amount to several hundred atmospheres. As liquefied ethylene does not solidify at even the lowest known temperature, it has the important advantage over carbonic anhydride and nitrous oxide of remaining transparent during its volatilisation, and of thus permitting the effects on the substances immersed in it to be readily observed. The drops of liquid ethylene are allowed to pass with moderate velocity into a test-tube containing the substance, and this tube is concentrically enclosed in another glass vessel, the air in the intervening space being completely desiccated, so that no deposition of ice can take place on the cooled tube. The author has obtained by liquid ethylene a degree of cold indicated by — 107° on a sulphide of carbon thermometer.

A Convenient Temperature Regulator. By W. T. RICHMOND (*Amer. Chem. J.*, 5, 287—289).

Use of Mercury Thermometers, with particular Reference to the Determination of Melting and Boiling Points. By J. M. CRAFTS (*Amer. Chem. J.*, 5, 307—338).

Thermo-chemistry of Haloïd Salts. By BERTHELOT (*Ann. Chim. Phys.* [5], 29, 198—288).

In this series of eight papers the author, by adducing the data for the application of his general theory to the case of the double haloïd salts, adds a new chapter to the researches on chemical mechanics which he has pursued for so many years. A complete theory of saline reactions requires that *all* the compounds capable of being formed under the given conditions of the experiment shall be taken into account. Thus, the heats of formation and of dissociation, not only of the simple salts, but those also of all the acid, the basic, the double, the hydrated, and the anhydrous salts that can possibly be formed under the circumstances, must be determined beforehand. This has been done in many cases in the present series of papers, and the observed reactions explained by the principle of maximum work, as in the theory of chemical equilibrium already advanced in the author's *Essai de Mécanique chimique.* The first paper merely states the range of the investigation. The second gives the thermal data for double salts formed of mercury, of potassium, or of both, united with one or two of the three halogens, chlorine, bromine, iodine, or with their analogue, cyanogen. Some interesting particulars are noted concerning the successive physical and chemical changes of such salts. Thus, the heat of combination from the simple salts is very small, except when the iodide is one component, when the heat, reckoned from the yellow iodide, is about the same as that disengaged in the transformation of yellow to red iodide. The combination of potassium iodide with mercuric cyanide liberates much heat, and the author regards the resulting product as a triple salt formed by a union of mercuric iodide with a double cyanide of mercury and potassium.

In the third paper, it is shown that haloïd salts of mercury, like those of other metals, combine with their corresponding hydracids, forming well-defined, crystallised acid salts. Red crystallised mercuric iodide dissolves readily in dilute hydriodic acid with disengagement of heat, and there is evidence of the stability of the compound thus formed, which may be regarded as mercuro-hydriodic acid, corresponding with a whole series of double salts, and analogous to the well-known complex acids derived from metallic cyanides. The heat of formation of acid chloride of mercury is less than that of the acid bromide, and much less than that of the acid iodide, whilst mercuric cyanide disengages scarcely any appreciable heat with hydrocyanic acid. The next paper treats of the heat of neutralisation of hydracids by the oxides of mercury and of potassium.

In the fifth paper are discussed the isomeric states of the haloïd salts. The heat of transformation of 227 grams yellow mercuric iodide into red is 1·5 cal. In the formation of silver iodide by precipitation with potassium iodide, a succession of transformations occur in the amorphous state of the substance, and its passage from the last amorphous condition to the crystalline is not accompanied by any sensible thermic phenomenon, that is to say, the sum of the work done in the transformation is sensibly *nil.* The same thing happens when an organic substance passes into an isomeride of the same chemical functions. But when there is a change of condensation (polymerisation), or a change of chemical function with the same condensation, a notable disengagement of heat is usually observed.

The sixth paper is devoted to a study of the double decompositions of the haloïd salts of mercury, and the numerical results confirm in all respects the author's principles. In all cases, the system which disengages the most heat is formed by preference whether as regards dissolved or insoluble substances, and Berthollet's laws are sometimes verified and sometimes quite contradicted, just as they are or are not in accordance with the thermochemical previsions.

The seventh and eighth papers deal with the haloid salts of silver, in the reactions of which there are certain special distinctive circumstances, such as the inverse displacements to which attention has lately been called. The author explains these by the formation of a double salt and the consequent separation of the alkaline salt along with the haloid salt in the solid form. The displacement of hydrochloric acid united to silver, by hydrobromic and hydriodic acids, whether free or combined with alkalis, takes place by reason of the thermic preponderance of these last acids, and would exclusively take place but for the existence of double and acid salts capable of giving rise to inverse reactions, which however are limited by the dissociation of the double salts. And with the silver salts, as with the mercuric, the whole resolves itself into one fundamental action, namely, that which corresponds with the thermic maximum.

Molecular Volumes of Salt Solutions. By W. W. J. NICHOL (*Chem. News*, **49**, 37).—In August, 1883, the author published (*Phil. Mag.*) results of experiments on molecular volumes of salt solutions of various strengths, wherein he found that in the case of ten potassium and sodium salts the difference in molecular volume of a solution, produced by the substitution of one metal for the other, or one radical for another, was in each case a constant quantity. The chlorides, sulphates, nitrates, chlorates, and hydroxides were examined. From the results, he inferred that the volumes of these elements and radicals, if determined in aqueous solutions and under similar conditions, are independent of the mode of combination; and, moreover, that when salts are dissolved in water the molecular interspaces in various solutions are nearly co-extensive. Recently these conclusions have received support from the results of Groshans (this vol., 143) and of Bender (*ibid.*, 144). Under these circumstances, the author now deduces the following law:—The volume of a metal in a salt, in dilute solutions (1 to 200 H_2O), is independent of the non-metallic radical associated with it, and the volume of the radical is independent of the metal. The author has investigated the reactions between barium nitrate or chloride, and potassium or sodium sulphate, and finds that within certain limits the volume change is constant.

Some Convenient Quantitative Lecture Apparatus. By A. MICHAEL (*Amer. Chem. J.*, **5**, 353—359).

Inorganic Chemistry.

Atomic Weight of Oxygen. By T. Hilditch (*Chem. News*, **49**, 37—38).—In this paper, attention is drawn to the errors that may be encountered by using hydrogen prepared from zinc, or by diffusion of air through india-rubber connections, or by weighing the copper oxide in air, and the reduced copper in a vacuum or *vice versâ*. The author then recommends the employment of electrolytic hydrogen purified by passing it over hot spongy platinum, and subsequently drying it with sulphuric acid or phosphoric anhydride in any future determination of the atomic weight of oxygen. D. A. L.

Carbonic Anhydride in the Atmosphere. By A. Müntz and E. Aubin (*Bied. Centr.*, 1883, 649).—Recent researches on the composition of the atmosphere have tended greatly to change the prevalent ideas on this point; this is especially the case as regards the carbonic anhydride in the air; for experiments have proved that the amount of this gas in the atmosphere is considerably lower (compare Abstr., 1883, 285, 614) than it was supposed to be, and, moreover, is subject to but slight variation. In order to inquire more completely into this matter, the authors took advantage of the Transit of Venus Expeditions; air was collected at the various stations in proper apparatus (Abstr., 1883, 121), and they now publish the results of the examination. The causes of variation are the different conditions of the sky and the force of the wind:—

	Vol. of CO_2 in 10,000 vols. of air.	
	Day samples.	Night samples.
Haïti	2·704	2·920
Florida	2·897	2·947
Martinique	2·735	2·850
Mexico	2·665	2·860
Santa Cruz (Patagonia)	2·664	2·670
Chubut (Patagonia)	2·790	3·120
Chili	2·665	2·820

It will be observed that these results differ but slightly from the numbers obtained for different places in France (North France, 2·962; neighbourhood of Vincennes, 2·54; the summit of Pic du Midi, 2·86). Calculated from the authors' results, the universal mean is 2·78; the mean for the northern hemisphere being 2·82, and that for the southern 2·71. It can therefore be assumed that the amount of carbonic anhydride in the air is lower in the southern than in the northern hemisphere: an assumption which finds support in the fact that the water is cooler in the former than in the latter hemisphere, and, according to Schlösing, there is a tension-equilibrium between carbonic anhydride in the sea and that in the air which is greatly influenced by temperature. D. A. L.

Moist Phosphorus, Air, and Carbonic Oxide. By A. R. LEEDS (*Chem. News*, **49**, 73).—In support of the author's results already communicated (this vol., 15), he refers to Baumann's contribution (*ibid.*), and in addition to the result given in the latter Abstract, quotes the following:—30 litres of air containing 2·45 litres of carbonic oxide yielded 64·6 mgrms. of carbonic anhydride, showing that 1·3 per cent. of the entire carbonic oxide was oxidised (comp. Remsen and Keiser, *ibid.*, 149). D. A. L.

Dissociation of Brass. By R. B. WARDER (*Chem. News*, **49**, 74).—A piece of brass wire, 150 mm. long and 1·43 mm. diameter, weighing 2·0570 grams, containing 36·02 per cent. of zinc, was heated to redness in a stream of hydrogen in a porcelain tube for several hours. The weight was taken from time to time, and it was observed that the rate of loss diminishes much more rapidly than the whole quantity of zinc present; for example:—

Hours.	Loss per hour.	Zinc present.
1	0·1442	0·5967
2	0·0601	0·5366
3	0·0672	0·4694
12	0·0095	0·3178

Combined Action of Potassium Dichromate and Chlorine on Ethyl Alcohol. By GODEFROY (*Bull. Soc. Chim.* [2], **40**, 167—173).—When chlorine is passed into a mixture of ethyl alcohol and powdered potassium dichromate, a violent reaction takes place which converts the dichromate into a brown powder. If the action of the chlorine is continued beyond this stage, the brown compound disappears and is converted into a pink solid. The products at the end of the first stage of the decomposition are potassium chloride and an oxide of chromium of the composition $Cr_2O_4,3H_2O$, which is insoluble in dilute acids. This oxide is more easily obtained by the action of iodine on alcohol and potassium dichromate. It is a brown crystalline powder, which decomposes with incandescence at a red heat. At 300°, it slowly decomposes, losing water and oxygen, and passes into a black sesquioxide of chromium. At a red heat, the black sesquioxide is converted into the ordinary green variety.

The final inorganic products of the action of chlorine on alcohol and potassium dichromate are chlorides and oxychlorides of chromium, which have not yet been examined, and a double chloride of potassium and chromium, $4KCl,Cr_2Cl_6,H_2O$. This substance exists as a red powder. When heated, it loses a molecule of water and turns blue. It is decomposed by solution in water, forming potassium chloride and chromium oxychloride.

The organic products of the reaction are aldehyde, ethyl chloride, acetic chloride, and ethyl acetate; a mixture of complicated chlorine derivatives is also formed towards the end of the operation.

W. C. W.

A New Rhodium Salt. By T. WILM (*Ber.*, **16**, 3033—3044).—The method by which the author obtained perfectly pure rhodium, chiefly from chloropurpurorhodium chloride, is fully described in the first part of this paper. The pure metal (1·5 to 2 grams) was treated by Wöhler's method with sodium chloride and chlorine; part of the metal remained unattacked and part formed a red powder which was insoluble and probably an indifferent sesquichloride. The formation of the double salt is more easily effected by exposing the metal for some time to the air and afterwards igniting it in a current of hydrogen gas. The sodium chloride double salt was converted into the corresponding ammonium chloride salt, but owing to the quantity of sodium chloride present it was impossible to obtain good crystals until the sodium chloride had been precipitated by or crystallised out in presence of fuming hydrochloric acid.

From the solution of the ammonium chloride double salt, the two crystalline forms obtained by Claus were prepared:—No. 1,

$$Rh_2Cl_6,6NH_4Cl,3H_2O,$$

in beautiful long four-sided columns from a solution containing little or no aqua regia, and No. 2, $Rh_2Cl_6,4NH_4Cl,2H_2O$, in octahedric, short, well-formed pyramids from the same solution by allowing it to stand or evaporating quickly with heat. If, however, the solution contains large quantities of aqua regia and a slight excess of ammonium chloride, the new salt crystallises out in raspberry-red flat crystals which, examined microscopically, are found to consist of regular six-sided plates, and have the formula $Rh_2Cl_4,8NH_4Cl,7H_2O$. The author has confirmed his results by again carefully preparing this salt from the purified metal, as the formation of a salt containing less chlorine in presence of excess of aqua regia was unexpected. This new salt was also prepared from salts No. 1 and No. 2 by warming them in excess of aqua regia and sufficient ammonium chloride—the change in colour and crystalline form being very distinct. By dissolving the new salt in water, a solution is obtained which at first has a raspberry-red colour, but on standing or, more quickly, on heating, it changes first into the red colour of No. 1 salt, and finally into the yellowish-red colour of No. 2. This solution can be converted again into the new form by treatment with excess of aqua regia and ammonium chloride. A. B.

Mineralogical Chemistry.

Minerals from Lehigh Co. By E. F. SMITH (*Amer. Chem. J.*, 5, 272—279).—*Allophane* from Allentown, near Ballietsville; mamillary and stalactitic incrustations, with mother-of-pearl appearance, coating pockets in the iron ore:—

H_2O.	SiO_2.	Al_2O_3.	$CaCO_3$ and $MgCO_3$.	
40·86	21·39	35·20	1·96	= 99·41.

Fluorite, finely coloured, in limestone, near the above locality.

Zircon in minute crystals in loose quartz fragments; locality, near Macungie. Very fine specimens of *wavellite* are also found near this locality, as is also decomposed wavellite.

Corundum from Shimersville, in very fine gray and red crystals, containing Al_2O_3 85·75, and Fe_2O_3 4·26 per cent.

Tourmaline occurs in several localities. *Garnet* also often occurs, sometimes in large quantity and of various colours and degrees of translucency. *Stilbite*, from Hosensack. *Pyrolusite*, in crystals upon the inside of limonite nodules from Lehigh mountain. A little west of this locality *chloropal* is found, of an olive or greenish-yellow colour; no trace of crystallisation is present; it is decomposed completely by hydrochloric acid.

The following analyses are given:—(1.) Yellow; (2.) Dark yellow; (3.) Greenish-yellow: (4.) Yellowish-green; (5.) Yellowish-green; (6.) Light yellow; (7.) Brownish-yellow; (8.) Brownish-yellow; (9.) Brownish-yellow; (10.) Brown; (11.) Yellowish-brown; (12.) Specimen almost white:—

	H_2O.	SiO_2.	Fe_2O_3.	FeO.	P_2O_5.	MgO.	K_2O.	Al_2O_3.

(12.) ..	17·65	44·52	11·04	—	—	trace	0·94	25·95	=	100·10

Note.—These numbers give the ratio $H_2O : SiO_2 : Fe_2O_3 = 4{\cdot}3 : 3 : 1$, *i.e.*, nearly those given by Naumann for nontronite, 5 : 3 : 1, but quite different from the formulæ proposed for chloropal, viz.,

$(Fe_2)Si\ O_9,3H_2O$ and $FeSi_3O_7,3H_2O$. H. B.

Minerals from Berks Co., Pa. By D. B. Brunner and E. F. Smith (*Amer. Chem. J.*, 5, 279—281).—*Stilbite*, from Wheatfield mines. *Deweylite*, from Ruth's mine; whitish and brownish resinous coatings upon aragonite and with serpentine:—

H_2O.	SiO_2.	F_2O_3.	MgO.	CaO.	
19·49	45·65	0·20	34·38	trace	= 99·69
19·03	42·34	1·39	36·77	trace	= 99·53

Vesuvianite, from Fritz Island; was previously supposed to be garnet.

Titanite.—*Brucite* in distinct crystalline forms upon a dolomitic rock, near Reading in Fritz Island; also found near Sinking Spring, Spring Township. H. B.

Organic Chemistry.

Reactions of Tellurium. By E. Demarçay (*Bull. Soc. Chim.*, 40, 99—100).—The tellurides are generally supposed to form reddish-violet solutions; but it is pointed out in this paper that this colour is due either to the presence of polytellurides or to some suboxide of tellurium. For if an alkaline solution of a telluride be boiled for some time with a reducing agent, such as phosphorus or aluminium, the violet colour disappears to reappear on contact with air.

The best process of obtaining methyl or ethyl telluride consists in warming at a temperature of about 80° the iodides of the corresponding hydrocarbon with finely-powdered tellurium. Dimethyl or ethyl tellurium diodide is formed, from which the other derivatives can be obtained. V. H. V.

Decomposition of Chlorotribromopropionic Acid by Alkaline Hydroxides. By C. F. Mabery (*Amer. Chem. J.*, 5, 255—256).—This acid is completely decomposed if heated with baryta-water, $(C_3HClBr_3O_2)_2Ba = C_2HClBr_3 + BaBr_2 + 2CO_2$; the distillate collected in bromine-water yielded C_2HClBr_4, melting at 33°, and therefore probably identical with chlorotetrabromethane melting at 32—33°, prepared by Wallach and Bischof by the decomposition of β-dichloracrylic acid and treatment of the chloracetylene obtained with bromine.

By the action of alcoholic potash solution on chlorotribromopropionic acid, which is probably expressed by $CBr_2Cl.CHBr.COOH$, a small quantity of tribromacrylic acid is formed. H. B.

Substituted Acrylic and Propionic Acids. By C. F. Mabery and F. C. Robinson (*Amer. Chem. J.*, 5, 251—255).—β-Dibromacrylic acid, unlike the isomeric α-acid, will not unite with bromine at ordinary temperatures. At 100°, with pure bromine, union takes place easily, with production of *tetrabromopropionic acid.* This acid may be crystallised from carbon bisulphide or water, and melts at 118—120°. The barium, calcium, and potassium salts were prepared, and found to contain respectively, ½, 1. and 2 mols. H_2O. The barium salt heated in aqueous solution or distilled with baryta-water is decomposed:—$Ba(C_3HBr_4O_2)_2 = 2C_2HBr_3 + BaBr_2 + 2CO_2$); the distillate absorbed in bromine-water yielded pentabromethane. When treated with an alcoholic potash solution, tribromacrylic acid is formed. β-Dibromacrylic acid is probably $CBr_2 : CH.COH$.

Chlorine acts like bromine on β-dibromacrylic acid; hydrobromic acid acts only very partially.

Bromine monochloride acts on bromopropiolic acid, but pure preparations could not be obtained; chloroform saturated with chlorine yields bromodichloracrylic acid. H. B.

Amidated Acids of α-Caproic Acid. By E. Duvillier (*Ann. Chim. Phys.* [5], **29**, 164—178).—Amido-α-caproic acid was obtained by Hufner (*Zeits. f. Chem* [2], **4**, 166); methylamidoacetic acid (sarcosine) by Liebig (*Annalen,* **62**, 310); methylamido-α-propionic acid, by Lindenberg (*J. pr. Chem.*, **70**, 244); and methylamido-α-butyric acid by the author (*Ann. Chim. Phys.* [3], **20**, 188). The latter has now obtained another homologue of the series, viz., methylamido-α-caproic acid, $CH_2Me.CH_2.CH(NH.Me).COOH$, by acting on pure methylamine with α-bromocaproic acid prepared with caproic acid, obtained during butyric fermentation. The acid is white, crystalline, and soft to the touch; soluble in water and in boiling alcohol, but not in ether. The aqueous solution is neutral, and of a bitter taste; it does not give any precipitate with silver or mercurous nitrate. The preparation and properties of the sulphate, hydrochloride, platinochloride, and aurochloride, and also the cupric salt, are described at length in the paper.

By acting on ethylamine with α-bromocaproic acid, the author has in like manner obtained ethylamido-α-caproic acid,

$$CH_2EtCH_2.CH(NHEt).COOH,$$

a homologue of the already known ethylamido-acetic and ethylamido-α-butyric acids. Its properties closely resemble those of the corresponding methyl compound, and similar metallic and acid derivatives of it have been formed and examined. R. R.

Propimine Thiocyanate. By J. Tscherniac and T. H. Norton (*Amer. Chem. J.*, **5**, 227—231).—By the action of ammonium thiocyanate on monochloracetone, ammonium chloride and acetone thiocyanate are formed, which latter by the further action of ammonium thiocyanate is converted into the thiocyanate of propimine thiocyanate, $CH_2(SCN).CMe : NH_3.SCN$, with elimination of water. The salt thus obtained forms large crystals melting at 114—115°, soluble in alcohol and water from which it readily crystallises. By adding concentrated potash solution to these crystals, extracting with ether, and evaporating on a water-bath, an oily liquid is obtained; this is the free base, propimine thiocyanate. It is obtained pure by distillation in a vacuum, boiling at 30 or 40 cm. at 136°, and at 760 mm. at about 232°; it forms a colourless crystalline mass melting at 42°. It is very soluble in water, and the solution has an alkaline reaction. By treating the thiocyanate of the base with silver nitrate or sulphate, the nitrate, $C_4H_6N_2S,HNO_3$, and the sulphate, $C_4H_6N_2S,H_2SO_4 + 2H_2O$, both crystalline salts, are obtained. On adding platinic chloride to a solution of the base in hydrochloric acid, the salt,

$$(C_4H_6N_2S)_2,H_2PtCl_6,$$

is precipitated. The free base heated with acetic anhydride yields acetyl-propimine thiocyanate, $CH_2(SCN).CMe \colon N\overline{Ac}$, a crystalline solid melting at 134°. Methyl iodide heated with the free base unites with it violently to form hydroiodide of methyl-propimine thiocyanate, $CH_2(SCN).CMe \colon NMeHI$, crystallising from water in scales melting at 159·5°. H. B.

Parabromobenzyl Compounds. By C. L. JACKSON and G. T. HARTSHORN (*Amer. Chem. J.*, **5**, 264—269).—The corresponding chlorine compounds have been previously described.

Parabromobenzylsulphonic acid.—The potassium salt was obtained by heating potassium sulphite with parabromobenzyl bromide; it is crystalline and anhydrous. By precipitation with lead acetate, and decomposition of the precipitated lead salt by sulphuretted hydrogen, the free acid was obtained, and thence the pure calcium, barium, and lead salts; the barium salt contains 1 mol. H_2O. On treating the potassium salt with phosphorus pentachloride, the chloride of the acid was obtained; it is crystalline, and melts at 115°.

Parabromobenzyl sulphide is easily formed by the action of sodium sulphide in alcoholic solution on parabromobenzyl bromide; it forms large crystals melting at 59°. If treated with chromic acid in acetic acid solution, it is oxidised to parabromobenzylsulphone.

The *parabromobenzyl mercaptan* was made by the action of an alcoholic solution of potassium sulphydrate on the parabromobenzyl bromide, and precipitation with water; it melts at about 25°, and by the action of the air soon changes into the bisulphide; mercury parabromobenzyl mercaptide is formed by the action of mercuric oxide and water on the mercaptan; it crystallises easily. Parabromobenzyl bisulphide was prepared by the action of air on the mercaptan, and also directly from sodium bisulphide and the bromide; it is crystalline, and melts at 87—88°. H. B.

Some Reductions with Zinc and Ammonia. By W. G. MIXTER (*Amer. Chem. J.*, **5**, 282—286).—In a previous paper (*Amer. Chem. J.*, **5**, 1) the author described the reduction of nitracetanilide; parazoxyacetanilide crystallised out, and the filtrate contained *parazoacetanilide*; it is now shown that a large amount of paraphenylenediamine is also formed, and may be removed from the dried residue by very dilute hydrochloric acid.

Parazoacetanilide treated with hot concentrated hydrochloric acid yields the hydrochloride of a base, which is also formed by saponification. Analysis showed the base to be *parazoaniline.* It unites with 2 mols. HCl, and nascent hydrogen converts it into paraphenylenediamine, hence its formula is $NH_2.C_6H_4.N_2.C_6H_4.NH_2$; it melts at 235—240°. Chrysoïdine melts at 110°, and yields with nascent hydrogen aniline and triamidobenzene, hence the constitution of this isomeride is $C_6H_5.N : N.C_6H_3(NH_2)_2$. Attempts have been previously made to prepare parazoaniline by reducing paranitraniline, but the hydrazo-compound alone was obtained.

Parazoxybenzanilide has been prepared in a manner similar to the meta-derivative (previous paper), viz., by reduction of paranitrobenzanilide. It is pure yellow, and melts at 310°. The azo-compound does not appear to be simultaneously formed; amidobenzanilide is formed, and a large quantity of the nitro-compound remains unacted on.

Azoxybenzotoluide.—Nitrotoluidine, melting at 77·5°, was treated with benzoic chloride, and the nitrobenzotoluide reduced with zinc and ammonia; the product melts at 290°, and is insoluble in water and alcohol. Attempts to replace the benzoyl group by hydrogen were unsuccessful.

The azoacetanilide and azoaniline complete the analogy indicated in the former paper between the reduction-products of nitrobenzene and those of paranitracetanilide, with the exception that no hydrazobenzene or benzidine analogue has as yet been obtained. The metaoxybenzanilide is the only meta-compound of the series investigated; no results have been obtained with ortho-derivatives. The use of zinc and ammonia seems to possess considerable advantages as a reducing agent; probably sodium-amalgam with a large excess of ammonium chloride would act in the same way. H. B.

Method of Preparing Borneol from Camphor. By C. L. JACKSON and A. E. MENKE (*Amer. Chem. J.*, 5, 270—271).—The camphor is dissolved in 10 parts of alcohol, a small excess of sodium gradually added, and the alcohol distilled off; water precipitates crude borneol. After washing with water it is crystallised from alcohol. The reaction is expressed: $C_{10}H_{16}O + H_2 = C_{10}H_{18}O$; the yield is excellent, 94 per cent. of the theoretical amount being obtained.

H. B.

Constitution of Chlorophyll. By E. SCHUNCK (*Chem. News*, 49, 2).—The author extracts leaves with boiling alcohol, and after some time filters; the filtrate is mixed with its own volume of ether and two volumes of water; it then forms two layers, which are separated. The lower layer is yellow, and reduces Fehling's solution. The upper layer is green, and contains all the chlorophyll; it is thoroughly washed free from everything soluble in water. When the ether is evaporated the bright green residue, dissolved in alcohol and treated with alcoholic potash, does not reduce Fehling's solution, but if it is previously treated with concentrated sulphuric acid in the cold, or if its alcoholic solution is boiled with hydrochloric or sulphuric acid, the alcohol driven off, the residue treated with water, filtered, and the filtrate made alkaline, mixed with Fehling's solution and boiled, the usual glucose reaction is obtained. The glucose or glucose-like substance is a pale-yellow gummy compound. The author, therefore, concludes that chlorophyll is either a glucoside or is associated with a glucoside (compare Tschirch, *Trans.*, 1884, 57—62). D. A. L.

Physiological Chemistry.

Development and Nutrition of Japanese Silkworms (Bombyx Mori). By O. Kellner (*Landw. Versuchs.-Stat.*, **30**, 59—86).—The rearing of the larger agricultural animals, such as the cow and horse, is not much attended to in Japan, but the cultivation of the silkworm and of the mulberry trees needed for its food has been a favourite industry for ages; the tendency of the people to excel in smaller industries rather than larger has brought everything connected with silkworm culture to a high state of perfection.

The author refers to the researches of Peligot as the principal contribution to a knowledge of the chemical constitution and food assimilation of the worm, but his investigations left very numerous questions unsolved, which the author, living at the oldest seat of the industry, has endeavoured to answer.

A number of worms were taken after hatching, and fed with weighed and analysed food, the worms being analysed at certain periods, four of which were the periods of casting their skins, when they cease to feed, and the intestine is empty; 5th period, when they were ready to spin; 6th, when the pupa becomes hard in the cocoon, and the butterfly as it leaves the cocoon; the excrement, when large enough to be removed, was examined by itself. The variety is very hardy, as out of 13,916 but 19 worms died in course of the experiments, whilst in European silkworm culture the average loss is 15 per cent.

The mulberry trees are cultivated somewhat like our basket willows, cut back, and the yearling shoots only used. The analyses are given very fully in tabular form and minute detail, some of which are of interest. It appears that the silkworm is unable to digest the fibrous portion of the leaves. Albumin and fat were digested to an amount not exceeded by ruminants; non-albuminous nitrogenous substances appear to be but slightly absorbed.

Table A contains the chemical analyses of the worms in their different stages, of the empty cocoon, the pupa, and the butterfly. It will be seen that the insect contains a very large proportion of water, which gradually increases until it is ready for the cocoon.

Table B shows the increase of weight of the worm, which is enormous. When ready to spin it has increased its living weight 5400 times.

Influence of Cotton-seed Cake on the Secretion of Milk.—By M. SIEWERT (*Landw. Versuchs.-Stat.*, 30, 145—160).—Cotton-seed cake made from whole seeds has lately been used in England for feeding cattle in place of linseed cake, and with good results: the cake which finds its way into Germany has, however, up to the present been made from the shelled seeds, and has been described as injurious when given to young cattle, although this may be due to the high concentration of the contained nutriment. To obtain exact information on the nutritive qualities of the two kinds of cake, experiments were instituted at various farms in the north of Germany, specially with a view of ascertaining the influence of the cake on the production of milk. Out of eight series of experiments, six agreed in the result that the quantity of milk decreased, while the percentage of sugar was raised at the expense of the other solid constituents, independently whether whole or shelled seed cake was used. The favourable report of English consumers was probably based on the fattening qualities of the cake.

Chemistry of Vegetable Physiology and Agriculture.

Function of Silica in the Growth of Maize. By V. JODIN (*Ann. Agronomiques*, 9, 385—392).—A grain of maize was submitted to water culture in 1875 in a solution containing suitable proportions of nitric, phosphoric, hydrochloric, and sulphuric acids, potash, soda, lime, magnesia, and ferric oxide, but as free as possible from traces of silica. A grain from the crop obtained was sown in a similar solution in 1876, and yielded a plant and seeds with which the experiment

was repeated in 1877. This time also a crop was obtained, a seed of which was sown in 1881, yielding a plant the seeds of which did not come to maturity. Another seed of the third generation (1877), however, when sown in only 82 grams of garden soil, and watered with the mineral solution, yielded an abundant crop with 24 ripe grains, so that the seeds had by no means lost their fertility by the three successive cultivations in a liquid deprived of silica. The effect of this cultivation on the mineral constituents of the plant, as compared with plants grown normally in soil, is shown by the appended ash analysis (p. 669).

The most striking point is the feeble mineralisation of the plants from the seed of the 3rd generation of water-culture sown in soil, although watered with an abundant supply of minerals. It contained less than one-sixth the normal proportion of potash, but recovered something like the original proportion of silica. The facts accord with Déhérain's conclusion that a large proportion of the mineral constituents of plants is not assimilated because essential to plant growth, but is deposited in the tissues of the plant as bye-products or residues of the various physical and chemical processes of growth.

J. M. H. M.

Nature of the Gases contained in Vegetable Tissues. By J. Boehm (*Ann. Agronomiques*, 9, 418—422; from *Bot. Zeit.*, 1883, Nos. 32, 33, 34).—The author's experiments have been made by exhausting cylinders of cork and wood with a mercury pump, and submitting the extracted gases to analysis.

Cork, whether in its natural condition or after desiccation, yields gas containing 25 to 34 per cent. of oxygen; when the cork is dried at 100° a little carbonic anhydride is found.

Cylinders turned out of the dead heart-wood also yield gas rich in oxygen, but if the exhaustion is continued for some time at the ordinary temperature of the air, the oxygen becomes gradually replaced by carbonic anhydride.

Cylinders of mahogany prepared from heart-wood, sap-wood, and from a small branch, were examined immediately after preparation; again after drying in the air for a year; and again after a further desiccation over sulphuric acid and potash. When they were freshly prepared, the percentage of oxygen ranged from 4·83 to 16·40; in the dried samples, it rose to 24·29 to 34·40.

The author ascribes this richness in oxygen to the fact that oxygen traverses cellular membranes more freely than nitrogen. The substance of the cells themselves appears to have no power of absorbing or condensing oxygen.

J. M. H. M.

Contributions to a Knowledge of Chemical Processes in the Plant. By A. Emmerling (*Landw. Versuchs.-Stat.*, 30, 109—144).—In a previous paper (*ibid.*, 17, 161) it was shown that oxalic acid decomposes calcium nitrate, with formation of crystallised calcium oxalate and free nitric acid. This reaction was made use of by Holzner in explaining the existence of calcium oxalate in plant cells, and he further considered the oxalic acid to be a decomposition-product of albumin. De Vries, on the contrary, supposes the oxalate of lime to be merely the form in which superfluous lime is separated from the sap, and occurs when the plant is situated in a soil very rich in lime. Holzner's hypothesis, however, finds confirmation in the chemical reactions known to occur when oxalic acid is brought into contact with any salt of lime, and gives the most simple explanation of the frequent occurrence of calcium oxalate in the plant.

In the further pursuance of this investigation, the author has endeavoured to determine the action of oxalic acid on potassium nitrate. A qualitative result had been previously obtained by means of diffusion, but to determine the exact amount of decomposition, the action of various mixtures of oxalic acid and potassium nitrate or nitric acid on marble plates was the method employed. The action of nitric acid alone in various degrees of dilution was studied, and this was found to vary directly with the quantity of nitric acid in solution, and the temperature employed, whereas oxalic acid alone reacts but very slightly, as the marble quickly becomes covered with an impenetrable coat of calcium oxalate, which prevents further action. The addition, however, of a small quantity of nitric acid alters this completely, a lively and continuous reaction setting in, and lasting as long as any unsaturated acid remains. 1 gram-mol. HNO_3 in 1004 litres water dissolved 70 mgrms. calcium carbonate in 72 hours, whilst 1 mol. nitric acid with 25 mols. oxalic acid in the same quantity of water dissolved 1180 mgrms. in 72 hours. The reaction takes place in two stages, calcium nitrate being first formed, which is decomposed into calcium oxalate and free nitric acid, the latter beginning its action again. The quantity of nitric acid must not, however, be too small, 25 mols. of oxalic to 1 of nitric acid being the limit beyond which it is not possible to go without disturbing the rapidity of the reaction.

The effect of nitric acid alone decreases with the time it has been in contact with the marble, so that its action during any given part of the time could be calculated, and was found to agree fairly well with the practical results of experiment.

The experiments with mixtures of nitric and oxalic acids in various proportions and dilutions showed that generally speaking the action of such a mixture is, *cæteris paribus*, proportional to the sum of the molecules of both acids in the volume-unit of liquid. This law, however, holds good only between certain limits; as mentioned above, the quantity of nitric acid must not be too small, and it must likewise not greatly exceed the amount of oxalic acid present, as a mixture of even equal parts of the two acids is never equal in its action to nitric acid alone, owing to the mechanical hindrance effected by the formation of crusts of calcium oxalate on the marble plate, which only after a time fall off.

Mixtures of oxalic acid and potassium nitrate were used in the same proportions as those of the two acids, and it was found that the quantity of potassium nitrate remaining constant, the action varied directly with the amount of oxalic acid when the concentration was not too great. In other words, oxalic acid and potassium nitrate act like a mixture of the two acids on calcium carbonate. This fact, however, gave no light as to the amount of potassium nitrate decomposed by oxalic acid under various conditions, but by use of the numbers given by Thomsen for the proportions of the avidities of acids for bases, the author arrives at a formula for the determination of this coefficient, and finds it to vary from 54 to 14 per cent., as the potassium nitrate is present in proportions of 0·1 to 2 mols. to 1 of oxalic acid.

The above experiments show clearly that oxalic acid attacks potassium nitrate with formation of free nitric acid, and that the presence of a small quantity of the latter is sufficient to produce a continuous action of oxalic acid on calcium carbonate. In certain cases, true raphidic crystals of calcium oxalate were obtained. J. K. C.

The Sum of Mean Temperatures in Relation to the Cultivation of Corn and Maize. By F. SESTINI and A. FUNARO (*Landw. Versuchs.-Stat.*, **30**, 97—108).—Some previous experimenters on this subject have stated that a certain sum of mean temperatures is necessary to the ripening of various kinds of corn: the total amount, however, varies with the climate. and in northern countries is less than is necessary further south. In the growth of maize, for instance, the observed totals of mean temperatures vary from 2463 to 3163°, and further observations might lead to even greater differences. The authors' own experiments were arranged as follows:—Three small plots of land were planted in the usual manner with maize; Plot A was covered with a tent of white calico, B with black, and C was left open: the temperatures of the soil and air were carefully observed the whole time in each of the three experiments, and the condition of the plants also noted from time to time.

The plants in B were weak, and died off in the middle of July, while those in A grew faster than any of the others, and gave a much larger yield than those in the open (30 kilos. against 26·3). Analysis, however, showed that the quality of the former was very much inferior to that of the latter. The sum of mean temperatures did not vary greatly in either of the three cases. A was, however, in this respect slightly superior to C, but the difference was not sufficient to account for the considerable variation in the yields obtained, and this shows that the quantity of heat supplied was only one factor in the conditions governing the growth of the plant. J. K. C.

Rice Culture in Japan. By O. KELLNER and J. SAWANO (*Landw. Versuchs.-Stat.*, **30**, 18—41).—The many varieties of rice grown in Japan may be classed in two groups—mountain rice and marsh rice; the former thrives on dry soil, and perishes when sown in the wet rice valleys, where the second flourishes, to die in its turn if sown on dry soil. The two classes are morphologically the same, and the cause of this great difference is yet undiscovered. The general mode of rice culture is as follows:—The seed for the next year's sowing is selected before the plants are cut, the best developed ears are chosen, and the fullest grains struck out by hand, sorted by throwing them into water, and dried by being packed in straw and hung up in a dry airy place. When the time of sowing arrives, the seeds are steeped in water until they swell, an average of about ten days; they are then spread on mats in the sun during the day, removed to the house at night, and covered. After about five days the plumule appears; in cold localities the seeds are often watered with tepid water, or even buried in the compost heap. The seed-bed is now carefully dug, and worked until it is a fine slimy mud. When the plumules are about 6 mm. long, the seeds are sown broadcast in it, the water is let on during the nights, and turned off during the day, that the seeds may be protected from frosts at night, and get the full benefit of the warmth of the sun in the day; in 40 to 56 days the young plants have attained a height of 18 to 24 cm., and are then transplanted to the field, previously well dug, and manured with green or other available manures; the plants are put in tufts or bunches equidistant, varying according to the fertility of the soil. The irrigation of the growing crop is a most trying operation, manual labour only being employed; the removal of weeds also requires constant care. The period of blooming is a very critical and anxious one for the farmer; wind and damp are both injurious. The harvest lasts from the end of September to the end of November, and the grain is cut with the sickle; the yield varies with the quality of the land, and for all Japan averages 27·3 hectolitres per hectare. The authors experimented in three directions:—

1. Culture in water, in order to find whether the marsh rice draws its supply of nitrogen from ammoniacal compounds or from nitrates.
2. On the process of nitrification in rice-fields.
3. On the composition of the irrigation-water before and after use.

The water culture was carried out in pots filled with carefully washed sea-sand, and, except for some hours each afternoon, they were covered up with distilled water; when the experimental solutions were applied, matters were so arranged that the rootlets touched their surface.

The solutions of nitrates and ammonium compounds were so arranged that each contained equal amounts of nutritive material. The authors give in tabular form analyses of the plants in different stages of their growth, and observations on the appearance of the plants, from which they draw the conclusions that the rice plant can supply itself with nitrogen equally well from dilute solutions either of nitrates or of ammonium compounds, when one class of bodies only is present with the necessary mineral constituents. Solutions containing nitrates only, cause a very slow progress in the first few weeks of the plant's life, afterwards the growth is normal. Ammoniacal solutions on the contrary, stimulate early growth, and do not act so favourably in the later periods, which makes the authors think manures for rice should contain nitrogen in both forms.

Experiments on nitrification of the soil of rice-fields under water were made, but without satisfactory results.

The examination of the water before and after use in irrigation was the next subject of investigation. The whole time of irrigation was divided into three periods, and the water daily examined with such precautions as the authors thought necessary so as to avoid error. The outflowing waters were found poorer in mineral matters than when they were let in on the field; a portion was undoubtedly directly taken up by the plants, and another portion retained by the soil; the greatest loss was in nitric acid, while the ammonia was much higher in the outflowing water, the probable reason being that it was very low in ammonia on entering the field, or it might be that the water dissolved some of the ammoniacal compounds in the soil, the loss of nitric acid may have had some influence on the increase of ammonia. The authors consider that relative proportions of nutritive matter in the water at entrance and exit depends on such a number of varying conditions that further experiments are desirable.

On an occasion about the end of August, when irrigation had been discontinued for some time and the fields dry, a heavy rain fell, and there was an opportunity of estimating what solid matters were removed by the pure water.

100 litres of the water collected as it ran off contained—

Vegetables used as Food in Japan. By O. KELLNER (*Landw. Versuchs.-Stat.*, **30**, 42—51).—Vegetables form a large part of the people's food in Japan; the varieties in use are many, and the methods of cooking numerous; some are preserved by simple air-drying; others are made into jams, pickled with sugar or acidified. The soja bean is the foundation of an almost universally used sauce, *Schoyu;* of a vegetable cheese, *Miso;* and of a highly albuminous jelly, *Tofu;* a large number of the plants are indigenous, others peculiar to warm climates, and few have hitherto been submitted to chemical examination, the accompanying tables being in many cases the first published analyses. Rice is the largest article of consumption, and of it there are many varieties, all of which are grouped in two divisions: one, the mountain rice grown on dry ground; the other marsh rice, cultivated in irrigated fields, both being botanically the same. Of the marsh rice there are also two principal divisions—ordinary and glutinous rice; the following analyses of dry matter in the three kinds are given:—

	Ordinary.	Glutinous.	Mountain.
Proteïn matter	7·00	5·87	8·75

difference is accounted for by the author's samples being undressed grain, whereas the samples examined by other investigators have been of the dressed and well cleaned commercial article. *Panicum italicum*, a species of millet, is, after rice, the principal food of the poorer classes. *Sorghum saccharatum* is an introduction from America. *Phaseolus radiatus* is a bean largely cultivated and highly esteemed; it differs but little from the European variety, *Phaseolus vulgaris*.

Canavalia incurva, another sort of bean, is a climber not much cultivated; the pods are about 20 cm. long, bearing 6—8 rose-coloured seeds, weighing on an average 2·5 grams each; they have, when ripe, a disagreeable smell, and are generally eaten unripe. *Solanum melongena*, or egg plant, is largely cultivated, and many varieties of it exist; it is reared from seed, and bears fruit for a long time. The specimen of fruit examined weighed 64 grams; its value as food about equals that of the pumpkin or gourd. Young shoots of the *Bambusa puerula*, and three other varieties of bamboo, are very much in favour. As soon as they appear above the earth in spring, they are dug out and eaten, dressed as asparagus. Different kinds of the sweet potato (*Batatas edulis*) are largely cultivated, and are great favourites; their long succulent stems interlace and cover the soil, keeping it moist. Their deficiency in nitrogen and the small amount of ash compared with other root vegetables, is remarkable.

Dioscorea japonica is of limited cultivation, and used by the wealthier classes. *Arctium Lappa*, the seeds of one variety, *Ummeda Gobo*, reach an extraordinary size, a length of 1 meter, and circumference of about 30 cm. *Colocasia antiquorum*, the sweet Japanese potato, is extensively cultivated; like the common potato, it is grown from the sliced tubers. *Conophollus Konjak* is a somewhat similar plant; the root is rich in starch; it is used in the preparation of a gelatinous sort of food called konyaku, peeled, dried, and rubbed to powder; milk of lime, or the soluble salts from wood-ash is added to it, and stirred up to a stiff paste; it dries to a clammy mass. *Brassica rapa rapifera*, a turnip, is a favourite food. *Raphanus sativus* is a kind of radish which grows to an enormous size, specimens weighing 2½—3 kilos. are not uncommon, and one sort is much esteemed for its sweet taste; the radish is one of the most esteemed vegetable foods of Japan.

J. F.

Contribution to the Chemical Study of Soils. By DUGAST (*Ann. Agronomiques*, 9, 470—478).—The author has made very full analyses of three soils, A, B, and C; the first of which always yields better crops than the second, but also always smaller than the third (C). The three soils are from the district of Marché Neuf (Loir Inferiéure).

A is a stony soil formed by disintegration of, and resting on, a conglomerate consisting of siliceous fragments of Pliocene age, bound together by a ferruginous cement.

B is a similar soil, but the layer of half-disintegrated subsoil is thicker. B is more stony than A, and contains a notable proportion of organic matter.

C is a stiff clay soil, difficult to work dry or wet, and resting on a subsoil of impermeable clay at a depth of half a metre. The soils are cultivated in an irregular rotation, comprising a cereal crop followed by two years of pasture or forage crops, and these by two or three years of culture comprising cabbage, beet, buckwheat, rye, potatoes, or maize. The mean produce of wheat is 16—17 hectolitres per hectare.

The samples of soil were taken according to the instructions in Grandeau's *Traité d'Analyse des Matières Agricoles;* the surface samples to a depth of 0·2 metre, and the subsoil samples to a second depth of 0·2 metre.

Mechanical Analysis and Physico-chemical Analysis of the Fine Earth.—The method devised by Schlösing, and described by Grandeau was exactly followed. According to this plan, instead of submitting the crude fine earth to elutriation, the carbonate of lime is first removed by dilute acid, the *true clay* next washed out by a modified process of levigation; then the humus is removed from the sand by ammonia, and the purified sand is finally separated by elutriation in the ordinary manner into "coarse sand" and "fine sand:"—

Potash in gravelly sand	0·0400 "

Potash, lime, and magnesia are deficient in all three soils, and phosphoric acid in B and C; the deficiency in phosphoric acid rendering B less fertile, notwithstanding its good supply of nitrogen. Soil C, naturally the most fertile of the three, has been partially exhausted by successive cereal crops. J. M. H. M.

Examination of certain Soils in Japan. By O. Kellner and H. Imai (*Landw. Versuchs.-Stat.*, 30, 1—17).—Many visitors to Japan praise the richness of the vegetation and the fertility of the soil. The author, agricultural chemist at the College of Tokio, says that from a study of the weeds and wild plants natural to the country, it is evident that the soil is not rich, but that the luxuriance of certain crops at their season is caused principally by the method of manuring, which consists in applying the manure at frequent intervals during the growth of the crops, and in the immediate neighbourhood of the roots; the furrows in which seeds are sown and the holes into which plants are set, are all carefully prepared with manure. The Japanese also have a strong objection to break up new ground unless they have the necessary quantity of manure at hand, and have a custom of planting exhausted fields with nut trees so as to prepare the soil for being again broken up.

Trustworthy examinations of the ordinary arable soil, and comparison with the land under rice plantations, had not yet been made when the author undertook them at the experimental farm of the College, the soil of which was of volcanic origin, containing much iron and soluble silicates; a portion of the farm was laid out as a rice field. The chemical analysis is given in Table I:—

TABLE I.

A circumstance which greatly modifies the nature of the surface soil in Japan, is the continuance of long droughts and high winds, the fine sandy soils become very fine dust, and is blown in great clouds over the face of the country, collecting behind hedges and walls after the manner of snow-drifts; in some places it is heaped up in large quantities, the rice fields being less dry do not suffer, but retain some of the dust from arable soils; the farmers prize this highly; but any analysis of the surface soil under such conditions cannot be of permanent value. J. F.

Determinations of Nitrogen in the Soils of Experimental Fields at Rothamsted, and Bearing of the Results on the Question of the Sources of the Nitrogen of our Crops.* By Sir J. B. Lawes and J. H. Gilbert (*Ann. Agronomiques*, 9, 393—418, 451—465).—Included in the scheme of the experimental fields at Rothamsted there are certain plots on which wheat, barley, roots, beans, clover, and ordinary rotation crops have each been grown, year after year, either without any manure or with a purely mineral (non-nitrogenous) manure for periods, in some instances, of over 40 years.

Determinations of the nitrogen contained in these crops have been regularly made, and at certain intervals the soil of each plot has been sampled, as well as the soils of adjacent plots receiving various nitrogenous manures, and the nitrogen per acre contained in the fine mould of these soils to a certain depth has been carefully estimated. The results of these determinations are set forth in the present paper and discussed in connection with the question, whether our farm crops derive any considerable proportion of their nitrogen from other sources than the soil and manure. The annexed table (p. 683) shows the yield of nitrogen per acre per annum in the various crops grown without nitrogenous manure.

Root Crops.—The results with mineral manure only are given, as without any manure the produce becomes almost *nil* after a few years. The average yield of nitrogen is very much higher in the first few years with root crops than with either wheat or barley, and the subsequent decline is much more rapid.

Leguminous crops, such as beans and clover, which are said by some to rely almost exclusively on atmospheric sources for their nitrogen, nevertheless fall off in yield in a most striking manner when not supplied with nitrogenous manures, even although abundance of mineral manure is provided. The clover crop succeeded only in 6 years out of the 22. The nitrogen yielded by these crops is very much greater than in the case of the cereals or roots, but the decline after the first few years is extremely marked.

Rotation of Crops.—As only the average yield of the whole 28 years is given, a decline in nitrogen cannot be inferred from these figures. The effect of rotation is to raise very considerably the yield of nitrogen over that given by cereal crops grown successively. A dressing of superphosphate increases the nitrogen in the turnip crop, reduces it in the succeeding barley, greatly increases it in the clover, and slightly in the succeeding wheat. In an adjoining plot where fallow was substituted for clover, the nitrogen yielded by the rotation was very much less.

Mixed Herbage of Grass Land.—The yield of nitrogen and the botanical composition of the crops from the plots which received no nitrogenous manure, are given in Table II (p. 684).

In interpreting this table, it should be borne in mind that gramineous crops contain much less nitrogen than leguminous crops; nevertheless, nitrogenous manures have a striking effect in increasing their growth. Leguminous crops, although containing much nitrogen, do not respond to nitrogenous manures, but are largely increased by mineral manures, especially potash. The first three plots show a marked falling off in nitrogen yielded; the fourth, in which the Leguminosæ were greatly encouraged by the application of potash, shows, on the contrary, a slight tendency to increased yield. It is noteworthy that mineral manures applied to mixed herbage increase the yield of Gramineæ much more than when applied to the Gramineæ grown separately.

Melilotus Leucantha (*Bokhara Clover*).—This plant has been grown since 1878 on a plot which had been devoted to unsuccessful attempts to grow red clover consecutively from 1849. For 30 years this plot had received no nitrogenous manure, yet it has yielded crops of *Melilotus* averaging 70 lbs. nitrogen per acre per annum 1878–81, whilst the crop of the fifth year, 1882, is still more luxuriant, and is estimated to contain 150 lbs. nitrogen.

From the foregoing it will be seen that in all the experiments on ordinary arable land, with or without mineral manure, *the decline in the annual yield of nitrogen, none being supplied by manure, was very great*. Bokhara clover is, so far, an exception.

The authors go on to consider the amount of combined nitrogen annually supplied to the soil by rain, and after citing all the published determinations of nitric and ammoniacal nitrogen in the rainfall over given periods, they conclude that not more than 5 lbs. of nitrogen per acre per annum is supplied to the soil of Rothamsted from this source. Passing in review the well-known researches of Boussingault, and of Lawes, Gilbert, and Pugh, on the one side, and of Ville on the other, extending from 1837 to 1858, they reaffirm their conviction that the evidence is strongly against the supposition that either the Gramineæ or the Leguminosæ assimilate the free nitrogen of the atmosphere. They next consider the evidence furnished by analysis of the soils of the Rothamsted plots as to the source of the greater part of the nitrogen of crops.

---

Nitrogen in the Soils of Experimental Wheat Plots.—Passing over isolated samples of soil taken in the early years of the series, and in 1856, as not being sufficiently numerous or uniform, there remain for comparison the samplings of 1865 and 1881. In 1865, eleven plots were sampled, eight samples from each plot being taken, each sample 12 × 12 inches area with a total depth of 27 inches, divided into three portions of 9 inches each. In 1881, twenty plots were sampled; the samples (six to each plot) were 6 × 6 inches in area, and again taken to a depth of 27 inches in three successive instalments of 9 inches. The various samples of surface soil (first 9 inches) from each plot were mixed, a portion of each, however, being kept to furnish check analyses. The mixed samples were broken up, dried at 130° F. to arrest nitrification, the stones removed by successive sieves of 1-inch, ½-inch, and ¼-inch mesh, and the remaining *fine mould* powdered and sifted for analysis, the result being calculated on the *fine mould dried at* 100° *C.* The two series of subsoil samples (second and third 9 inches) were treated in a similar manner, but the results are given for the surface soils only. The calculated quantity of dry mould per acre (first 9 inches) was in 1865 (mean of 80 samples) 2,299,038 lbs., and in 1881 (mean of 114 samples) 2,552,202 lbs., showing that the state of consolidation of the soil was different at the two periods. The normal quantity of fine mould per acre (first 9 inches) is assumed to be 2,300,000 lbs., and the results obtained in 1881 are corrected by supposing the samples to contain one-tenth of their weight of subsoil (second 9 inches), and proportionately raising the percentage of nitrogen in the remaining nine-tenths. The actual and corrected results are in Table III (p. 686).

During the 16 years from 1865 to 1881, therefore, the three plots (3, 5*a*, 16*a*) receiving no nitrogen as manure have suffered a very striking decrease in the nitrogen contained in their surface soils; whilst the other plots, receiving nitrogenous manure, show in some cases a slight loss, in others, a gain. The excess of nitrogen in these latter plots over that in Plot 5*a* (complete mineral manure without N) varies considerably, as shown in the table; it has no relation to the quantity of nitrogen supplied in the manure, but, as shown by the authors in a supplementary table, it is directly related to the average crop yielded by each plot. In other words, loss of manurial nitrogen is not prevented by any retentive property of the soil, but by its conversion into crop residue—stubble and roots—which varies with the amount of crop. The authors estimate that in the 30 years, 1852–81, the unmanured plot yielded an average of 18·6 lbs. nitrogen in the crop, and lost 10·3 lbs. in the drainage—a total loss of 28·9 lbs. per annum over that period. In like manner, Plot 5 yielded an average of 20·3 lbs. N in the crop, and 12 lbs. in the drainage, in all 32·3 lbs. per acre per annum. About 30 lbs. N per acre per annum therefore has been contributed from some source to crop and drainage together. Analysis shows a loss of about two-thirds of this amount annually to a depth of 27 inches. There remains, therefore, about 10 lbs. to be contributed by seed, by rain, and condensation from the atmosphere,

TABLE III.

* 13 years to 1861; unmanured since.

and by all the other supplies of combined nitrogen which have been supposed to be available. Of this about 2 lbs. will be due to seed, and supposing only 5 lbs. annually to be supplied by rain and minor aqueous deposits, there is but little left to be provided by all the other sources assumed.

Nitrogen in Soil of Barley Plots.—In 1868, four samples, 6 × 6 inches by 9 inches deep, were taken from each of four plots; only one of these plots had received no nitrogenous manure. In 1882, twenty-six plots were sampled to a total depth of three times 9 inches, four samples, 6 × 6 inches area, being taken from each plot. The plot which received mixed mineral (non-nitrogenous) manure alone contained in 1868, 0·1202 per cent. N in the first 9 inches of dry mould; in 1882, 0·1124 per cent. N.

Nitrogen in the Soil of Root Plots.—These plots have carried roots (turnips, swedes, sugar-beet, or mangel) for 40 successive years (1843–1882), with the exception of 3 years, in which barley was sown. The soils were sampled only in 1870, so that no comparison at different dates is yet possible. Some of the percentages of N found in 1870 are—

Plot 3. Unmanured	0·0852	per cent. N (in 1st 9 ins.).
,, 4. Mixed mineral manure	0·0934	,, ,, ,,
,, 5. Superphosphate only	0·0888	,, ,, ,,
,, 6. Superphosphate and potash	0·0867	,, ,, ,,
Mean of Plots 4, 5, and 6	0·0896	,, ,, ,,

These plots, after receiving no nitrogenous manure for 27 years, show a smaller percentage of nitrogen in the surface soil than has been found in any of the other experimental fields.

Nitrogen in the Soil of Bean Plots.—The determinations are not given, but are stated to lead to the conclusion that there has been a gradual decrease of nitrogen in the surface soil.

Nitrogen in the Soil of Clover Plots.—The want of success attending all attempts to grow clover continuously on the same plot, renders only a few special comparisons possible. The red clover plot, which yielded only six clover crops from 1849–1870, and very few afterwards, was sampled in 1881 in five places to a depth of 9 inches for comparison with an adjoining wheat plot 30 years under alternate wheat and fallow. Neither of these plots had received any nitrogenous manure for 30 years.

Nitrogen per Cent. in 1st 9 inches of Dry Mould (1881).

	Clover land.	Wheat and fallow.
Mean of determinations on 5 separate samples	0·1067	0·0925
Mean on the mixture of the 5 samples	0·1055	0·0984
Mean	0·1061	0·0955

The N in the surface soil of the clover plot is low, and has probably declined, although it is higher than in the adjacent wheat and fallow plot.

The next results refer to the plot (see Table I) which in 1873 had grown six successive corn crops by artificial manures alone, and was then divided, one-half carrying barley, and the other clover. In 1874 barley was taken on both halves. In 1873 the barley crop contained 37·3 lbs. N, and the clover crop 151·3 lbs. N. In 1874 the barley after barley yielded 39·1 lbs. N, whilst the barley after clover yielded 69·4 lbs. N, so great an improvement had the previous year's clover crop effected, notwithstanding the fact of the large quantity of nitrogen removed in that clover crop. The soil was sampled in October, 1873, with the results given in Table IV:—

TABLE IV.

Nitrogen per Cent. in 1st 9 inches of Dry Mould (1873).

	Clover land.	Barley land.
Sample No. 1 (12 × 12 × 9 inches) ..	0·1574	0·1468
„ No. 2 (12 × 12 × 9 „ ..	0·1529	0·1341
„ No. 3 (12 × 12 × 9 „ ..	0·1484	0·1431
„ No. 4 (12 × 12 × 9 „ ..	0·1631	0·1405
Mean on the four separate samples (12 × 12 × 9 inches)	0·1554	0·1411
Mean on a mixture of the four samples (12 × 12 × 9 inches)	0·1566	0·1387
Mean on a mixture of six samples (6 × 6 × 9 inches)	0·1578	0·1450
General mean	0·1566	0·1416

These results illustrate forcibly the necessity of taking numerous samples, but the mean of the three sets of determinations leaves no doubt that the surface soil of the clover plot contained a considerably higher percentage of nitrogen than that of the barley plot—and this, too, after all visible vegetable *débris* had been removed as completely as possible. Samples taken in 1877 still showed a higher percentage in the clover plot than in the barley. It is obvious that the surface soil of the clover plot gained nitrogen either from the atmosphere or from the subsoil—and, so far as the determinations of nitrogen in the subsoils go, the indication is that if from below it is at least mainly from a lower depth than 27 inches. The authors observe that it is natural to assume the atmosphere as the source of this nitrogen, but that there is absolutely nothing in favour of this view excepting the fact that an explanation is needed; whilst there is much more evidence in favour of the view that the subsoil has been the source of at least much of it.

Soils of Melilotus Leucantha and White Clover Plots.—The soil of the melilotus plot was sampled in 1882, after the fifth large consecutive crop on soil which had repeatedly refused to grow clover, and to which no nitrogenous manure had been applied for 30 years. A sample of soil from the corresponding white clover plot was taken at the same time, in each case to a depth of six times 9 inches, in all

54 inches. The examination of these samples is still incomplete, but the following evidence is forthcoming. The strong roots of the melilotus were found to penetrate to the lowest depth of the samplings, the soil being disintegrated, and having lost approximately 540 tons per acre more water than the corresponding 54 inches of white clover soil, in which there was very little development of root below the first 9 inches. Determinations of nitric acid in the two soils gave the results recorded in Table V :—

TABLE V.

	Per million, dry soil.		Per acre.		
	Melilotus soil.	White clover.	Melilotus soil.	White clover.	Difference.
			lbs.	lbs.	lbs.
First 9 inches.......	1·28	3·24	3 39	8 59	5·20
Second 9 inches......	0·36	1·10	0·97	2 97	2·00
Third 9 inches	0·21	0·66	0·61	1·91	1·30
Fourth 9 inches......	0·33	1·03	0·99	3 09	2·10
Fifth 9 inches........	0·28	1·46	0·84	4·38	3·54
Sixth 9 inches	0·55	1 77	1·65	5 31	3·66
Total	—	—	8·45	26·25	17·80

There is here direct evidence that the soil is the source of at least some of the excess of nitrogen of the melilotus over that in the white clover.

The authors next adduce determinations of nitrogen as nitric acid in various soils, in order to show the amount available for vegetation. Thus the soil of the unmanured wheat plot contained in October, 1881, 9·7 lbs. per acre nitric N in first 9 inches, 5·2 lbs. in second 9 inches, and 2·8 lbs. in third 9 inches; total, 17·7 lbs. N per acre. The soils of three of the wheat plots which had received nitrogenous manures in the form of ammonium sulphate or sodium nitrate contained 39·9, 38·8, and 54·4 lbs. nitric nitrogen per acre respectively in the first 27 inches. Samples collected from four of the rotation plots in September, 1878, showed in the first 18 inches :—

N as nitric acid after fallow, 36·3 and 48·8 lbs. per acre,
N as nitric acid after beans, 10·6 and 20·5 „ „

the larger quantity being in the plots receiving nitrogenous manure.

Samples taken at the same time to the same depth on the alternate wheat and fallow plots showed :—

N as nitric acid after fallow, 33·7 lbs. per acre.
N as nitric acid after wheat, 2·6 „ „

Samples taken from two other fields after a year's fallow contained in 27 inches depth, 58·8 and 56·5 lbs. N as nitric acid per acre.

These figures indicate a considerable amount of nitrogen available after fallow, which disappears during the growth of a crop, but it is admitted that they do not show enough nitric nitrogen in the depths examined, to account for the large accumulation of nitrogen in the crop and in the surface soil observed in the case of the experimental clover and barley soils.

Nitrogen in the Soils of the Experimental Mixed Herbage Plots.—On referring to the table given above, it will be seen that the plot receiving complete mineral manure yielded 22·6 lbs. N per acre per annum above that yielded by the unmanured plot. Analysis of the soils indicates that the soil of the mineral manured plot has become impoverished in nitrogen to a greater degree than that of the unmanured plot. The results of the first 9 inches of soil are:—

	1870. Per cent.	1876. Per cent.	1878.
Plot 3. Unmanured	0·2517	0·2466	—
Plot 7. Mixed mineral manure with potash	—	0·2236	—

The quantity of nitrogen lost by Plot 7 over Plot 3 amounts to 506 lbs. per acre over the 20 years of experiment, equal 25·3 lbs. per acre per annum, in this case showing a remarkable correspondence with the excess of nitrogen carried off in Plot 7, viz., 22·6 lbs. per acre per annum. The leguminous plant most encouraged by the mineral manure of Plot 7 was *Lathyrus pratensis*, which threw out a great mass of roots in the surface soil.

Source of the Nitrogen of Clover grown on Rich Garden Soil.—Although all attempts to grow red clover continuously on ordinary arable land have been unsuccessful, it has been grown for 29 years in succession on a small plot of rich garden soil. The experiment was commenced in 1854; the soil was sampled in 1857 and 1879. The nitrogen in the first 9 inches is given below:—

1857. Nitrogen per cent. of dry mould 0·5095 = 9528 lbs. per acre.

$$1879. \quad " \quad " \quad " \quad \left\{\begin{matrix} 0\cdot3635 \\ 0\cdot3640 \\ 0\cdot3626 \end{matrix}\right\} = 6796 \quad " \quad " \quad \text{(mean).}$$

In accordance with this large decline of soil nitrogen, there has been a decided falling off in the crops obtained, the produce from the three sowings of the first 14 years, being nearly double of that from the ten sowings which were found necessary to keep up a plant during the next 15 years. Estimating the average yield of nitrogen at 200 lbs. per acre per annum over the 21 years, the nitrogen lost by the surface soil (first 9 inches) is 130 lbs. per acre per annum, or about two-thirds of that carried off by the clover. The authors admit in this case the possibility of a loss by the soil of free nitrogen, and do not include the loss by drainage; on the other hand they point out that some of the nitrogen of the clover was doubtless supplied by the subsoil. They remark that there are very strong grounds for concluding that much, and perhaps the whole, of the nitrogen of the clover was derived from the soil.

Summing up on the whole paper, they submit that there is much more of direct experimental proof of the soil than of the atmosphere as the source of the nitrogen of our crops, both cereal and leguminous. If this be accepted it follows that the fertility of arable soil is to some extent measured by its stored-up nitrogen, and that soil is in fact a "mine" as well as a laboratory. J. M. H. M.

Analytical Chemistry.

Determining Left-handed Rotation with the Scheibler-Ventzke-Soleil Polariscope. By G. S. EYSTER (*Chem. News*, **49**, 67).—The author suggests the use of a quartz plate of known dextrorotatory power, with lævorotatory solutions of less rotating power. The difference between the reading with the quartz plate alone and the reading with the quartz plate and solution together is then, obviously, the lævorotatory power of the solution. This is for use with instruments not graduated for left-handed rotations.

D. A. L.

Litmus, Rosolic Acid, Methyl-orange, Phenacetolin, and Phenolphthaleïn as Indicators. By R. T. THOMSON (*Chem. News*, **49**, 32—35, 38—41).—In previous communications (Abstr., 1883, 612, 824, and 827) the author has published the results of his investigations on the use of these indicators in the analysis of some potassium, sodium, and ammonium compounds, and of free acids. He has now extended this useful work to the analysis of a few calcium, barium, and magnesium compounds.

Application of the Indicators to the Determination of Lime as Hydroxide in Presence of a Small Proportion of Carbonate.—For each experiment in this series, 200 c.c. of lime-water, previously treated in the cold with 0·0265 gram of sodium carbonate, and containing 0·2724 gram of total lime (CaO), 0·2584 as hydroxide, and 0·014 gram as carbonate, were titrated with $\frac{N}{2}$ hydrochloric acid, a deduction being made for the sodium hydroxide produced by the action of the sodium carbonate. The results obtained are as follows:—

Indicator.	Total CaO found.	CaO as hydrate found.	CaO as carbonate found.
	grams.	grams.	grams.
Litmus	0·2716—0·2730	—	—
Rosolic acid	0·2716—0·2716	—	—
Methyl-orange	0·2716—0·2716	—	—
Phenacetolin	0·2730—0·2716	0·2562—0·2576	0·0154—0·0154
Phenolphthaleïn	0·2716—0·2716	0·2590—0·2576	0·0140—0·0154

With *litmus* or *rosolic acid*, titration is conducted in the cold until change of colour takes place; the solution is then boiled, and the addition of standard acid continued until a permanent change of colour is effected. *Methyl-orange* is not altered by carbonic anhydride, therefore boiling is not necessary when it is used as indicator. *Phenacetolin* (compare Lunge, Abstr., 1883, 828) may be used for the determination of lime, both as hydroxide and carbonate, the changes being the same as already described (*loc. cit.*, 683), viz., rose for hydroxide, subsequent change to yellow for carbonate. Liberated carbonic anhydride must be boiled off. When using this indicator for the determination of lime as hydroxide, the final change of colour is not very distinct, owing to the interference of carbonic anhydride. *Phenolphthalein* behaves with lime as with soda (*loc. cit.*), the whole of the lime as hydroxide, and only half that as carbonate being estimated, calcium hydrogen carbonate being neutral. The total lime can be determined by adding excess of standard acid and titrating back. Experiments prove that light flocculent calcium carbonate, freshly precipitated from a cold solution, gives an alkaline reaction with phenolphthalein, whilst after boiling, when it is dense and granular, it gives no reaction with this indicator, and therefore calcium hydroxide can safely be determined in the presence of calcium carbonate by simply adding standard hydrochloric acid to a boiling solution, until the red colour of the phenolphthaleïn is gone.

Comparative experiments in which lime and carbonic anhydride were determined in a sample of slaked lime by the ordinary gravimetric methods, and by titration, using phenolphthaleïn as indicator, prove that the results obtained in the two cases are practically the same. *Determination of Lime as Carbonate:* in addition to the above remarks, it may be noted that *litmus, rosolic acid, phenacetolin* and *methyl-orange* can be used with advantage in this determination, especially for the light flocculent carbonate, the first three are not so delicate with the dense form. *Phenolphthaleïn* is already fully discussed. *Determination of Barium Hydroxide and Carbonate:* the results obtained with lime are equally true of barium. Barium carbonate even when precipitated in the cold is neutral to phenolphthaleïn.

Determination of Magnesium Hydroxide and Carbonate.—Total magnesia can be determined by dissolving in excess of standard acid, expelling carbonic acid and titrating back; any indicator being used. Magnesia as hydrogen carbonate can be determined directly with standard acid either in the cold with methyl-orange or in the boiling solution with any of the other indicators. Phenacetolin and phenolphthaleïn cannot be employed successfully for the determination of magnesium hydroxide in the presence of carbonate. The author alludes to Hehner's method for the determination of the hardness of water (*Analyst*, 8, 77), in which the temporary hardness is best estimated by titrating a hot solution, using phenacetolin, whilst for the permanent hardness the calcium and magnesium salts are converted into carbonates by boiling with a measured excess of standard sodium carbonate; the precipitate is filtered off, and the excess of sodium carbonate titrated with standard acid. It is necessary in such determinations to take into account any sodium carbonate present in the water.

Calcium, Barium, and Magnesium Chloride, Nitrate, and Sulphate, are neutral to all the indicators with the exception of methyl-orange, which requires more standard acid to produce the final full change of colour when these salts are present than when they are absent. Barium and calcium carbonate being neutral to phenolphthaleïn (see above), the amount of calcium may be determined in any neutral salt or barium in its chloride by titrating with sodium carbonate in the following manner. Add phenolphthaleïn to the solution to be examined; if acid neutralise with sodium hydroxide, then add standard sodium carbonate until a permanent red is developed. These determinations cannot be made in the presence of magnesium.

Calcium and Magnesium Sulphites.—For each experiment, 0·525 gram of normal calcium sulphite = CaO 0·242 was employed. Magnesium sulphite acts in the same way. The results are—

Indicator.		c.c. $\frac{N}{2}$ hydrochloric acid consumed.	Grams CaO found.
Litmus		8·5	0·1190
Rosolic acid	cold	—	trace
	boiling	0·4—0·5	0·0056—0·0070
Methyl-orange		8·7—8·75	0·1218—0·1225
Phenacetolin		8·5	0·1190
Phenolphthaleïn	cold	—	trace
	boiling	—	—

The *litmus* and *phenacetolin* reactions are both unsatisfactory, and as is evident from the appended table, calcium (magnesium) hydrogen sulphite is neutral to them as well as to *methyl-orange* which, however, gives a delicate end-reaction. The normal salt is neutral to *rosolic acid* and *phenolphthaleïn*, to the former only in the cold, to the latter both when cold and boiling. Upon this last fact is founded a method for the estimation of sulphurous anhydride, which gives good results when compared with the iodine method. The method of procedure is as follows: methyl-orange is added to the sample under examination, which is neutralised either with hydrochloric acid or caustic soda, phenolphthaleïn or rosolic acid is now added, and normal or half-normal sodium hydroxide run in until the characteristic colour appears. The number of c.c. used during the second stage multiplied by 0·064 equals grams of sulphurous anhydride present. Phosphoric acid and carbonic anhydride interfere with this reaction.

Calcium, Magnesium, Potassium, and Ammonium Borates behave like sodium borate already described (Abstr., 1883, 825), and therefore can only be titrated with methyl-orange as indicator.

Calcium Phosphates.—Tricalcium phosphate is neutral to all indicators, monocalcium phosphate is neutral to *methyl-orange*, and acid to the other four. Attempts were made to determine the amount of monocalcium phosphate in presence of calcium chloride by the combined use of methyl-orange and phenolphthaleïn, and titration with $\frac{N}{2}$ soda, the results were always too high owing to formation of a basic phosphate. With regard to Mollenda's method for determining phosphoric acid in superphosphate (*Chem. News*, **47**, 231), the author finds that even when indicators are used, only approximate results are obtained.

Phenol is neutral to litmus, rosolic acid, methyl-orange, and phenacetolin, and does not destroy the colour. Titration with *phenolphthaleïn*, the reaction is not distinct. In an experiment with sodium sulphide prepared from hydrogen sulphide and caustic soda, on adding acid in excess, the colour of methyl-violet was destroyed.

The paper concludes with a tabulated arrangement of all the results obtained both on the present occasion and on the previous occasions already referred to. The following is a summary of the table.

With K, Na, NH_4, Ca, and Ba *hydroxides*, all five indicators give good results and delicate end-reactions, with the exception of phenolphthaleïn with ammonia.

With K, Na, Ca, Ba, Mg *carbonates*, K, Na, Ca *hydrogen carbonates*, K, Na *sulphides*, and Mg *oxide*, methyl-orange alone is good in the cold, and all the others are good in boiling solutions, except phenolphthaleïn with Ba and Ca *carbonates* and Ca *hydrogen carbonate*. With NH_4 *carbonate* and *sulphide*, methyl-orange alone is good; all the others except phenolphthaleïn may be used if excess of acid is added and subsequently titrated back. With K, Na, Ca, Mg, and NH_4 *sulphites*, K, Na, NH_4 *hydrogen phosphates*, methyl-orange indicates for 50 per cent. of base present, and gives delicate end-reactions. The other indicators are uncertain or indicate for smaller quantities only. K, Na, Ca *dihydrogen phosphates* are neutral to methyl-orange, and acid to all the others. For K and Na *silicates*, litmus and methyl-orange are best, the others, phenolphthaleïn excepted, are good. For Na, K, NH_4, Ca, and Mg *borates*, methyl-orange alone is efficient. In the presence of freshly precipitated *alumina*, phenacetolin and phenolphthaleïn only are useful for estimation of alkalis. All are good for titration of acids, and give delicate end-reactions with HCl, HNO_3 and H_2SO_4, whilst litmus, rosolic acid, and phenolphthaleïn only are good for *oxalic acid*, and phenolphthaleïn alone for $\overline{Ac}HO$, $\bar{T}(HO)_2$, and $\overline{Ci}(HO)_3$. Phenolphthaleïn can be employed as indicator in the titration of several fatty and resin acids and natural fats with standard alcoholic potash. D. A. L.

Estimation of Chlorine, Bromine, and Iodine in Presence of one another. By F. M. LYTE (*Chem. News*, **49**, 4).—It has been shown (this vol., 393—394) that bromine decomposes silver chloride, and that iodine decomposes silver bromide. The author now communicates a convenient method of applying these reactions for quantitative purposes. The silver precipitate, containing all the halogens, is dried, weighed, and then dissolved in 30 to 40 times its weight of water, by adding the smallest possible quantity of potassium cyanide. A quantity of potassium bromide equal in weight to the precipitate is now added, and the cyanide decomposed by excess of dilute sulphuric acid. The precipitate which contains bromide and iodide (any chloride being now bromide) is dried, weighed, and then redissolved as before. One and a quarter times the weight of the original precipitate of potassium iodide is now added, the cyanide decomposed as above, and the precipitate dried and weighed. The quantity of chlorine, bromine, and iodine present is easily calculated from the differences in the weights of the three weighings. D. A. L.

Improved Form of Orsat's Apparatus for the Estimation of Oxygen. By J. B. C. Kershaw (*Chem. News*, 49, 73—74).

Volumetric Estimation of Potash. By E. Marchand (*Ann. Agronomiques*, 9, 465—469).—The basis of this method is the diminution of acidity caused by the separation of insoluble hydrogen potassium tartrate from a mixture of sodium hydrogen tartrate with a neutral solution of a potassium salt.

Standard sodium hydrogen tartrate is prepared of such a strength that 1 c.c. will precipitate 10 mgrms. of potash (K_2O): 40 c.c. of this solution are added by means of a pipette to 10 c.c. of a carefully neutralised solution containing 0·5 gram of the potash salt to be tested. The mixture is left at rest during the night, and a similar flask containing 50 c.c. of water is placed beside it. The bulb of a minimum thermometer is plunged in the water of the second flask, and the lowest temperature reached is noted in the morning. A solution of cochineal containing 0·1 gram per litre is used as indicator, and the 10 c.c. of the mother-liquor from which the cream of tartar has separated are diluted with the coloured liquid to 30 or 40 c.c., and titrated with standard alkali delivered from a 10 c.c. burette graduated to $\frac{1}{10}$ c.c., but so narrow that $\frac{1}{100}$ c.c. may be judged by the eye (1 c.c. occupies about 3 cm. of this burette). The burette is drawn out to a capillary jet at the lower end, and is furnished with a stopcock at its upper end, being filled by suction through a caoutchouc tube attached above the stopcock.

The quantity of standard alkali consumed being accurately noted, the required percentage of potash is found by reference to a table opposite the minimum temperature at which the potassium hydrogen tartrate was deposited. Thus, if the acidity of the 40 c.c. of standard sodium hydrogen tartrate is lowered in an experiment from 8·00 c.c. standard alkali to 2·79 c.c., with a minimum temperature of 9°, the percentage of potash in the salt examined is found to be 56·3. If under the same circumstances the minimum temperature were 14°, the percentage would be 58·8. This method is applicable in presence of sodium, calcium, and magnesium salts, and succeeds equally well with the chloride, nitrate, or sulphate of potassium. Ammonium salts must of course be absent. The standard sodium hydrogen tartrate may be preserved indefinitely by addition of a little camphor, if kept in the dark. The empirical table referred to above is not yet published. J. M. H. M.

Volumetric Estimation of Mercury. By G. Kroupa (*Chem. News*, 49, 14).—Recently precipitated mercurous chloride is readily converted into sulphide and hydrochloric acid by means of hydrogen sulphide solution, therefore by determining the chlorine in solution the quantity of mercury present can be calculated. With mercuric salts, when required, a sufficient quantity of sodium chloride is added, then a solution of ferrous sulphate and potash. The mixture is well stirred, and after a few minutes is strongly acidified with dilute sulphuric acid. The mercurous chloride thus obtained or that precipitated direct from mercurous salts, is filtered, washed, and with the filter placed in and covered with hydrogen sulphide solution. The hydrochloric acid produced is neutralised with barium carbonate, the excess of hydrogen sulphide got rid of by means of zinc acetate, the zinc sulphide filtered off, well washed, and the chlorine titrated in the filtrate. D. A. L.

The Ammonia Process for Water Analysis. By N. H. DARTON (*Chem. News*, **49**, 65—67).—In the ordinary course of water analysis, the non-ammoniacal volatile nitrogenous (organic) matters are not estimated, because they do not act on Nessler solution. The author determines this amount of nitrogen by dividing the distillate for ammonia-testing into two equal parts; the one part he Nesslerises in the ordinary manner, the other he distils with ammonia-free alkaline potassium permanganate and Nesslerises the distillate; the difference between the two Nessler testings is due to the volatile organic nitrogenous matter decomposed during the second distillation. The author considering this to be of great importance, has examined the physiological action of the concentrated volatile nitrogenous organic matter obtained from various pump-waters from the cities of New York and Brooklyn; these waters are well polluted, and contain plenty of these nitrogenous matters. He finds that when injected under the skin of rabbits, the concentrated nitrogenous matters generally produce unpleasant symptoms, mostly of diarrhœa, sometimes accompanied by vomiting, and frequently followed by death. By subsequent experiments, he shows that these effects are really due to the matters in question, and accounts for their varying in action by assuming that these volatile matters include both virulent and harmless amine-compounds. The following is the manner of concentrating these matters:—5 litres of water are distilled in half litres at a time, collecting in each case 100 c.c.; the litre of combined distillates is subjected to similar treatment, and the two 100 c.c. thus obtained are mixed, treated with the calculated quantity of phosphoric acid to fix free ammonia, distilled, and 50 c.c. of distillate collected, and after redistilling, is found to be free from ammonia. In this way two-thirds (of the amount found by analysis) of the ammonia of the volatile nitrogenous matter is obtained, other bodies, chemical and organised, being left behind. In some injection experiments the original waters were found to produce symptoms similar to those induced by the concentrated, thus supporting the suggestion of the pre-existence of those substances in the waters. D. A. L.

Estimation of Tannin in Vegetable Products. By M. PERRET (*Chem. News*, **49**, 52).—In the process recommended, the clear aqueous extract of the substance under examination is concentrated, and while warm is mixed with a measured quantity of solution of egg-albumin in excess, heated to 100°, decinormal aluminium sulphate is then run in from a burette until the deposit becomes granular and settles down. This is filtered on a tared filter, washed, dried, and weighed. The weight of the tannin is obtained by deducting the weight of the albumin and aluminium sulphate added, as well as the weight of the filter-paper from the total weight. D. A. L.

Technical Chemistry.

Coal-gas as a Source of Heat. By T. FLETCHER (*Chem. News*, 49, 74—86).

Zinc in Drinking Water. By C. W. HEATON (*Chem. News*, 49, 85).—Water from a spring at Penderry of the composition given below was passed for about half a mile through a galvanised iron pipe, with the following result:—

	Grains per gallon.	
Constituents.	Spring.	Pipe.
Total solids	10·80	18·90
Chlorine	1·47	1·45
Ammonia	none	0·008
Nitrogen as nitrate	0·056	none
Zinc carbonate in solution in carbonic acid	none	6·41

This result was confirmed in a subsequent experiment, when the solution of the zinc was effected by passing a stream of oxygen and carbonic anhydride for half an hour through distilled water containing fragments of the pure metal. The author remarks on the reduction of nitrates to ammonia by the action of zinc. D. A. L.

Use of Carbolic Acid in the Disinfection of Sewage. By O. KELLNER and others (*Landw. Versuchs.-Stat.*, 30, 52—58).—During a cholera epidemic in Japan, 1882, the Government ordered that all human excrement should be treated with carbolic acid and ferrous sulphate. This description of manure is that most largely used in Japanese agriculture, and when the farmers refused to purchase, fearing to injure their crops by the disinfectants, it became a serious matter for both towns and country. With a view of learning whether the use of carbolic acid was really hurtful to growing crops, the Government ordered experiments to be made at their experimental farm. The mode of cultivation in Japan is particularly adapted to show injurious properties in the manure if it possessed any, as the manure is spread, or distributed if fluid, immediately before sowing, and the seeds put in immediately. The experiment consisted in steeping a number of seeds for a certain time in solutions of carbolic acid of different strengths, then placing them between filter-paper in covered beakers until germination took place, the papers being frequently moistened with the proper solution. Parcels of 200 seeds each, of *Phaseolus radiatus*, were placed for 42 hours in 100 c.c. of the following concentrations and inspected at regular periods.

Experiment	1.	2.	3.	4.	5.	6.
Per cent. carbolic acid ..	0	0·025	0·05	0·10	0·15	0·20
Hours after steeping.	Number of seeds germinated.					
48	40	34	21	0	—	—
72	52	43	30	8	—	—
96	38	44	52	6	—	—
120	13	22	28	2	—	—
144	8	6	10	6	—	—
168	5	15	13	4	—	—
192	17	10	12	10	—	—
8 days	173	174	166	36	—	—
Per cent.	86·5	87	83	18	—	—

According to these figures, a solution of 0·05 of carbolic acid in 100 c.c. water clearly weakened the germinating power of the seeds, and with a solution of 0·1 per cent. only one-third of the possible seeds germinated, and in all cases the acid delayed the process of germination. A second series of experiments was made with wheat, the results being similar, the acid in all cases delaying germination. Field experiments were then undertaken, and the injurious effects of the disinfected manure showed in the growth of wheat and barley when the land was cultivated in the manner usual in Japan, but when the manure was applied earlier, for example in October, ploughed in and left to the rains of winter, the author thinks the carbolic acid was carried into the subsoil out of the reach of the roots. Wheat, barley, and buckwheat behaved in a similar manner, the injurious effects of the acid being but feebly apparent when the manure was applied early. J. F.

Formation of Sulphuric Acid in the Lead Chambers. By G. Lunge (*Chem. News*, **49**, 13—14).—This communication is based on results of observations made in a works in Switzerland. Firstly, with regard to *nitrogen peroxide;* as this substance takes no part in the formation of sulphuric acid, its presence is not necessary in the lead chambers; in fact, it is only a secondary product formed under special conditions. For example, it is produced in the last chamber when there is a large excess of nitrous gas, and where the quantity of sulphuric acid formed is small. Its production is apparently greatly favoured by absence or reflux of sulphurous acid, whilst it is not affected by the amount of oxygen present. Nitrogen peroxide is

never found in tower acid (compare Abstr., 1882, 1010, 1162). When the gaseous mixture in the chambers is yellow, there is considerable loss in nitrous anhydride and nitrogen peroxide in the Guy-Lussac tower, when, on the other hand, it is colourless, the loss as nitrate is great, and the escaping gases contain nitric oxide, sulphurous anhydride, and only traces of the above gases. The *oxidation of sulphurous anhydride* goes on rapidly at first, 75 per cent. is converted into sulphuric acid by the time the gaseous mixture has reached the centre of the first chamber; only 4 per cent. more undergoes conversion from the centre to the end of this chamber, whilst 10 per cent. is changed in the pipe connecting chambers 1 and 2. The employment of a series of several chambers connected by small pipes is very favourable to the good working of a plant; the pipes seem to effect the compression, and therefore the more intimate mixture of the gases. The *mixture of the gases* is complete in the centre of the first chamber (compare Abstr., 1883, 129), the composition being constant at different heights, there is, however, in the centre from 0·1 to 0·2 per cent. more sulphurous anhydride than along the sides. The *temperature* rises 5° to 6° in the first quarter of the first chamber, and then falls slowly, the decrease becoming stronger towards the end of the series of chambers. In the middle of first chamber, the temperature at the bottom is 5° lower than at the top. The temperature is about the same whether steam or water spray is employed. Increasing the size of chambers for the same quantity of sulphur causes a diminution of temperature. The *cooling effect of the sides of the chambers* scarcely penetrates more than 25 cm. into the interior, for example: external temperature being 19°, at 5 to 10 cm. from the side reduction of temperature is 2°, at 10 to 25 cm. only 1°; whilst from 25 cm. (from side) to centre of chamber difference is 5°, and from side to centre 8°.

Barium and Strontium in a Boiler Incrustation. By C. L. Bloxam (*Chem. News*, **49**, 3).—The incrustation examined was deposited in a kitchen boiler from water from a deep chalk well in Harrow, which contained, in grains per gallon, 14·48 SO_3, 8·88 Cl, 7·21 CaO (SrO,BaO), 5·61 MgO, 15·20 Na_2O, 12·60 CO_2 (combined), 1·28 SiO_2. The deposit contained only a small quantity of barium sulphate, but 1·54 per cent. of strontium sulphate. The precipitates of both these metals were examined spectroscopically.

Sorgho-sugar Making in America. By G. Dureau and Pellet (*Bied. Centr.*, 1883, 788).—The yield of sap from 100 kilos. sorghostalk is 65 kilos., containing 12·5 per cent. crystallisable sugar, and 3·7 per cent. molasses. Pellet finds in raw sorgho-sugar 92 per cent. sugar and 2·56 per cent. glucose.
J. K. C.

Composition of Residues obtained in the Beet-sugar Manufacture. By A. Pagnoul (*Bied. Centr.*, 1883, 789).—In fresh residues, the sugar varies from 6·5 to 0·48 per cent., the former being obtained from the hydraulic press, and the latter by maceration; the percentage of nitrogenous substance varies from six in the former to twelve in the latter. Similar differences are observable in the residues which have been kept. J. K. C.

Russian Cheese. By A. Kalantaroff (*Bied. Centr.*, 1883, 719). —Five analyses are given as follows:—

Constituent.		1.	2.	3.	4.	5.
Water		29·80	32·51	35·44	34·68	31·26
Fat		37·20	29·68	28·97	32·53	32·94
Albuminoids		20·57	26·16	28·81	24·15	24·54

Action of Aluminium Sulphite on Manganic Hydroxide. By G. Scurati-Manzoni (*Gazzetta*, 13, 567).—It is well known that stannous chloride converts manganic hydroxide into soluble manganous chloride, and is itself converted into insoluble stannic acid—a reaction which is utilised for facilitating the fixation of certain colours on cotton and wool fibres, the stannic acid acting as a mordant. Now, aluminium sulphate acts in exactly the same way, giving rise to soluble manganous sulphite and insoluble aluminium hydroxide, which is deposited on the fibre, and renders it capable of receiving a dye. In the bleaching of textile fibres with potassium permanganate, the cleansed or scoured fibres are coloured brown by the manganic hydroxide produced, and require to be bleached by sulphurous acid. Now, by employing aluminium sulphite instead of sulphurous acid, the bleaching and aluming of the fibres may be effected in one and the same operation. H. W.

Action of Sunlight, Daylight, and Electric Arc Light on Water and Oil Colours used in Dyeing and Painting. By M. Decaux (*Chem. News*, 49, 51).—The colours in wool dyed in the vat with Prussian blue, cochineal, madder, weld, and fustic, are more permanent than those obtained with Nicholson blue, magenta, jaune d'or, and picric acid. Naphthol carmine, orange No. 2, chrysoïdine, and artificial alizarin, are more stable than other coal-tar colours. Pigments are divided into permanent, moderately permanent, and fugitive. Used with water, all the most beautiful reds, carmine, carmine lake, most madder lakes, and vermilion are classed as fugitive. With oil, madder lakes are moderately permanent. The electric arc light acts like sunlight, but with one-fourth the power.

General and Physical Chemistry.

Absorption Spectrum of Water. By J. L. Soret and E. Sarasin (*Compt. rend.*, **98**, 624—626).—A beam of light passed through a thickness of 2·2 metres of water shows a faint and narrow absorption-band in the orange at about wave-length 6000. With a thickness of 3 3 metres, this band is slightly more distinct and there is general absorption of the extreme red, and with a thickness of 4·5 metres the absorption-band is darker, but still remains faint, and the general absorption in the red is increased. This absorption-band is observed with water from different localities, with ordinary distilled water, and with most carefully purified distilled water, and it must therefore be due to the water itself and not to any substance dissolved in it.

Even with a thickness of 8 metres, the authors were unable to distinguish the absorption-band between *a* and *b* seen by Vogel in the light in the grotto of Capri, hence it would seem that this band is due to some substance in solution in sea water. C. H. B.

Influence of the Chemical Nature and Pressure of Gases on the Generation of Electricity by an Induction Machine. By W. Hempel (*Ber.*, **17**, 145—148).—A Töpler's induction machine was so arranged in a glass case, that it could be worked in an atmosphere of gas at any required pressure. The results showed that with air at 2 atmospheres pressure, an amount of electricity was developed about twice as great as at 1 atmosphere pressure under like conditions, whilst on diminishing the pressure to ½ atmosphere, scarcely any electricity was generated. With regard to the influence of different gases, it was found that on working under like conditions in hydrogen, air, and carbonic anhydride, the quantities of electricity obtained had the ratios 9 : 45 : 47. A. J. G.

The Clausius-Williamson Hypothesis. By S. Arrhenius (*Ber.*, **17**, 49—52).—This is a reply to Jahn (*Ber.*, **16**, 2449) in defence of the above hypothesis.

Freezing Point of Solutions of Salts of the Alkali-metals. By F. M. Raoult (*Compt. rend.*, **98**, 509—512. Compare Abstr., 1883, pp. 7, 278, 952, and this vol., 254).—The author has extended his researches to solutions of various salts of the alkali-metals. The results are given in tables, and the salts employed are divided into five groups. The first group consists of normal or acid salts which contain one atom of the alkali-metal, and in this group the molecular reduction of the freezing point varies between 27 and 36, the mean being 32. Normal salts of oxyacids give a reduction approaching 31; normal salts of hydracids give a reduction approaching 35. The rare instances in which the reduction approaches 27 are di-acid salts, which are partially decomposed by water. The second group consists of salts which contain two atoms of the metal; the molecular reduction is about 40. Salts containing three atoms of the metal give a molecular reduction of about 48, but this number is somewhat too high, because these salts are partially decomposed by water. Salts which contain four atoms of the metal, *e.g.*, pyrophosphates and ferrocyanides, produce a molecular reduction of about 47. The fifth group contains potassium ferricyanide and cobalticyanide, which are regarded as containing six atoms of the base in the molecule. The molecular reduction is about 96, a number which is quite abnormal, and indicates that the molecular weight ascribed to these salts is, when they are in solution, double the true molecular weight.

C. H. B.

Law of Thermo-Chemical Moduli or Constants of Substitution. By Berthelot (*Compt. rend.*, **98**, 400).—The author shows that this law is altogether inapplicable to soluble salts of mercury. Tommasi considers, however (*ibid.*, 637), that the heats of formation of these salts have not yet been determined with sufficient accuracy.

C. H. B.

Absorption of Gases of Platinum. By Berthelot (*Ann. Chim. Phys.* [5], **30**, 519—538).—A study of the phenomenon of electrolytic polarisation induced the author to investigate the heat changes involved in the absorption of gases by platinum. Three forms of the metal were used, *viz.*, platinum-dust, metal reduced by formic acid, and platinum-black; the action on them of oxygen and hydrogen was studied. The method of investigation is also given in detail.

Platinum-dust.—From the experimental results it is deduced that for every gram of hydrogen absorbed by the dust and susceptible of oxidation in the cold by oxygen, heat is developed 9·5 cal.

Metal Reduced by Formic Acid.—This form seems to combine with hydrogen in two successive stages, one hydride being oxidised by oxygen in the cold, but the other only at high temperatures. The results were as follows:—

	Cal.
1. Formation of hydride saturated with hydrogen, $Pt_x + H_3 = Pt_xH_3$ ……………………	+ 42·6
2. Formation of the same from an unsaturated hydride, $Pt_xH_2 + H = Pt_xH_3$ …………..	+ 8·7

Therefore

3. Formation of the unsaturated hydride from its elements $Pt_x + H_2 = Pt_x + H_2$ ………..	= 33·0

In the production of this latter 17·0 cal. are developed for every equivalent of hydrogen. The value for x in the above formulæ is approximately 60; the formula of the hydrides is thus $Pt_{60}H_3$ and $Pt_{60}H_2$.

Platinum-black.—The results obtained with this form are not sufficiently definite, the phenomenon being complicated by the presence of some suboxide, which absorbs and reacts with the hydrogen.

Absorption of Oxygen.—The quantity of heat developed in the absorption of oxygen by platinum is very small, and the results here adduced are probably too high. The relative volume of the oxygen absorbed to the platinum is too small for calculation.

Form of metal.	Weight of metal.	Heat developed.
Platinum-dust	117·6	0·0083 cal.
Platinum reduced by formic acid	66·3	0·0094 „
Platinum-black	—	0·0180 „

As regards the last results, it was observed that the heat developed was diminished each time that the metal was heated to 200° in a vacuum; this diminution seems to point to a change in state of the platinum-black on heating.

These investigations show that the electromotive force required to decompose water in the presence of platinum is equivalent to the difference between the heat changes corresponding with the separation of hydrogen and oxygen (+ 34·5 cal.), and the sum of the heat changes corresponding to the formation of the first hydride (+ 17 cal.) and of the suboxide of platinum. This last factor is unknown, but is doubtless considerable. The energy necessary for the change is present in the system at the commencement of the reaction, but is arrested temporarily by the chemical changes supervening on the surface of the platinum.

The phenomenon of the so-called spontaneous combustion of hydrogen and oxygen in presence of platinum can also be explained by the aid of these researches; at first the unstable hydride of platinum is formed, with development of heat, and this is oxidised by the oxygen with a still further development of heat. By a continued repetition of the above changes, the platinum is raised to the temperature necessary for the ignition of the gaseous mixture. This explanation conforms to the observed succession of phenomena.

V. H. V.

Reciprocal Displacements of Hydrofluoric Acid and other Acids. By BERTHELOT and GUNTZ (*Compt. rend.*, 98, 395—399).—A comparison of the quantities of heat developed in each of the four reactions which may take place between hydrofluoric and hydrochloric acids and the corresponding potassium salts, shows that in every case the maximum thermal effect corresponds with the formation of potassium hydrogen fluoride, and this conclusion is verified by experiment. If a current of dry hydrochloric acid gas is passed over dry potassium fluoride at the ordinary temperature, the hydrochloric acid is absorbed, and potassium chloride and potassium hydrogen fluoride are formed, but no hydrofluoric acid is given off. If, however, the substances are heated, the acid fluoride decomposes into hydrofluoric acid, which is given off, and the normal fluoride. The latter is converted by a further quantity of hydrochloric acid into the chloride and acid fluoride; this acid fluoride is in its turn dissociated, and the same series of changes goes on until the whole of the fluoride is converted into chloride. In the same way, when dry hydrofluoric acid gas acts on potassium chloride in the cold, hydrochloric acid is given off, and potassium hydrogen fluoride is formed, but at a moderately high temperature the chloride is gradually converted into the normal fluoride.

If these substances are in solution, the base is unequally divided between the two acids, as Thomsen has previously shown, but the authors regard this result as due entirely to the formation of potassium hydrogen fluoride and its partial dissociation in presence of water, and not, as Thomsen supposes, to a special coefficient of affinity proper to each acid. The results of experiment are in complete agreement with the deductions from thermochemical data: whether the substances are solid or in solution, the maximum thermal effect corresponds with the formation of the acid fluoride.

Precisely similar results are obtained with nitric acid: in the case of sulphuric acid, an acid sulphate and an acid fluoride are first formed, but are afterwards decomposed by heat.

In the case of acetic acid, thermochemical data indicate that the base will be divided between the two acids, and this is confirmed by experiment. The partial displacement of hydrofluoric acid by acetic acid is due to the formation of the acid fluoride. Oxalic and tartaric acids, whether solid or in solution, behave in a similar manner, the acid fluoride being formed together with the acid tartrate or oxalate as the case may be.

Similar considerations indicate that hydrofluoric acid should be partially displaced by hydrocyanic acid, and it is found that at a dull red heat there is a sensible displacement of hydrofluoric acid, with formation of potassium cyanide. In the cold the same change also takes place, but more slowly. Inversely, hydrofluoric acid decomposes potassium cyanide with formation at first of the acid fluoride.

C. H. B.

Hydrogen Potassium Fluoride in Solution. By GUNTZ (*Compt. rend.*, **98**, 428—431).—The proportion of hydrogen potassium fluoride existing in a solution is diminished by dilution, but increases with an increase in the proportion of hydrofluoric acid. When the normal potassium fluoride is added to a solution of hydrofluoric acid, the amount of acid fluoride formed increases with the proportion of normal fluoride. The conditions of equilibrium are analogous to those observed by Berthelot and Péan de Saint-Gilles in the formation of ethers; in both cases, the effect of the acid is greater than that of the other compound (normal salt or alcohol).

For the degree of dilution employed in these experiments (1 gram-equivalent in 2 kilos.), the amount of dissociation is twice as great in a solution containing equal equivalents of the normal salt and acid, as in a solution containing a large excess of normal salt, and two and a half times as great as in a solution containing a large excess of acid.

C. H. B.

Double Salts formed by Fusion. By BERTHELOT and ILOSVAY (*Ann. Chim. Phys.* [5], **29**, 295—342).—This paper contains an account of the study of the thermal phenomena attending the production by fusion of a large number of double salts.

The method of investigation consisting in the determination (1) of the heat of solution of the simple salts used; (2) of the heat of solution of the same after fusion; (3) the heat of solution of the double salts immediately after preparation, and also after keeping for some time. The results obtained have enabled the authors to draw the following conclusions. A large number of double salts can be prepared by fusion, such as double chlorides, chlorobromides, double carbonates, and double sulphates, which retain even at the ordinary temperature a positive heat of formation; these form stable compounds, and may also be prepared in the wet way. On the other hand, the heat of solution of some systems of double salts is greater than the sum of those of their constituents. The instability of these systems is shown by this difference gradually decreasing after the double salts have been kept for some time. Further, the heat disengaged when a system assumes its final state becomes less as a rule in the case of simple salts than in that of systems formed by the fusion of two mixed salts, which, in all probability, may be due to the existence at the temperature of fusion of the double salts belonging to the same chemical types as the double chlorides, chlorobromides, double sulphates, and double carbonates. Such are the double chlorides of potassium, and of sodium, or of barium, or strontium, &c.: compounds becoming endothermic in cooling, but which are analogous to the double chlorides of potassium and of magnesium, or of calcium, the formation of which remains exothermic in the cold. So also the chlorobromide, chloriodide, and iodobromide of potassium are endothermic compounds in the cold, but are analogous to the chlorobromide of barium, which remains exothermic in the cold. In like manner the double sulphates of potassium, of sodium, or of barium, or of strontium, are endothermic in the cold, although they are analogous to the double sulphates of magnesium, the formation of which remains exothermic in the cold. A similar instance is found in the case of the double carbonate of potassium and barium, which is endothermic in the cold, but is analogous to the double carbonate of potassium and sodium. The authors point out that it is quite possible that the association of two simple salts may give rise to combinations which remain exothermic at the ordinary temperature, whilst other combinations differing in the relative amounts of the constituents become endothermic in the process of cooling. The double carbonate of potassium and sodium exhibits the same phenomenon.

The systems $K_2CO_3 + Na_2CO_3$, $K_2CO_3 + 2Na_2CO_3$, and $2K_2CO_3 + Na_2CO_3$, become exothermic from the first moments of cooling. The following, $Na_2CO_3 + 3K_2CO_3$, $K_2CO_3 + 5Na_2CO_3$ and $Na_2CO_3 + 4K_2CO_3$, become exothermic after some time, and finally the system $K_2Co_3 + 4Na_2CO_3$ remains endothermic to the end of two months. Some double salts in the anhydrous state are endothermic at the ordinary temperature, but may become exothermic by the aid of water of crystallisation; again, the formation by fusion of the double anhydrous salts may be attended with development of heat. The double salts of the different kinds just described play a very important part in many reactions and metamorphoses produced in the dry way.

As, for instance, the crystallisation of barium sulphate and strontium sulphate from their double sulphates. Barium carbonate also crystallises at the expense of the fusible double carbonate containing it. The crystalline silicates formed by the devitrification of glass, the formation of corundum, ruby, and the crystalline silicates, as obtained by Fremy and Feil, are all formed under conditions of the same order; in other words, double salts are first formed by fusion, from which their components separate in the crystalline state by the dissociation and final decomposition of the double salts, this decomposition taking place at times at the moment of solidification, at others slowly in the solidified mass, but never without a continuous and characteristic development of heat. The most important application of the existence of these double salts is to be found in their intervention in such double decompositions as that of barium sulphate by potassium and sodium carbonates by fusion. Reactions of this character are never complete, when equivalent quantities are used, requiring as they do for their completion an excess of the carbonates of the alkali-metals. The true reaction does not take place between four simple salts alone—such as barium carbonate and sodium carbonate, or barium sulphate and sodium sulphate; double carbonates of barium and of sodium, and double sulphates of barium and sodium are formed, the dissociation of which double salts results in the formation of the simple salts derived from them. If the latter be eliminated their formation becomes complete, if they remain in the presence of their components then their formation is limited in a definite manner by the dissociation of the double salts to an extent dependent on their relative proportions, the conditions regulating this species of reaction being exactly similar to those which obtain in reactions between salts in solution. In both cases, the equilibrium is effected by the intervention of secondary compounds existing in a state of partial decomposition. P. P. B.

Some Mercuric Salts. By BERTHELOT (*Ann. Chim. Phys.* [5], **29**, 351—353).—Mercuric acetate, $Hg(C_2H_3O_2)_2$, forms white well-defined crystals, is easily soluble in cold water, its solution decomposes on boiling or keeping with formation of basic salts. The heat produced by neutralising mercuric oxide by acetic acid was found indirectly to be 3·04 cal., and by direct experiment to be + 3·17.

Heat of Formation of Mercuric Acetate.—(1.) From its elements—

$$C_4\ (\text{diamond}) + H_6 + Hg + O_4 = C_4H_6HgO_4 = +112{\cdot}1\ (\text{cal}).$$

(2.) Hydrated solid—

$$2C_2H_4O_2\ (\text{crystalline}) + HgO + H_2O\ (\text{solid}) = C_4H_6HgO_4\ (\text{cryst.}) + 2H_2O\ (\text{solid}) = +3{\cdot}2\ (\text{cal.})$$

(3.) From anhydrous acid—

$$2C_2H_4O_2\ (\text{liquid}) + HgO = C_4H_6HgO_4\ (\text{solid}) = +12{\cdot}0\ (\text{cal.})$$

With gaseous acid...................... $= +15{\cdot}3$ „

Mercuric oxalate, HgC_2O_4, is obtained by precipitating mercuric acetate with oxalic acid. The heat of neutralisation of mercuric oxide by oxalic acid is + 14·1 (cal.).

Heat of Formation of Mercuric Oxalate in Solid State.—(1.) From the acid and oxide—

$$C_2H_2O_4 \text{ (cryst.)} + HgO + 2H_2O \text{ (solid)} \\ = HgC_2O_4 + 3H_2O \text{ (solid)} = 13{\cdot}2$$

(2.) From its elements—

$$C_2 \text{ (diamond)} + Hg + O_4 = HgC_2O_4 \ldots\ldots\ldots = 170{\cdot}8 \text{ (cal.)}$$

From this last number one can understand the explosive decomposition of mercuric oxalate, a phenomenon which may be easily produced by heat, as the following numbers show :—

$$HgC_2O_4 = 2CO_2 + Hg \text{ (liquid) gives out } + 18{\cdot}8 \text{ (cal)}$$

P. P. B.

Heat of Formation of Mercuric Oxybromides. By G. André (*Compt. rend*, **98**, 515—516).—These compounds were obtained by heating mercuric bromide with the requisite quantity of red mercuric oxide in sealed tubes for six hours at about 300°. They are crystalline, of an iron-grey colour, and when treated with potash they yield yellow mercuric oxide. Their heats of formation were determined by dissolving them in an excess of hydrobromic acid, when the following results were obtained :—

$HgO + HgBr_2 = Hg_2OBr_2$ develops $+3{\cdot}32$ cal.
$2HgO + HgBr_2 = Hg_3O_2Br_2$ „ $+4{\cdot}40$ „
$3HgO + HgBr_2 = Hg_4O_3Br_2$ „ $+6{\cdot}32$ „
$4HgO + HgBr_2 = Hg_5O_4Br_2$ „ $+7{\cdot}80$ „

These numbers are slightly lower than those for the corresponding compounds of lead, and also lower than those for the corresponding oxychlorides, except in the case of the first term of each series ($HgBr_2,HgO$ and $HgCl_2,HgO$), when the values are the same.

The author was unable to obtain in the wet way the oxybromide, $3HgO,HgBr_2$, described by Rammelsberg and Loewig. The product obtained by the action of sodium carbonate in varying proportions on an aqueous solution of mercuric bromide at different temperatures is the oxybromide $4HgO,HgBr_2$. C. H. B.

Heat of Formation of Antimony Oxychlorides. By Guntz (*Compt. rend.*, **98**, 512—514).—*Antimony Chloride.*—The heat of formation was determined by dissolving the oxide in hydrochloric acid, and also by dissolving corresponding weights of the chloride and oxide respectively in very dilute hydrofluoric acid, and comparing the thermal effects. The mean result obtained was Sb_2O_3, prismatic, anhydrous, + 6HCl gas = $2SbCl_3$, solid, + $3H_2O$, solid, develops + 94·8 cal.

Antimony Oxychloride, SbOCl.—This compound was obtained by decomposing 10 parts of the chloride with 7 parts of cold water, and its heat of formation was determined by dissolving in dilute hydrofluoric acid as in the case of the chloride: Sb_2O_3, prismatic, + 2HCl, gas. = 2SbOCl, solid, + H_2O, solid, develops + 38·8 cal.

Antimony Oxychloride, $Sb_4O_5Cl_2$.—This compound was obtained in triclinic prisms by decomposing the chloride with its own weight of water at 250°, and the heat of formation was determined as in the previous cases. $2Sb_2O_3$, prismatic, + 2HCl, gas, = $Sb_4O_5Cl_2$, solid, + H_2O, solid, develops + 41·2 cal.

From these numbers it follows that—

$$SbCl_3 \text{ sol.} + nH_2O = SbOCl \text{ sol.} + (n - 1)H_2O + 2HCl$$
$$\text{develops} + 8{\cdot}36 - 2A_1 \text{ cal.};$$

$$SbCl_3 \text{ sol.} + nH_2O = \tfrac{1}{3}Sb_4O_5Cl_2 \text{ sol.} + (n - \tfrac{5}{4})H_2O + \tfrac{5}{2}HCl$$
$$\text{develops} + 8{\cdot}46 - \tfrac{5}{2}A_2 \text{ cal.};$$

$$SbCl_3 \text{ sol.} + nH_2O = \tfrac{1}{2}Sb_2O_3 \text{ sol.} + (n - 1{\cdot}5)H_2O + 3HCl$$
$$\text{develops} + 7{\cdot}1 - 3A_3 \text{ cal.};$$

where A is the heat developed by the dilution of one equivalent of hydrochloric acid by a large quantity of water. The maximum thermal effect corresponds with the formation of the oxychlorides, and if A is relatively considerable, and if $8{\cdot}36 - 2A > 8{\cdot}46 - 2{\cdot}5A_2$, the maximum thermal effect corresponds with the formation of SbOCl. Since, however, the state of dissociation of the hydrates in the liquid is not known, the value of A, and consequently the value of *n*, cannot be accurately calculated. The order of the reaction will, however, be first the formation of the oxychloride, SbOCl, and afterwards the production of the compound, $Sb_4O_5Cl_2$. These conclusions agree with Sabanejeff's observations.

The author criticises Thomsen's previous determinations of the heats of formation of the compounds. C. H. B.

Density of Metals in the Liquid State. By W. C. ROBERTS and T. WRIGHTSON (*Ann. Chim. Phys.* [3], **30**, 274—288*).—In this memoir are collected together the results of the authors' investigations on the density of metals in the liquid state by the "oncosimeter" method; these are compared with those obtained by Mallet's cone method.

Metal.	Density of liquid metal.		Density of solid metal.	Percentage change of volume.
	By cone method.	By oncosimeter method.		
Bismuth	10·039	10·055	9·82	− 2·30
Copper	—	8·217	8·80	+ 7·10
Lead	10·650	10·370	11·40	+ 9·93
Tin	6·994	7·027	7·50	+ 6·76
Zinc	6·550	6·480	7·20	+11·10
Silver	9·400	9·510	10·57	+11·20
Iron	—	6·880	6·95	+ 1·02

---

* By a printer's error this is paged 174—188.

As the errors involved in this process are inappreciable, the results may be considered sufficiently final. The objections brought forward against the process, viz., that the floating metallic ball may be of bad quality or form, and that the dilatation of the ball at the moment of immersion may cause an internal pressure within the ball, are met and discussed. The first source of error is completely avoided, and secondly the determination of the density of the liquid metal is inscribed automatically and at once before the volume of the ball can be appreciably modified. Since some of these results were published, Nies and Winkelmann have carried on investigations in the same direction, but by a different process (Abstr., 1883, 545); these results show that the eight metals examined by them are less dense in the solid state, and at a temperature near their point of fusion than when they are melted. The aim of the authors' experiments was to determine the actual density of the metals at the lowest temperature at which they remain perfectly liquid. V. H. V.

Melting Points of Haloïd Salts in Relation to the Contraction occurring during their Formation from their Elements. By W. MÜLLER-ERZBACH (*Ber.*, **17**, 198—200).—From a comparison of the melting points of the haloid compounds of certain metals, as determined by Carnelley and Williams (Trans., 1879, 563), with the theoretical melting points, as calculated by the formula

$$t = \frac{s_1v_1w_1 + s_2v_2w_2}{v_1w_1 + v_2w_2}$$

(in which s = melting point, v the combining weight, and w the specific heat of the element), the author deduces the rule: That for the haloïd salt of each element, the greater the difference between the found and calculated melting points, the greater the contraction occurring during the formation of the salt from its elements.

A. J. G.

Gaseous Explosive Mixtures. By BERTHELOT and VIEILLE (*Compt. rend.*, **98**, 545—550, and 601—606).—By measuring the displacement of a piston of known section and mass, the authors have determined the pressures developed by the explosion of a large number of gaseous mixtures in closed vessels. In these two papers, tables are given showing the observed pressures, and the maximum and minimum limits of temperature, dissociation, and apparent specific heat calculated from the pressures by the methods previously described (Abstr., 1883, 771). The discussion of these values is reserved for subsequent papers. C. H. B.

Inorganic Chemistry.

Chlorine Monoxide for Lecture Experiments. By V. MEYER (*Ber.*, **17**, 157).—Chlorine monoxide requires a rather lower temperature for its liquefaction than that usually given. This is best effected by passing the gas through a Y-tube, the upper part of which is surrounded by alcohol that has been cooled to —40° in a small ice machine. The liquefied monoxide can be collected in small test-tubes, cooled with a mixture of ice and salt, and placed below the lower limb of the Y. A few drops only should be collected in each tube.

A. J. G.

Action of the Silent Discharge on Oxygen and Nitrogen in Presence of Chlorine. By P. HAUTEFEUILLE and J. CHAPPUIS (*Compt. rend.*, **98**, 626—627).—A mixture of pure chlorine and pure oxygen can be subjected to the action of the silent discharge without undergoing any alteration, but if nitrogen is also present, a white solid substance is deposited on the walls of the tube, and as the passage of the discharge is continued this deposit increases, and eventually assumes arborescent forms resembling ice crystals. This solid substance has practically no vapour-tension at 15°, but it readily volatilises in a vacuum at a moderate temperature, and can thus be purified from admixed foreign matter. It remains unaltered at 100°, but at 105° it rapidly decomposes without melting, and gives off nitrogen oxides. It rapidly absorbs moisture from the air, forming a strongly acid liquid, and when this is neutralised by potash or baryta the solution gives the reactions for nitrates and perchlorates. Analysis shows that it has the composition N, 9·01; Cl, 22·71; O (by diff.), 68·28 = N_2O_6,Cl_2O_7.

It is probable that iodine and bromine form similar compounds under like conditions.

C. H. B.

Carbonic Anhydride in the Atmosphere. By A. MUNTZ and E. AUBIN (*Ann. Chim. Phys.* [5], **30**, 238—248). See this vol., p. 659.

Sulphurous Anhydride in the Air of Lille. By A. LADUREAU (*Ann. Chim. Phys.* [5], **29**, 427—432). The amount of this gas in the air was determined by drawing a known volume of air through concentrated sulphuric acid, and then through vessels containing pure potassium hydroxide. The amount of sulphurous anhydride taken up by the potassium hydroxide was determined by converting it into sulphate, and estimating as barium sulphate. The results show the presence of 1·8 c.c. of this gas in 1 cm. of air; on calm days this amount was found to increase to 2 c.c., and to decrease to 1·4 c.c. on stormy days. The examination of carefully collected rain-water has shown it to contain sulphur compounds corresponding to 0·022 gram of sulphuric acid per litre.

The author observes that although the presence of this gas in the atmosphere of towns such as Lille and other manufacturing towns, may be conducive to slight ailments of throat, &c., and minor inconveniences, still its antiseptic properties in case of epidemics compensate to a large extent for its evil effects. P. P. B.

Behaviour of Air and Moist Phosphorus towards Carbonic Oxide. By I. REMSEN and E. H. KEISER (*Ber.*, **17**, 83—92).—The authors refer to their previous experiments (*Amer. Chem. J.*, **4**, 454; also this vol., p. 149) and to the opposite results obtained by Leeds (this vol., p. 15) and by Baumann (this vol., p. 14). They have repeated the experiment with a greater volume of air and with apparatus made wholly of glass, and their results show that under these conditions carbonic anhydride is actually produced when carefully purified air alone is employed and no carbonic oxide introduced. The formation of the carbonic anhydride is found to be due to the presence of carbon in the phosphorus (probably in combination), and the amount produced is distinctly influenced by the rate of the air current, by the temperature, and by the amount of phosphorus. Comparative experiments have also been made with and without carbonic oxide, and no difference could be detected in the amount of precipitation in the baryta solutions in the two cases. It is, therefore, inferred that carbonic oxide is not oxidised by air and moist phosphorus. The fact that the authors did not detect carbonic anhydride in their first experiments was due to the small volume of air employed.

A. K. M.

Production of Crystalline Borates. By A. DITTE (*Ann. Chim. Phys.* [5], **30**, 248—265).—On adding hydroxide or carbonate of the metal to a concentrated solution of boric acid, crystalline tetraborates of the general formula $4B_2O_3,M''O,nH_2O$ are produced, provided the acid be in excess. On raising the temperature these salts are decomposed by water, half the boric acid going into the solution, with deposition of a biborate of the formula $2B_2O_3,M''O,nH_2O$. This result is only produced when the biborate crystallises from a small quantity of mother-liquor, for if the solution of the tetraborate be warmed and then allowed to cool, the inverse reaction is produced, and the biborate formed is reconverted into the tetraborate. The biborates in their turn are decomposed by pure water, provided that they are in the form of crystals or precipitates obtained by processes of double decomposition; they lose boric acid and are transformed into neutral borates of general formula, $B_2O_3,M''O,nH_2O$. The borates of these metallic oxides which form compounds with ammonia, give complex ammoniated borates, of which those of copper may be taken as typical: $2B_2O_3,CuO,2NH_4O$. When heated these salts lose ammonia, and are converted into anhydrous borates in the form of amorphous powders. In the original paper. a full account is given of the various hydrated borates of the alkaline earths, magnesium, cadmium, zinc, nickel, cobalt, and silver. As regards the last-named, it has been observed by Rose that a concentrated solution of sodium biborate gives, with silver nitrate, a white precipitate of silver borate, but a dilute solution of the same salt gives a grey deposit of the oxide. In this paper, the changes produced by the successive additions of water to the precipitated silver biborate are minutely examined, and it is shown that the proportion of boric acid to silver diminishes as the water present is increased. V. H. V.

Preparation of Sodium Bicarbonate. By H. Gaskell and F. Hurter (*Dingl. polyt. J.*, **251**, 228).—For the preparation of sodium bicarbonate, the authors subject the anhydrous normal carbonate to the simultaneous action of steam and carbonic anhydride. The apparatus employed consists of a rotary cylinder, similar in construction to that used by Carey. D. B.

Density of Milk of Lime. By G. Lunge (*Dingl. polyt. J.*, **250**, 464—466).—The author states that the table constructed by Mateczeck, showing the amount of lime in milk of lime of different strengths (*ibid.*, **215**, 72) is incorrect. He therefore gives the following values :—

Table showing the Amount of Quicklime in Milk of Lime at 15°.

Baumé.	1 litre of milk of lime weighs grams.	CaO in 1 litre, grams.	CaO per cent. by weight.	Baumé.	1 litre of milk of lime weighs grams.	CaO in 1 litre, grams.	CaO per cent. by weight.
1	1007	7·5	0·745	16	1125	159·0	14·13
2	1014	16·5	1·640	17	1134	170·0	15·00
3	1022	26·0	2·540	18	1142	181·0	15·85
4	1029	36·0	3·500	19	1152	193·0	16·75
5	1037	46·0	4·430	20	1162	206·0	17·72
6	1045	56·0	5·360	21	1171	218·0	18·61
7	1052	65·0	6·180	22	1180	229·0	19·40
8	1060	75·0	7·080	23	1190	242·0	20·34
9	1067	84·0	7·870	24	1200	255·0	21·25
10	1075	94·0	8·740	25	1210	268·0	22·15
11	1083	104·0	9·600	26	1220	281·0	23·03
12	1091	115·0	10·540	27	1231	295·0	23·96
13	1100	126·0	11·450	28	1241	309·0	24·90
14	1108	137·0	12·350	29	1252	324·0	25·87
15	1116	148·0	13·260	30	1263	339·0	26·84

It is useless to carry the table beyond 30° B., as in that case the milk of lime would become too thick. D. B.

Preparation of Strontia. By H. Niewerth (*Dingl. polyt. J.*, **251**, 191).—The author mixes cœlestin with equivalent quantities of coal and brown iron ore, and subjects the mixture to a roasting process. On lixiviating the roasted product with water, strontium hydroxide and iron sulphide are produced. Lead oxide or other metallic oxides can be used in the place of ferric oxide. D. B.

Barium Oxychloride. By G. André (*Compt. rend.*, **98**, 572—574).—The author has previously described (Abstr., 1881, 979) an impure barium oxychloride, obtained by boiling barium oxide with a solution of barium chloride, and Beckmann (*Ber.*, **14**, 2151) has described a similar compound. If 200 grams of barium chloride are dissolved in 500 grams of boiling water, the solution allowed to cool slightly, 30 grams of finely powdered barium oxide added, and the mixture heated nearly to boiling for five minutes and then filtered, the filtrate on cooling deposits the oxychloride, $BaCl_2,BaO,5H_2O$, in nacreous lamellæ, free from excess of either barium oxide or chloride. If 60 grams of barium oxide are used instead of 30 (as originally described, *loc. cit.*), the filtrate at about 60° deposits the same nacreous lamellæ, containing, however, a slightly higher proportion of water, and if the liquid is quickly filtered when the temperature has fallen to 50°, the oxychloride is obtained in a state of purity, but if the liquid is allowed to cool further, large white lamellæ of barium hydroxide are deposited along with the oxychloride. C. H. B.

Researches on the Complex Inorganic Acids. By W. GIBBS (*Amer. Chem. J.*, **5**, 391—413).—A short notice of this subject has already been given (this vol., 161).

Phospho-vanadio-molybdates.—These salts are generally formed when phospho-vanadates are digested with molybdic tetroxide; when vanadio-molybdates and alkaline phosphates are heated together, especially in presence of an acid; and when vanadic pentoxide is heated with an alkaline phospho-molybdate. They are generally less stable than the vanadio-molybdates, yet well defined and usually highly crystalline; they are of an orange, deep garnet, or ruby-red colour.

Before determining the phosphoric acid by precipitation with magnesia mixture, it is necessary to remove vanadic oxide by boiling the slightly alkaline solution with a large quantity of ammonium nitrate, and after standing filtering off the ammonium metavanadate. By precipitation with mercurous nitrate and mercuric oxide, and ignition of the precipitate with sodium tungstate, the sum total of the acid oxides is determined, the molybdic oxide being then found by difference.

When the salt $10MoO_3,2P_2O_5,5(NH_4)_2O + 6H_2O$ and ammonium metavanadate are dissolved together, there appears to be no reaction, but if a small excess of hydrochloric acid be added, and the solution boiled, a deep orange-red crystalline precipitate is formed; it may be washed with cold water, but is decomposed by hot water; its composition is $48MoO_3,2P_2O_5,V_2O_5,7(NH_4)_2O + 30H_2O$.

The phospho-molybdates of ammonium, containing $24MoO_3,P_2O_5$ and $22MoO_3,P_2O_5$, slowly dissolve when boiled with a solution of ammonium metavanadate, and the solution after standing a few hours deposits deep ruby-red crystals. These may be recrystallised from hot water; the solution gives characteristic precipitates with several reagents. Analyses lead to the formula

$$14MoO_3,P_2O_5,8V_2O_5,8(NH_4)_2O + 50H_2O.$$

If vanadic oxide be written $V_2O_2 \cdot O_3$, and be regarded as standing in the same relation to phosphoric oxide as does molybdic oxide, then this salt belongs to the same type as the original phospho-molybdate, viz., $22MoO_3,P_2O_5,xR_2O$. Other salts are formed at the same time, but in small quantity only.

The *phospho-vanadio-tungstates* generally resemble and are prepared like the preceding salts. Phosphoric oxide is estimated by direct precipitation with magnesia mixture, but requires reprecipitation. Vanadic oxide is estimated by boiling with strong hydrochloric acid, and collecting the chlorine evolved in potassium iodide. Oxidation with potassium permanganate cannot be relied upon. When ammonium phosphotungstates containing $22WO_3,P_2O_5$, or $24WO_3,P_2O_5$, are dissolved in ammonia, ammonium metavanadate and then a slight excess of hydrochloric acid added, a lemon-yellow crystalline precipitate soon forms on boiling; the precipitate requires washing with dilute ammonium nitrate solution. Its composition is

$$60WO_3,3P_2O_5,V_2O_5,10(NH_4)_2O + 60H_2O.$$

A boiling solution of ammonium metavanadate dissolves the white insoluble phosphotungstate of ammonium quite readily to a very deep orange-red solution, from which in a few days deep orange or garnet-red crystals separate; they may be recrystallised from water. The salt has the composition $16WO_3,3V_2O_5,P_2O_5,5(NH_4)_2O + 37H_2O$.

When the baric phosphotungstate (20 : 1 : 6) previously described is boiled with vanadic hydrate, an orange-red solution is formed, and on cooling octahedral crystals of a red colour separate, having the composition $60WO_3,3P_2O_5,2V_2O_5,18BaO + 144H_2O$. The crystals dissolve rather easily in hot water, but are at the same time decomposed, with formation of other salts.

The phosphotungstate of sodium, $24WO_3,P_2O_5,2Na_2O,4H_2O$ + 23Aq, is readily dissolved on boiling it with a solution of ammonic metavanadate; this solution does not deposit crystals, but on adding a large excess of potassium bromide, an orange-red crystalline precipitate forms. Its composition is expressed by the formula

$$18WO_3,4V_2O_5,3P_2O_5,8K_2O + 32H_2O.$$

Hot water dissolves, but decomposes this salt, an orange-brown crystalline salt, having the formula $7WO_3,V_2O_5,P_2O_5,3K_2O + 11H_2O$ being formed. The existence of other, *i.e.*, sodium, ammonium, and trimethylammonium-vanadio-phosphotungstates is pointed out.

Vanadio-vanadico-molybdates.—These and other similar salts contain two oxides, viz., R_2O_5 and $R'O_2$, in which, however, R and R′ may be identical. They are very readily formed by boiling a mixture of the two oxides of vanadium with an acid molybdate; by the partial reduction of vanadio-molybdates; or by digesting solutions of acid molybdates with solutions which contain vanadic dioxide and pentoxide. By igniting ammonium divanadate and boiling the residue with acid ammonium molybdate (viz., the salt 14 : 6), a solution is obtained, which, on evaporation, deposits pale greenish-yellow crystals; these may be recrystallised; their composition is expressed by

$$28MoO_3,4V_2O_5,VO_2,11(NH_4)_2O + 20H_2O.$$

Barium chloride added to the mother-liquor of the preceding salt, gives a pale-yellow crystalline precipitate, having the composition $30MoO_3,2V_2O_5.3VO_2,14BaO + 48Aq$.

Vanadio-vanadico-tungstates.—By boiling a commercial vanadic pentoxide with acid sodium tungstate (viz., the salt 12 : 5) and evaporating to a syrup, large orange-red crystals, probably having the formula $12WO_3,2V_2O_5,3VO_2,6Na_2O + 43Aq$, are obtained. In an exactly similar manner a potassium and an ammonium salt, probably

$$12WO_3,2V_2O_5,3VO_2,6(NH_4)_2O + 12Aq,$$

may be obtained. These salts give with silver nitrate a scarlet crystalline precipitate, $12WO_3,2V_2O_5,3VO_2,6Ag_2O + 8Aq$. The preparation of these salts could not be repeated, using a mixture of vanadic dioxide and pentoxide, and the analyses being incomplete, the formulæ given cannot be considered as definitely proved.

Phospho-vanadio-vanadico-tungstates.—These salts, which may be regarded as double salts, are formed whenever phosphotungstates are mixed with vanadates in presence of vanadic dioxide; when vanadio-vanadico-tungstates are heated with alkaline phosphates or phosphoric acid; and when phosphovanadates and alkaline tungstates are brought together in presence of a reducing agent and of an acid. They are either green or orange-red. When the residue left on heating ammonic vanadate is added gradually to a boiling solution of barium phosphotungstate, $2WO_3,P_2O_5,6BaO$, and the solution filtered and evaporated, deep green crystals are obtained, having the composition $60WO_3,3P_2O_5,V_2O_5,VO_2,18BaO + 150H_2O$. This and similar salts are oxidised by bromine or nitric acid, but not by cold potassium permanganate solution; probably the salt $60WO_3,3P_2O_5,V_2O_5,V_2O_5,18BaO + 144H_2O$ already described is formed. In many cases these complex salts may be considered as double or triple salts, in which the individual members belong to or at least correspond with known classes of salts. The salts described belong to the four classes—

1. $mRO_3.nV_2O_5.pR'_2O$;
2. $mRO_3.nP_2O_5\,pV_2O_5.vH_2O$;
3. $mRO_3.nP_2O_5.pV_2O_5.rVO_2.vH_2O$;
4. $mRO_3.nV_2O_5.pVO_2.vH_2O$.

In other communications the author will show that other metals than vanadium may occupy the place of $R'O_2$, that other pentoxides than P_2O_5,As_2O_5, and V_2O_5 may occupy the place of R_2O_5 in the above formulæ, and that the complex inorganic acids form a new department of inorganic chemistry, and not a series of isolated compounds.

H. B.

Arsenomolybdic Acid. By O. PUFAHL (*Ber.*, **17**, 217—218).—By decomposing barium molybdate suspended in an aqueous solution of arsenic acid with sulphuric acid, a yellow liquid is obtained, which on evaporation yields arsenomolybdic acid, crystallising in two forms, in groups of doubly refracting orange-red needles, and in efflorescent yellow tabular crystals (apparently monoclinic). The pure saturated aqueous solution has the sp. gr. 2·45 at 18·3°. The yellow crystals probably differ from the red merely in containing a larger amount of water of crystallisation. Analysis of the somewhat impure acids gave for the red crystals the atomic ratios 1 As_2O_5 : 18·09 MoO_3 : 29·97 H_2O, for the yellow crystals 1 As_2O_5 : 18·96 MoO_3 : 39·35 H_2O. Numerous salts have been prepared, and will be described later.

A. J. G.

Mineralogical Chemistry.

Pachnolite and Thomsenolite. By DES CLOIZEAUX (*Ann. Chim. Phys.* [5], **29**, 392—400).—The crystallographic and optical examination of these two minerals, which according to Brandl differ in chemical composition (Abstr., 1883, 29), shows them to be two distinct species. In pachnolite the axes have the proportion $c : b : a$ = 1·326676 : 1 : 0·859495. β = 89·41°; in thomsenolite the proportions $c : b : a$ = 1·0883 : 1 : 0·998741. β = 89·1°.

P. P. B.

Manganese in the Cipolin Marbles of Primary Formations. By DIEULAFAIT (*Compt. rend.*, **98**, 634—636).—The term "cipolin marble" is given to concretionary masses of limestone found in the lower parts of beds of gneiss, sometimes in large quantities, sometimes in isolated lenticular masses, and which are evidently contemporaneous with the rocks by which they are enclosed. The author has examined more than a thousand specimens of these marbles from different parts of the world, and finds that in all cases manganese can be detected in 0·5 gram of the marble, and in the majority of cases in a few centigrams.

When calcium carbonate is brought in contact with water containing an iron and manganese salt in solution, the iron is completely precipitated, but the greater part of the manganese salt remains in solution. In the case of a magma having the composition of gneiss, *i.e.*, composed mainly of silica and alumina, and containing a notable quantity of calcium carbonate and sensible quantities of iron and manganese, water charged with carbonic acid would dissolve out the calcium carbonate and the manganese, and would leave the greater part of the iron undissolved. The calcium carbonate afterwards deposited from this solution would be white, and would retain the greater part of the manganese which had dissolved with it. This theory explains the concentration of manganese in these cipolin marbles, also how a white and approximately pure marble can be formed in presence of a complex and highly coloured substance such as gneiss, and why the cipolin marbles are generally lenticular in shape and concretionary in structure.

It follows that the cipolin marbles and the gneiss surrounding them must be contemporaneous, and must both have been formed under water. This last conclusion is supported by many other facts.

C. H. B.

Felspar. By BECKER (*Dingl. polyt. J.*, **251**, 287).—The author states that the largest supplies of felspar come from the Norwegian towns Moss, Christiania, Bergen, and Arendal. Swedish felspar is principally obtained from the quarries owned by the Rörstrand Company. The author gives analyses of the following specimens :—I and II, red and white Rörstrand spar; III, grey Norwegian spar; IV and V, light and dark Norwegian spar, examined by Aron :—

	SiO_2.	Al_2O_3.	CaO.	MgO.	K_2O.	Na_2O.	Fe_2O_3.
I ..	64·57	19·73	0·18	—	12·26	3 06	0·20

IV ..	65·12	18·00	—	traces	12·89	3·00	0·78
V ..	65·54	18·31	—	traces	12·53	3·17	0·74

D. B.

Gadolinite from Ytterby. (Part II.) By C. AUER v. WILSBACH (*Monatsh. Chem.*, **5**, 1—15).—A description of spectroscopic methods and apparatus used in this research.

Organic Chemistry.

Nitro-derivatives of Ethane. By A. VILLIERS (*Compt. rend.*, **98**, 431—433).—The author has previously shown (*Compt. rend.*, **97**, 258) that the first product of the reducing action of ammonium hydrosulphide on the potassium compound of tetranitro-ethylene dibromide is the compound $C_2K_2(NO_2)_4$. Prolonged action of the same reagent produces a base which contains potassium and sulphur, and forms a platinochloride, but this base has not yet been obtained in quantity sufficient for analysis.

When the potassium compound of tetranitro-ethylene dibromide, $C_2(NO_2)_4Br_3,K_2O$, is treated with free sulphurous acid, it is completely reduced with formation of ammonia, hydrobromic acid, and hydrocyanic acid. If, however, it is triturated with a solution of potassium sulphite and potassium carbonate, carbonic anhydride is given off, and a sulphur-yellow compound is obtained. This compound can be recrystallised from boiling water, and forms brilliant sulphur-yellow crystals of the composition $4C_2(NO_2)_4K_2 + 3K_2SO_4$. It explodes at about 210°, and in this respect resembles the compound $C_2(NO_2)_4K_2$. The same substance is formed by the direct combination of potassium sulphate with the compound $C_2(NO_2)_4K_2$ obtained by the action of ammonium hydrosulphide. Its formation by the first method takes place in accordance with the equation $C_2(NO_2)_4Br_2,K_2O + 2K_2SO_3 + H_2O = C_2(NO_2)_4K_2 + 2K_2SO_4 + 2HBr$, the theoretical yield being obtained. The liberation of hydrobromic acid necessitates the addition of potassium carbonate, otherwise the liquid would become acid, and total reduction would take place. The reverse reaction,

$$C_2(NO)_4K_2 + 2Br_2 + H_2O = C_2(NO_2)_4Br_2,K_2O + 2HBr,$$

takes place readily when bromine is added to an alkaline solution of $C_2(NO_2)_4K_2$. A similar reaction takes place with iodine or chlorine, and from the products in these cases tetranitro-ethylene chloride or iodide can be prepared.

When a hot concentrated solution of the compound

$$4C_2(NO_2)_4K_2,3K_2SO_4,$$

is treated with barium chloride and filtered, the filtrate on cooling deposits brilliant pale-yellow crystals of the compound $C_2(NO_2)_4K_2$, which can be easily prepared in this way. C. H. B.

Methylene Bromide. By L. HENRY (*Ann. Chim. Phys.* [5], **30**, 266—274).—Methylene bromide can be prepared without difficulty by the process indicated in outline by Butlerow, viz., by the decomposition of methylene iodide by bromine, $CH_2I_2 + 2Br_2 = CH_2Br_2 + 2BrI$. Thus obtained, methylene bromide is a colourless mobile liquid, of a sweet taste, boiling at 98·5° under a pressure of 756 mm. Its expansion may be expressed by the formula $V = 1 + 0·001001t + 0·0000001859t^2$, hence $\frac{dV}{dt^\circ} + \frac{V_{10}}{V_0} = 0·0009736$ = coefficient of expansion at 0°; its sp. gr. = 2·493. Methylene bromide is insoluble in water, soluble in alcohol; it does not solidify at −12°. On heating it with potassium phenate, it is converted into methylene diphenylate, $CH_2(OPh)_2$, a colourless liquid, boiling at 294°; sp. gr. = 1·1136.

A comparison of the chloro- and bromo-derivatives of methane shows that the replacement of chlorine by bromine in the molecule raises the boiling point by about 40°. The bromine derivatives of methane exhibit a remarkable gradation in their physical properties, as shown in the table appended:—

	Boiling point.	Specific gravity.
CH_4	Gas	—
CH_3Br	4·5	1·732
CH_2Br_2	98·5	2·493
$CHBr_3$	151·2	2·834
CBr_4	189·5	solid

It is to be observed that the differences between two consecutive terms are not constant, but they diminish as the series progresses; this is in accordance with the observed generality. Similarly the differences in volatility and density are more marked in the successive members of the iodo-substitution series, less marked in the bromo-, and least in the chloro-series, thus:—

	Difference of boiling point.	Difference of sp. gr.
CH_3Cl CH_2Cl_2	65	0·4081
CH_3Br CH_2Br_2	94	0·7610
CH_3I CH_2I_2	137	1·1430

V. H. V.

Action of Iodine Chloride on Monochlorethylene. By L. Henry (*Compt. rend.*, **98**, 518—520).—The author proposes to study the products obtained by the union of iodine monochloride with the monohaloïd derivatives of ethylene, with a view to determine the behaviour of the iodine and chlorine in contact with the two chains CHX and CH_2, and the influence exerted on the reaction by the nature of the haloïd X.

Monochlorethylene is slowly absorbed by an aqueous solution of iodine monochloride with formation of dichloromoniodoethane, $C_2H_3Cl_2I$, a colourless liquid which rapidly becomes purple on exposure to light. It has a faint ethereal odour, and a sharp, sweet taste: it boils at 171—172° with slight decomposition under a pressure of 774 mm.; sp. gr. at 0° = 2·2187. When treated with an equivalent quantity of potash in alcoholic solution, it is readily decomposed with precipitation of potassium chloride and iodide in the proportion of 4KI to KCl; with soda, a precisely similar decomposition takes place, but the sodium iodide remains in solution in the alcohol. When the alcoholic liquid is mixed with water, a heavy oily liquid separates out, and this on fractionation yields unsymmetrical dichlorethylene, $CH_2.CCl_2$, boiling at 35—37°, and a much smaller quantity of unsymmetrical chloriodo-ethylene, $CH_2.CClI$, boiling at 101—102° under ordinary pressure. Dichlorethylene, $CH_2.CCl_2$, has no action on alkaline iodides even in boiling alcoholic solution, and it follows that the chloriodo-ethylene is not the product of any secondary reaction. The product of the union of monochlorethylene and iodine monochloride is a mixture of the two isomerides,

$$CHCl_2.CH_2I, \text{ and } CHClI.CH_2Cl,$$

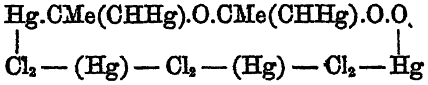
which cannot be separated by distillation because they have practically the same boiling points. It follows that the two radicles I and Cl in the system ICl combine simultaneously with each of the monocarbon chains CHCl and CH_2, but in unequal proportion, the chlorine combining most readily with the carbon to which chlorine is already attached, whilst the less negative radicle iodine combines most readily with the most highly hydrogenised carbon in the approximate ratio of 4 to 1.

When iodine monochloride acts on monobromethylene, the distribution of iodine and chlorine in the products, with respect to the two atoms of carbon, does not follow the same law as in the case of the monochlorinated derivative. C. H. B.

Action of the Hydrocarbons of the Acetylene Series on Mercuric Oxide and its Salts. By M. Kutscheroff (*Ber.*, **17**, 13—29).—The direct addition of the elements of water to the above hydrocarbons by the action of mercuric bromide was previously described by the author (Abstr., 1881, 883), who now shows that this reaction may be brought about to a greater or less extent by all mercuric salts. On passing allylene into a solution of mercuric chloride at the ordinary temperature, a white crystalline precipitate, $3HgCl_2,3HgO,2C_3H_4$, is obtained, whilst hydrochloric acid is liberated. The precipitate is insoluble in water and cold alcohol, but readily soluble in hydrochloric and acetic acids with formation of a mercuric salt and acetone. The process of hydration therefore consists of two reactions—

$$\text{I} \ldots\ 6HgCl_2 + 3H_2O + 2C_3H_4 = 3HgCl_2,3HgO,2C_3H_4 + 6HCl;$$
$$\text{II} \ldots\ 3HgCl_2,3HgO,2C_3H_4 + 6HCl = 6HgCl_2 + 2C_3H_6O + H_2O,$$

which, according to circumstances, may take place separately or simultaneously. If the precipitate is heated along with the acid liquid, the mercuric chloride is re-formed, and may thus be employed to convert unlimited quantities of allylene into acetone. The corresponding reaction between allylene and mercuric bromide takes plac to a much less extent, whilst with mercuric iodide there appears be no action. With mercuric sulphate, allylene yields a copi white precipitate, $HgSO_4,5HgO,3C_3H_4 + 7Hg_2O$, sparingly solubl sulphuric, readily in hydrochloric acid, whilst with mercuric ace it produces an amorphous precipitate, $Hg(O\overline{Ac})_2,3HgO,2C_3H_4$, w is readily decomposed by acetic and hydrochloric acids. The a regards these complex substances as compounds of basic mc salts, with the group C_3H_4HgO (*i.e.*, acetone in which Hg repl H_2), the general formula for them being $nHgX_2,pHgO,q(C_3H_4Hg$ but attempts to separate the compound C_3H_4HgO by the action alkali were without success. The formula,



$$\begin{array}{l} Hg.CMe(CHHg).O.CMe(CHHg).O.O \\ | \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad | \\ Cl_2 — (Hg) — Cl_2 — (Hg) — Cl_2 — Hg \end{array}$$

obtained from mercuric chloride indicates the way in which the elements may be assumed to be grouped.

By the action of ethylacetylene on mercuric chloride, the compound $3HgCl_2,HgO,C_4H_6HgO$, is obtained, and is perfectly analogous to the corresponding allylene compound; it dissolves readily in hydrochloric acid, yielding methyl ethyl ketone. When mercuric oxide, suspended in a large quantity of water, is agitated for several days with allylene, the gas is absorbed whilst the colour of the oxide changes to a dirty olive-green; on filtering and extracting with hot alcohol, a crystalline substance, $Hg(C_3H_3)_2$, may be obtained. It has a characteristic garlic odour, is insoluble in water, and almost insoluble in cold alcohol, whilst hydrochloric and acetic acids dissolve it with evolution of allylene. In alcoholic solution, it yields a white crystalline precipitate with mercuric chloride; this is insoluble in water and alcohol, but soluble in acids with production of acetone. The compound $Hg(C_3H_3)_2$ can also be obtained by the action of allylene on an alkaline solution of mercuric iodide in potassium iodide, or on an alkaline solution of mercuric chloride.

A. K. M.

Formation of Mannitol from Dextrose and Lævulose. By F. W. DAFERT (*Ber.*, **17**, 227—228).—The products of the oxidation of mannitol vary according to the nature of the oxidising agent, the temperature and the duration of oxidation; there have been observed carbonic anhydride, water, formic acid, mannitic acid, saccharic acid, inactive tartaric acid and probably glycollic acid; there are also invariably obtained by careful working a mannitan-like substance and mannitose. Mannitose is decidedly a glucose, it differs from dextrose in its behaviour with hydrochloric acid, sulphuric acid, Fehling's and Knapp's solutions, and in its optical inactivity. It shows the closest similarity with lævulose in all but its optical properties.

A. J. G.

Inversion of Cane-sugar by Acids. By F. URECH (*Bied. Centr.*, 1883, 501).—It is proved that when sugar is mixed with dilute acids, inversion goes on gradually in the cold. The relation between this reaction, which is always accompanied by development of heat, and time, and mass, and temperature, has now been investigated. The author watched the progress of inversion either in the polariscope, while the change was taking place, or by intermittent testings with Fehling's solution.

D. A. L.

Action of Dilute Hydrochloric Acid on Starch. By F. ALLIHN (*Dingl. polyt. J.*, **250**, 554).—The subjoined table gives the results of the author's experiments on the saccharification of starch by means of dilute hydrochloric acid. The starch used contained 98·6 per cent. of pure starch, 0·9 per cent. ash, and 0·3 per cent. insoluble residue:

Duration of experiment.	Proportion of hydrochloric acid used.				
	10 p. c.	5 p. c.	3·5 p. c.	2 p. c.	1·33 p. c.
	Proportion of starch saccharified.				
Minutes.	p. c.	p. c.	p. c.	p. c.	p. c.
2	92·6	—	—	—	—
5	92·1	—	—	—	—
10	—	90·6	—	—	—
15	91·7	—	—	—	—
30	89·6	94·3	93·27	89·94	—
50	87·4	93·3	—	—	—
60	—	—	94·65	93·68	87·85
90	—	—	94·49	95·05	92·87
105	—	—	—	94·89	—
120	—	—	—	—	93·84
150	—	—	—	—	94·65

Although it would not be practicable to use hydrochloric acid on a large scale for the saccharification of starch owing to the cost of its subsequent removal, its use is recommended for laboratory purposes, *e.g.*, for the preparation of grape-sugar from starch.

D. B.

Argentammonium Compounds. By A. REYCHLER (*Ber.*, **17**, 41—48).—When aldehyde is added to an aqueous solution of silver nitrate (1 mol.) and ammonia (1 mol.), a crystalline precipitate is obtained of varying composition; a similar result is obtained if diammonio-silver nitrate be employed. To obtain a pure product, 100 c.c. silver nitrate solution ($\frac{2}{3}$ normal) are mixed with 15 c.c. ammonia solution (4 times normal), the precipitated silver oxide separated, and then aldehyde added until the precipitate produced does not readily dissolve on shaking; a second quantity (15 c.c.) of ammonia solution is now added, when six-sided scales separate. The product, $C_4H_{10}N_3O_3Ag.\frac{1}{2}H_2O$, is sparingly soluble in water, less so in alcohol, and almost insoluble in ether, the aqueous solution yielding a silver mirror when warmed. It is gradually decomposed at 100°, melts somewhat higher and detonates. By the action of dry ammonia on the powdered substance, 2 mols. of the gas are absorbed with development of heat, the product containing 1 atom of silver to 4 atoms of ammoniacal nitrogen. To prepare the anhydrous compound $C_4H_{10}N_3O_3Ag$, a dilute alcoholic solution of aldehyde (20 c.c.) and ammonia (6—8 mols.) is precipitated with silver nitrate solution (1 mol.), when it is obtained in crystalline grains or scales. This compound also absorbs dry ammonia with formation of a product containing 4 atoms of ammoniacal nitrogen to 1 atom silver.

In explanation of the action of silver nitrate on aldehyde-ammonia, the author suggests the following equation:—

$$NO_3Ag + 2CH_3.CH(OH).NH_2 = N(OH)_2(OAg)(NH.CHMe.OH)_2.$$

By the abstraction of 2 mols. H_2O from the product, the anhydrous compound $C_4H_{10}N_3O_3Ag$ is produced, the constitution of which may be expressed thus: $N(OAg)\left(\begin{smallmatrix}O-\\NH\end{smallmatrix}\!>CHMe\right)_2$, and that of the compound obtained by the addition of ammonia is—

$$N(OAg)(NH_2)_2(NH.CHMe.OH)_2.$$

Diammonio-silver acetate, $C_2H_3O_2Ag,2NH_3$, is obtained by passing dry ammonia over silver acetate. The product is a white substance which loses ammonia on exposure to air, and dissolves readily in water. Its constitution may be expressed thus:

$$NH_2.CMe(OAg).ONH_4.$$

On adding aldehyde to an aqueous solution of diammonio-silver acetate, a crystalline precipitate is obtained, consisting, however, of impure silver acetate; a compound of silver acetate with ammonia and aldehyde could not be obtained. A. K. M.

Action of Acetic Anhydride on Amidines. By A. PINNER (*Ber.*, **17**, 171—178).—The author has already shown (Abstr., 1883, 1099) that acetic anhydride acts differently on various amidines; the present paper gives further studies on the subject. All the experiments were conducted in the same manner: the amidine hydrochloride was mixed with an equivalent quantity of freshly fused sodium acetate, so much acetic anhydride being added that the mixture formed a thick pulp, which was then heated to gentle boiling for 1—2 hours in a vessel provided with a reflux condenser.

From formamidine there was obtained diacetylformamidine,

$$\bar{A}cN:CH.NH\bar{A}c$$

(*loc. cit.*) and *triacetylforamidil*, $C_8H_{11}N_3O_3$. The latter crystallises in hard crusts formed of prisms, melts at 224°, is very sparingly soluble in cold water, more readily in hot water. It must be regarded as the triacetyl-derivative of the condensation product $C_2H_5N_3$, whose constitution is as yet uncertain. On boiling diacetylformamidine with water, it is decomposed with formation of acetamide; acetamide is also formed on heating it at 150°.

The product of the reaction of acetic anhydride on acetamidine was poured into aqueous soda, and the crystalline mass which separated recrystallised. It consisted of two substances, of which that soluble in water, *anhydrodiacetylacetamidil*, $C_8H_{11}N_3O$, crystallises with 2 mols. of water in groups of minute prisms, loses its water of crystallisation over sulphuric acid, volatilises slowly at 100°, and melts at 185°. It is readily soluble in alcohol and dilute acids, has marked basic properties, and yields a readily soluble platinochloride decomposing on fusion. The substance, insoluble in water, *anhydrodiacetylacetamidine*, $C_6H_8N_2O$, crystallises in lustrous needles, melts at 253° to a dark-coloured liquid, is sparingly soluble in cold, readily soluble in hot alcohol, very soluble in dilute acids. The platinochloride crystallises in yellow needles very soluble in water.

Capronamidine when treated in the manner described above yields capronitrile.

Further researches are necessary to ascertain the constitution of the new substances described.

AMIDINE SALTS. *Acetamidine hydrochloride* crystallises in long, brilliant, transparent prisms, is somewhat deliquescent, and melts at 164—165°. *Acetamidine platinochloride*, $(CMeN_2H_3)_2,H_2PtCl_6$, forms moderately soluble, yellowish-red prisms; on boiling it with water, ammonium platinochloride separates.

Propionamidine hydrochloride, $C_3H_8N_2,HCl$, forms deliquescent, long, broad needles, melts at 129°, is readily soluble in alcohol, insoluble in ether. The *platinochloride*, $(C_3H_8N_2)_2,H_2PtCl_6$, forms yellowish-red crystals, rather sparingly soluble in water; it melts with slow decomposition at 199—200°.

Capronamidine hydrochloride, $C_6H_{14}N_2,HCl$, forms large plates, melts at 106—107°, is somewhat deliquescent, and is readily soluble in alcohol. The *platinochloride*, $(C_6H_{14}N_2)_2,H_2PtCl_6$, forms yellowish-red plates, sparingly soluble in cold, readily soluble in hot water; it melts under hot water, but when dry melts with decomposition at 199°.

Capronimido-ether hydrochloride solidifies when cooled below 0°, and melts on heating to the ordinary temperature; when carefully decomposed with soda, it yields *capronimido-ether*, $C_5H_{11}.C(OEt):NH$, as a liquid of peculiar odour boiling at 168°, and but little soluble in water. A. J. G.

Action of Heat on Amidine Hydrochlorides. By A. PINNER (*Ber.*, 17, 179—182).—The author has shown (Abstr., 1883, 1090) that by heating ethylamine with a formimido-ether hydrochloride he obtained, not diethylformamidine hydrochloride as expected, but the salt of a base, $C_{10}H_{21}N_3$, derived from diethylformamidine by elimination of ammonia. The non-occurrence of diethylformamidine is now found to be due to its decomposition by the temperature employed in the reaction. A mixture of diethylamine and formimido-ether hydrochloride dissolved in absolute alcohol was allowed to remain for several weeks at the ordinary temperature; the products of the reaction were then found to be ammonia, diethylamine hydrochloride, diethylformamidine hydrochloride, and the hydrochloride of the base $C_{10}H_{21}N_3$.

Unsymmetrical diethylformamidine hydrochloride, $NEt_2\cdot CH:NH,HCl$, crystallises in brilliant, transparent, compact prisms, melts at 125°, is very hygroscopic, and is readily soluble in alcohol. The platinochloride, $(C_5H_{12}N_2)_2,H_2PtCl_6$, crystallises in yellowish-red prisms, melts at 208—209°, and is sparingly soluble in cold water. When the alcoholic solution of the hydrochloride is boiled it slowly evolves ammonia. Formamidine hydrochloride evolves streams of ammonia when heated in alcoholic solution. A. J. G.

Glucosamine Hydrochloride. By F. TIEMANN (*Ber*, **17**, 241—251).—G. Ledderhose gave the name glucosamine hydrochloride to a crystalline substance, $C_6H_{13}NO_5,HCl$, obtained by boiling chitin with concentrated hydrochloric acid. By double decomposition with silver salts, he obtained what he regarded as salts of glucosamine, and free glucosamine by treatment of the sulphate with barium hydroxide, all these substances being distinctly crystalline, but none of these derivatives from the hydrochloride could be obtained in a state fit for analysis. Moreover, on heating glucosamine hydrochloride with a nitrite, nitrogen was evolved, and he obtained a sugar (of the formula $C_6H_{12}O_6$?) as a dextrorotary syrup (this Journal, 1877, **1**, 64; *Zeitschr. Physiol. Chem.*, **2**, 213; **4**, 139).

To prepare glucosamine hydrochloride, the claws and shells of lobsters were treated at the ordinary temperature with concentrated hydrochloric acid until all mineral matters had been removed, and then dissolved in boiling hydrochloric acid. The solution was diluted with water, the excess of acid evaporated, filtered after some time to remove separated black decomposition-products, and finally crystallised. The last crystallisations are especially liable to contain gypsum, the presence of which leads to erroneous conclusions as to the crystallisation of the derivatives. Attempts to prepare the sulphate, nitrate, &c., and the free base were not more satisfactory than those of Ledderhose; syrups were obtained which only crystallised in part after standing for more than a year under absolute alcohol. There seems great doubt if some further decomposition had not occurred during these attempts to prepare the salts and the base, inasmuch as it was not found possible to reconvert these crystalline products into glucosamine hydrochloride. The author confirms Ledderhose's statement as to the action of nitrites on glucosamine hydrochloride, and was also unable to obtain the sugar in a state fit for analysis.

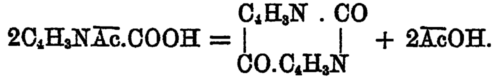
By careful oxidation of glucosamine hydrochloride with nitric acid, (sp. gr. 1·2) isosaccharic acid is obtained. If the reaction is allowed to become violent, oxalic acid is formed in large quantity, but with care its formation can be almost entirely avoided.

Isosaccharic acid, $C_6H_{10}O_8$, crystallises in anhydrous white rhombic crystals, melts at 185°, and is decomposed on stronger heating. It is readily soluble in alcohol and water, more sparingly soluble in ether. Its aqueous solution is dextrorotary. The barium salt, $C_6H_8BaO_8$, forms crystalline crusts; the copper salt, $C_6H_8CuO_8$, is obtained as a light green crystalline precipitate on adding alcohol to its aqueous solution; the calcium salt, $C_6H_8CaO_8$, forms pointed crystals. The silver salt, $C_6H_8Ag_2O_8$, is obtained as a white crystalline precipitate on adding silver nitrate to a concentrated solution of the calcium salt; on boiling its aqueous solution silver separates, in part as a mirror.

Ethyl isosaccharate, $C_6H_8O_6(OEt)_2$, crystallises in concentrically grouped needles, melts at 73°, is readily soluble in water, alcohol, and ether, sparingly soluble in chloroform and benzene. By carefully heating isosaccharic acid in a stream of carbonic anhydride nothing but a small carbonaceous residue is left, the acid being almost entirely resolved into carbonic anhydride, water, and pyromucic acid. A careful comparison of isosaccharic acid with the isomeric saccharic, mucic, and paramucic acids, clearly showed that it was not identical with any of them.

New Group of Nitrogen Compounds. By R. Engel (*Compt. rend.*, **98**, 574—576).—When ammonium lactate is dried in a slow current of dry ammonia gas and heated above 160°, it is completely decomposed; at 125—135° it gradually gives off water, and is mainly converted into lactamide; at 95—105° it loses water very slowly, but after 456 hours' heating the residue has the same composition as lactamide. The product, however, differs in its properties from both lactamide and alanine. It is a pale amber-coloured, syrupy uncrystallisable liquid, which decomposes at about 200°, and cannot be distilled. In contact with water, it immediately forms ammonium lactate, and the whole of the ammonia contained in it can be precipitated by platinum chloride in the cold. The constitution of this new compound may be represented by the formula $CHMe<\substack{NH_3\\CO-}>O$, it being formed from ammonium lactate by the loss of the alcoholic hydroxyl and one of the hydrogen-atoms in the ammonium. This formula explains the readiness with which the compound is converted into ammonium lactate, and also shows that it is intermediate between an ammonium salt and an amine. Hence the author proposes to call this new isomeride *lactamine*, and to give the generic name *acidamines* to other compounds of the same nature, which will be described in a subsequent paper. C. H. B.

Synthesis of Pyrocoll. By G. L. Ciamician and P. Silber (*Ber.*, **17**, 103—106).—This is effected by means of the acetyl-derivative of carbopyrollic acid. The authors prepare carbopyrollic acid by Schwanert's method (*Annalen*, **116**, 278) of heating ammonium mucate, and saponifying the carbopyrollamide obtained with baryta-water. They then convert the barium salt into potassium or sodium salt, add dilute sulphuric acid, and extract with ether. To prepare pyrocoll, carbopyrollic acid is boiled with an excess of acetic anhydride, and the latter then removed by distillation under diminished pressure. When the nearly black and thick oil obtained is further heated at about 160—190°, acetopyrroline passes over with the last traces of acetic anhydride; at a certain stage, however, the residue suddenly boils up with abundant evolution of acetic acid, and solidifies. The heating is then discontinued, and the product purified by crystallisation from glacial acetic acid and sublimation in a current of carbonic anhydride. Its properties agree with those of pyrocoll obtained from gelatin; it melts at 267°. The authors have not been able to isolate the acetyl-derivative of carbopyrollic acid, which appears to be decomposed by boiling with water. The production of pyrocoll may be explained by the equation:—



$$2C_4H_3N\overline{Ac}.COOH = \begin{array}{l}C_4H_3N\ .\ CO\\ |\qquad\qquad\ \ |\\ CO.C_4H_3N\end{array} + 2\overline{Ac}OH.$$

A. K. M.

Influence of Isomerism on Etherification. By N. MENSCHUTKIN (*Ann. Phys. Chim.* [5], 30, 81—144).—The greater part of the results and the deductions therefrom brought forward in this memoir have already appeared in abstract (Abstr., 1882, 383—388).

Some few miscellaneous experiments are added, together with general conclusions from the whole of the author's researches.

Etherification of Halogen-derivatives of Alcohols by Acetic Acid.

	Initial velocity.	Limit.
Glycol chlorhydrin, $CH_2Cl.CH_2.OH$	48·86	—
Glycerol dibromhydrin, $CH_2Br.CHBr.CH_2.OH$.	15·51	—

Etherification of Derivatives of Acids by Isobutyl Alcohol.

	Initial velocity.	Limit.
Monochloracetic acid, $CH_2Cl.COOH$..........	64·42	—
Metanitrobenzoic acid, $C_6H_4NO_2.COOH$	24·76	72·28

Etherification of Various Alcohols by Acetic Acid.

	Initial velocity.	Limit.
Propargylic alcohol, $CH : C.CH_2OH$..........	20·50	—
Ethyl isobutyl carbinol, $CHMe_2.CH_2.CEtH.OH$	18·23	63·06
Menthol, $C_{10}H_{20}O$	15 29	61·49
Borneol, $C_{10}H_{18}O$	25·12	62·46
Ethyl phenyl carbinol, $CHEtPh.OH$..........	18·89	—
Diphenyl carbinol, $CHPh_2.OH$	21·99	—

Conclusions.—The principal results of the author's investigations on the influence of isomerism of alcohols and acids on the formation of ethereal salts may be summed up as follows:—

Monatomic Alcohols.—(i.) The primary alcohols possess the highest limit of etherification and the greatest initial velocity, but these

values are different for different isologous series, the less saturated giving results lower than the most saturated. In the homologous series of these last, the velocity and limit vary regularly with the molecular weight.

(ii.) The initial velocity and limit of the secondary is less than that of the primary alcohols; analogous differences of composition correspond with analogous differences of etherification.

(iii.) The velocity and limit of the tertiary alcohols is very small, their salts of acetic acid are readily decomposed into the acid and the corresponding olefine.

(iv.) The phenols resemble the tertiary alcohols, although the process of etherification proceeds normally.

Polyatomic Alcohols.—(i.) The velocity and limit of polyatomic alcohols vary inversely as their atomicity.

(ii.) With alcohols of the same atomicity, the velocity and limit vary with their isomerism; the primary glycols give the highest results, then the secondary, and the tertiary the lowest. The diatomic phenols resemble the tertiary glycols.

Monobasic Acids.—(i.) The etherification of the primary monobasic acids is distinguished from that of all other acids by the high initial velocity and small limit. In the homologous series of normal primary acids, the limit and velocity vary regularly with the molecular weight of the acid.

(ii.) The secondary acids show smaller initial velocities, but higher limits than the primary acids; the effect of variation of composition is not marked.

(iii.) The tertiary monobasic acids, whether of the paraffinoïd or aromatic series, are characterised by the smallest velocity, but by the highest limit of etherification.

Polybasic Acids.—The limit of the polybasic acids is approximately equal to those of the monobasic; their initial velocity is, however, slightly greater. The influence of isomerism in both series exhibits the same characteristics.

Hydroxyl Acids.—(i.) The primary alcoholic acids show the highest limit of the etherification, on the action upon them of acids and alcohols, and in the process of internal etherification, or formation of anhydride.

(ii.) The phenolic acids belonging to the group of tertiary acids are characterised by the small limit in the action upon them of acids and alcohols; they do not undergo the change of internal etherification.

Ethylic Ethylacetocyanacetate and Methylacetocyanacetate. By A. Held (*Compt. rend.*, 98, 522—525).—When the sodium derivative of ethylic acetocyanacetate is heated with methyl or ethyl iodide, no substitution takes place. Ethylic ethylacetocyanacetate can, however, be obtained by treating ethylic ethylacetoacetate with sodium ethylate, and saturating the liquid with dry cyanogen chloride. On adding water, the product separates into two layers, the upper of which is washed with water and fractionated in a vacuum. Ethylic ethylacetocyanacetate is a colourless liquid, which gradually becomes yellowish. It has an agreeable ethereal odour, boils at 105—110°

under a pressure of 15 mm. to 2 mm. of mercury, and dissolves in all proportions in alcohol and ether, but is insoluble in water and in alkaline solutions; sp. gr. at 20° = 0·976. When boiled for several hours with potash solution, it yields ammonia, carbonic anhydride, alcohol, and acetic and butyric acids, and therefore has the constitution Me.CO.CEtCy.COOEt.

Ethylic methylacetocyanacetate is prepared in a similar manner. It is a colourless liquid, which boils at 90—95° under a pressure of 15—20 mm.; sp. gr. at 20° = 0·996. It has an ethereal odour, and is insoluble in water and alkalis. When boiled with potash, it splits up in the same manner as the preceding compound, but yields propionic acid in place of butyric acid, and it therefore has the constitution Me.CO.CMeCy.COOEt. C. H. B.

Reactions of Carbon Oxysulphide. By BERTHELOT (*Ann. Chim. Phys.* [5], **30**, 539—541).—Carbon oxysulphide and ammonia gases combine to form ammonium oxysulphocarbamate transformable into carbamide by elimination of hydrogen sulphide, thus: $NH_2.COSNH_4 - H_2S = NH_2.CO.NH_2$. On evaporating an aqueous solution of the salt, a crystalline mass is obtained, consisting principally of carbamide admixed with a considerable proportion of thiocarbamide. The formation of this latter may be due either to simultaneous production of two isomeric oxysulphocarbamates in the reaction of ammonia on carbon oxysulphide, such as $NH_2.CO.SNH_4$ or $NH_2.CS.ONH_4$, or to the concomitant elimination of hydrogen sulphide, or water from one oxysulphocarbamate. V. H. V.

Malonic Acid. By M. FREUND (*Ber.*, **17**, 133—138).—For the preparation of malonamide, the author recommends that malonic ether (50 grams) be treated with (150 c.c. of) concentrated ammonia solution (sp. gr. 0·925), and repeatedly shaken for 1—2 days. On heating an aqueous solution of the amide with freshly precipitated mercuric oxide, the compound  $CH_2{<}\genfrac{}{}{0pt}{}{CONH}{CONH}{>}Hg$ is produced, and separates on cooling as a heavy white amorphous powder, insoluble in alcohol and ether, sparingly soluble in hot water, readily in dilute hydrochloric acid. *Dimethylmalonamide*, $CH_2(CO.NHMe)_2$, is prepared by agitating malonic ether (1 mol.) with aqueous methylamine (2 mols.), and evaporating the solution to dryness. It crystallises from benzene in small flat deliquescent needles, melting at 128°. *Malonanilide*, $CH_2(CO.NHPh)_2$, obtained by boiling malonic ether (1 mol.) with aniline (2 mols.), crystallises from alcohol in white needles melting at 223°. It can also be prepared by boiling malonamide with aniline. It is not acted on by acetic chloride, even on heating. When malonamide (1 mol.) is heated with aniline (1 mol.) in an oil-bath, the temperature being gradually raised to 200—220°, and maintained at that for about half an hour, the product solidifies on cooling; the mass is powdered, boiled with water, and the solution filtered hot. The *monophenylmalonamide*, $NH_2.CO.CH_2.CO.NHPh$, thus obtained, crystallises from water or alcohol in slender white needles melting at 163°. When this is boiled with an excess of milk of lime, the calcium salt of malonanilic acid, $(NHPh.CO.CH_2.COO)_2Ca,4\frac{1}{2}H_2O$, is formed, crystallising in tufts of needles. The free acid, $C_9H_9NO_3$, forms large well-formed crystals melting at 132°. The silver salt, $C_9H_8NO_3Ag$, crystallises in small white needles. *Dimethyldiphenylmalonamide*, $CH_2(CO.NMePh)_2$, is prepared by boiling malonamide with an excess of methylaniline; it crystallises from water in rhombic plates and from ether in prisms melting at 109°. *Ethylenemalonamide*,

$$CH_2{<}\begin{matrix}CONH\\CONH\end{matrix}{>}C_2H_4,$$

is formed when ethylenediamine is heated at 170—180° with malonamide or boiled with ethyl malonate; it is very readily soluble in water, almost insoluble in alcohol. Phenylenediamine reacts in a similar way, yielding an amorphous grey substance, insoluble in water, alcohol, ether, glacial acetic acid, and benzene. A. K. M.

Derivatives of Malonic Acid. By L. RÜGHEIMER (*Ber.*, **17**, 235—236).—By heating equal molecular weights of aniline and ethyl malonate in sealed tubes at 160—170°, the author obtained, not the desired malonanilic acid, but, the dianilide of malonic acid, a substance crystallising in needles melting at 222—223°, soluble in alcohol and dilute acetic acid, insoluble in water and ether. Boiling acetic anhydride attacks this substance, converting it into a body which crystallises from light petroleum in broad needles. Treated with sulphuric acid at 150°, the dianilide yields an acid crystallising in large tables of the formula $C_{15}H_{12}N_2(SO_3H)_2 + 2H_2O$ (?).

Malonanilic acid appears to be formed by heating equal molecular weights of aniline and malonic acid at 105°. It crystallises in small prisms, melts with decomposition at 132°, and is much less soluble in water than malonic acid.

Aniline and ethyl malonylchloride, $ClCO.CH_2.COOEt$, dissolved in benzene, react at ordinary temperatures and yield aniline hydrochloride and a substance crystallising in needles melting at 208—210°, but not resolidifying after fusion, soluble in aqueous ammonia and soda, sparingly soluble in sodium carbonate. A. J. G.

Formulæ of certain Ammonium Salts. By R. ENGEL (*Compt. rend.*, **98**, 628—630).—It is well known that aldehydes have a tendency to unite with water, forming hydrates which are really bivalent alcohols, the ethers of which are the acetals, and hence the existence might be inferred of a hydrate of glyoxalic acid, COH.COOH, which would be dihydroxyacetic acid, $CH(OH)_2.COOH$. Notwithstanding the fact that glyoxalic acid and the glyoxalates contain a molecule of water which cannot be driven off without decomposing the compound, the formula COH.COOM is generally given to metallic glyoxalates, although the only fact which really supports this view is the composition of the ammonium glyoxalate, $COH.COONH_4$, which is regarded as a true ammonium salt, because it gives off ammonia when treated with potash, and undergoes double decomposition with other salts. The author, however, regards this compound, the corresponding ammonium mesoxalate, which contains 1 mol. H_2O less than other mesoxalates, and aldehyde-ammonium sulphites, which also contain 1 mol. H_2O less than the corresponding salts of other metals, as analogous to the lactamine described in a preceding communication. He regards ordinary ammonium glyoxalate and mesoxalate as glyoxalamine and mesoxalamine respectively, and concludes: (1) that the glyoxalates have the general formula $CH(OH)_2.COOM$; and (2) that to the acid alcohols of the formula $CH(OH).COOH$, there corresponds a series of nitrogen compounds which are not ammoniacal salts, because they contain an atom of water less, and are not amides because they behave like ammonium salts when brought in contact with water, but which occupy an intermediate position.

C. H. B.

Distinct Types of Glycollic Oxides. By L. HENRY (*Ann. Chim. Phys.* [5], **29**, 543—555).—It is here proposed to divide the substituted derivatives of the paraffins into two distinct types, 1st, the continuous, in which the replacing groups are attached to contiguous carbon-atoms, and 2nd, the discontinuous, in which these groups are attached to carbon-atoms, which are not contiguous. To the first class belong, for example, ordinary lactic acid, $COOH.CHMe.OH$, or propylene glycol, $CH_2(OH).CHMe.OH$; to the second class belong γ-oxybutyric acid, $CH_2(OH)(CH_2)_2COOH$, or γ-oxyvaleric acid,

$$CHMe(OH)(CH_2)_2COOH.$$

It would appear generally that a discontinuous compound functions as a series of distinct mono-carbon groupings detached from one another, but in the continuous compounds the proximity of the substituted groupings modifies its character. Such differences of chemical function are here illustrated in the case of two glycollic oxides derivable from hexylene, the one diallyl oxide,

$$CHMe{<}\genfrac{}{}{0pt}{}{CH_2.CH_2}{\text{—}O\text{—}}{>}CHMe,$$

the other mannitic oxide, $CHMe\underset{O}{\diagdown\diagup}CH.CH_2Et$. The former resembles ethyl oxide in dissolving in the halogen or sulphuric acids without chemical change or evolution of heat, and in being for the most part unaltered by phosphorus pentachloride. It is immediately oxidised by nitric acid. On the contrary, the latter resembles ethylenic oxide in combining directly with the halogen acids with considerable evolution of heat, and formation of a hydrine, $C_6H_{12}.OH$; by phosphorus pentachloride, it is converted into a dichlorhexane, $C_6H_{12}Cl_2$; by nitric acid, it is converted into a binitrate, $C_6H_{12}(NO_3)_2$. These facts illustrate the dynamical differences between two compounds, in both of which the relative arrangement of the carbon-atoms is the same, though the position of the oxygen-atom relative to the carbon-atoms is different.

V. H. V.

Gluconic Acid. Preliminary Notice. By H. KILIANI and S. KLEEMANN (*Ber.*, **17**, 143).—Gluconic acid is converted into caprolactone by heating it with concentrated hydriodic acid and amorphous phosphorus in a vessel provided with a reflux condenser; caproic acid does not appear to be formed simultaneously. By heating caprolactone with the same reagents in sealed tubes at 200°, caproic acid is obtained. A. J. G.

Action of Alkalis on Mucobromic Acid. By H. B. Hill (*Ber.*, **17**, 238—239).—The action of excess of baryta on mucobromic acid resolves it into formic and dibromacrylic acids (Hill and Jackson, Abstr., 1879, 224); if, however, any large excess of baryta is avoided, the reaction takes quite a different course. Mucobromic acid is suspended in water, neutralised with baryta, and baryta-water slowly added, until there is 1½ mol. of baryta to 1 mol. of mucobromic acid, the alkaline liquid is allowed to stand all night, the excess of baryta removed with carbonic anhydride, and the filtered liquid mixed with an equal volume of alcohol, when the barium salt of an acid, $C_4H_3BrO_4$, is precipitated. The free acid crystallises in small colourless oblique prisms, melts at 111—112°, is very soluble in water, alcohol, and ether, insoluble in chloroform, benzene, carbon bisulphide, or light petroleum. Its solutions decompose on evaporation, even at ordinary temperatures. It gives an intense garnet-red coloration with ferric chloride. The barium salt, $BaC_4HBrO_4 + H_2O$, crystallises in fine interlaced needles; the potassium salt, $K_2C_4HBrO_4 + H_2O$, crystallises in well formed rhombic tables; the silver salt, $Ag_2HC_4BrO_4$, is obtained as a crystalline precipitate readily soluble in nitric acid, the solution soon becoming turbid from deposition of silver bromide.

Aqueous solution of potassium phenylate reacts readily with mucobromic acid, forming *phenoxymucobromic acid*, $C_4H_2(OPh)BrO_3$.

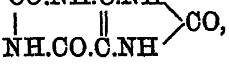
A. J. G.

Decomposition of Ethyl Carbamate. By G. Arth (*Compt. rend.*, **98**, 521—522).—Haller has shown that when campholurethane is treated with alcoholic potash, it splits up into potassium cyanate, borneol, and water (Abstr., 1883, 625 and 1213), and the author has found that the analogous compound obtained from menthol behaves in a precisely similar manner. He now finds that when crystallised ethyl carbamate, obtained by the action of urea nitrate on absolute alcohol, is boiled with the requisite quantity of alcoholic potash, it yields potassium cyanate, which is partially decomposed with evolution of ammonia. It appears therefore that the reaction observed by Haller is general, and that when carbamic ethers are treated with potash they decompose in accordance with the equation

$$CO.NH_2.OR + KOH = CNOK + R.OH + H_2O.$$

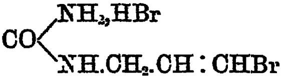
This observation furnishes an additional reason for placing the borneol and menthol derivatives referred to in the class of carbamic ethers. C. H. B.

Allylcarbamide. (Part I.) By R. Andreasch (*Monatsh. Chem.*, **5**, 33—46).—Looking upon Medicus' formula for uric acid,



$$\begin{array}{l}CO.NH.C.NH \\ \,|\qquad\quad \| \\ NH.CO.C.NH\end{array}\!\!>\!CO,$$

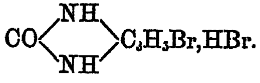
as probably correct, the author considers that for any synthesis of uric acid which shall be of use from a theoretical point of view, the starting point must be a carbamide derivative consisting of a closed ring containing three consecutive carbon-atoms. The present investigation was undertaken in the hope of obtaining such a body by splitting off the elements of hydrobromic acid from the dibromo-addition product of allylcarbamide. Allylcarbamide was prepared by the action of allylamine sulphate on potassium cyanate, and also by heating a solution of thiosinamine with silver nitrate. Allylamine was prepared by Hofmann's method of heating allylthiocarbimide (volatile oil of mustard) with strong sulphuric acid. *Allylamine sulphate*, $(C_3H_5.NH_2)_2,H_2SO_4$, is very soluble in water; its solution on evaporation forms a syrup which when left for some time over sulphuric acid solidifies to a crystalline mass. It is very soluble in alcohol, and exceedingly hygroscopic. *Allylcarbamide* forms a network of fine needles easily soluble in alcohol and water, very sparingly in chloroform and ether, and melting at 85°*. *Allylcarbamide nitrate* crystallises in groups of slender needles; it is easily soluble in water to an acid solution which decomposes with evolution of gas when heated. When an aqueous or alcoholic solution of allyl carbamide is treated with bromine, it takes up 1 mol. of the latter, forming *dibromopropylcarbamide*, $C_4H_8N_2OBr_2$. The reaction takes place quantitatively, and may be used as a means of titrating a solution of allylcarbamide. Dibromopropylcarbamide crystallises in thin plates or needles, easily soluble in warm water and in alcohol, sparingly so in cold water and chloroform, insoluble in ether. It melts at 109°. The aqueous solution is neutral in reaction, and gives no precipitate with silver nitrate. Heated with water, it is converted into an isomeric body which crystallises in needles belonging to the rhombic system; it melts at 158°, and is soluble in water and alcohol, insoluble in ether and chloroform. It forms a neutral aqueous solution, from which silver nitrate precipitates half the bromine present, thus proving the substance to be the hydrobromide of a brominated base. This substance has most probably one of the two following formulæ:—



$$CO\begin{cases}NH_2,HBr\\NH.CH_2.CH:CHBr\end{cases}$$

Bromallylcarbamide hydrobromide.

or



$$CO\begin{cases}NH\\NH\end{cases}C_3H_5Br,HBr.$$

Bromopropylenecarbamide hydrobromide.

From the neutral reaction of its aqueous solution, the author is inclined to regard the second as the more likely formula, for it seems improbable that a bromallylcarbamide would have such marked basic properties. *Bromopropylenecarbamide hydrochloride* is obtained by digesting the hydrobromide with freshly precipitated silver chloride. crystallises in concentrically-grouped needles, melting at 143°, and easily soluble in water and alcohol. The *platino-chloride*,

$$(C_4H_7BrN_2O)_2,H_2PtCl_6,$$

---

* *Note by Abstractor.*—Maly (*Zeitschr. Chem.*, 1869, 261) states that allyl carbamide crystallises in prisms melting at 241°.

crystallises in orange-yellow scales, soluble in water, insoluble in absolute alcohol or ether. *Bromopropylenecarbamide*, $C_4H_7BrN_2O$, is obtained from the hydrobromide by digesting it with silver oxide or by adding the calculated quantity of potassium hydroxide to its aqueous solution. It crystallises in well-formed silky needles which melt at 120°. It is sparingly soluble in cold water, easily so in boiling water, and forms a strongly alkaline solution. It dissolves in boiling alcohol, chloroform, and benzene, but crystallises out again, on cooling, in long needles. It forms neutral salts with acids. The *sulphate* is easily soluble in alcohol and water. With silver nitrate an aqueous solution of the free base gives a white precipitate soluble in nitric acid and ammonia; with mercuric chloride, it gives a heavy white flocculent precipitate. The author was unable to debrominate this base: tin and hydrochloric acid did not act on it, whereas the action of sodium-amalgam was too energetic and yielded no satisfactory results. Attempts to establish its constitution by decomposing it with alkalis or alcoholic ammonia, or by obtaining oxidation-products, also proved fruitless. L. T. T.

Action of Bromethylene on Benzene in Presence of Aluminium Chloride. By HANRIOT and GUILBERT (*Compt. rend.*, **98**, 525—526).—500 grams bromethylene were mixed with 230 grams benzene, and 20 grams aluminium chloride were added gradually to the cooled mixture in such a manner that the temperature did not rise above 50—60°. No gases were evolved, and the product was thrown into ice-cold water, dried over potash, and distilled in a vacuum. Two fractions were thus obtained, one boiling at 145—150° under a pressure of 0·03 m., and consisting of styrolyl bromide, $C_6H_5.C_2H_4Br$, the other boiling at 200—230°, and consisting of dibromodiethylbenzene, $C_6H_4(C_2H_4Br)_2$. Above 230° no definite fraction could be obtained, and an abundant black tarry residue resulting from the decomposition of higher brominated products was left in the retort. These results are very different from those obtained by Angelbis and Anschütz (*Ber.*, 1884, 167). C. H. B.

New Compound formed in the Preparation of Benzene Hexchloride. By J. MEUNIER (*Compt. rend.*, **98**, 436—438).—When benzene hexchloride is prepared by the action of chlorine on boiling benzene purified from thiophene, and the crude product is sublimed, obtuse or acute lamellæ are first obtained, but towards the close of the operation small octahedral crystals condense in the receiver. These octahedral crystals melt at about 300° and volatilise immediately. They have no action on polarised light and belong to the cubic system, the observed faces, in addition to those of the octahedron, being those of the cube, tetrahedron, and triakistetrahedron.

The chemical properties of this new compound are analogous to but distinct from those of ordinary benzene hexchloride. It decomposes in the same manner above 300° into hydrochloric acid and trichlorobenzene, the latter being apparently identical with that obtained from the hexchloride. The new compound is, however, much less readily decomposed by alcoholic potash, and is not attacked by an alcoholic solution of potassium cyanide. This latter property furnishes a method of separating the two substances.

The octahedral crystals are very soluble in benzene, but less soluble in alcohol. They have the composition $xC_6H_6Cl_6$, and are probably a polymeride of ordinary benzene hexchloride. C. H. B.

Nitriles and Carboxylic Acids from Aromatic Amines. By K. GOUSIOROWSKI and V. MERZ (*Ber.*, **17**, 73—74).—If formanilide is boiled alone, very little benzonitrile is produced, but the reaction is assisted by the addition of zinc-dust: $NHPh.COH + Zn = NPhC + ZnO + H_2$, and $NPhC = PhCN$. The production of benzonitrile may also be effected by passing formanilide vapour over zinc-dust heated nearly to dull redness, the distillate consisting of benzonitrile and aniline. Formorthotoluide and formoparatoluide yield orthotolunitrile and paratolunitrile respectively. The results are confirmed by vapour-density determinations and conversion of the nitriles into the carboxylic acids. A. K. M.

Action of Hydroxylamine on Nitriles. By F. TIEMANN (*Ber.*, **17**, 126—129).—When an aqueous solution of hydroxylamine hydrochloride with an equivalent quantity of sodium carbonate is agitated with a concentrated ethereal solution of benzaldehyde cyanhydrin, crystals of an addition compound, $C_8H_{10}N_2O_2$, gradually form at the surface of contact of the two solutions. It is sparingly soluble in cold, readily in hot water, is insoluble in benzene, sparingly soluble in ether, very readily in alcohol. It melts at 140°, and at a higher temperature suddenly decomposes with evolution of gas and formation of benzaldehyde. With the view of ascertaining if this compound still contained the cyanogen-group, it was submitted to the action of concentrated sulphuric and hydrochloric acids, but with negative results, the substance being recovered unchanged on dilution and neutralisation. It behaves as an amido-acid, dissolves with the greatest readiness in both acids and alkalis, and is reprecipitated on neutralising the solutions. It forms a sparingly soluble crystalline platinochloride, and yields white crystalline precipitates on adding barium chloride, zinc sulphate, lead acetate, and silver nitrate to its ammoniacal solution, and a green precipitate with copper sulphate. Its neutral solution is coloured blood-red by ferric chloride; it is not reduced by Fehling's solution. It yields an acetyl-derivative melting at 149°, and a benzoyl-derivative melting at 137°. An addition-compound of hydroxylamine with benzonitrile, $C_7H_8N_2O$, can also be obtained, thus: an alcoholic solution of hydroxylamine hydrochloride is treated with the equivalent quantity of sodium carbonate in aqueous solution and benzonitrile added, together with sufficient alcohol to form a clear solution. The mixture is heated for some hours at 60—80°, when the odour of benzonitrile disappears, and on then evaporating the solution, a heavy oil separates, solidifying to a crystalline mass. It crystallises from water in prisms melting at 70°, and volatile without decomposition; it dissolves sparingly in cold, readily in hot water, alcohol, ether, and benzene. It is very readily dissolved by acids and alkalis, and shows a similar behaviour to the above compound obtained from benzaldehyde cyanhydrin. The hydrochloride crystallises in concentrically grouped needles, and yields a moderately soluble platinochloride. Its aqueous solution is neutral, is coloured red by ferric chloride, and is not reduced by Fehling's solution. Its ammoniacal solution yields crystalline precipitates with barium chloride, zinc sulphate, lead acetate, and silver nitrate, and in the last case a silver mirror is obtained on warming. This condensation-product can only be represented by one of the formulæ, NH : CPh.NH.OH or NH_2.CPh : N.OH, and must therefore be either benzenyloxamidine or benzenylamidoxime. The condensation-product from benzaldehyde cyanhydrin and hydroxylamine would then be either phenyloxethenyloxamidine, CHPh(OH).C(: NH)NHOH, or phenyloxethenylamidoxime, CHPh(OH).C(NH_2)N.OH.

A. K. M.

Nitrosophenols. By H. Goldschmidt (*Ber.*, **17**, 213—217).—The author has already described the action of hydroxylamine on various diketones and quinones (*Ber.*, **16**, 2176). He now considers its action on benzoquinone and β-naphthaquinone.

Concentrated solutions of hydroxylamine hydrochloride and benzoquinone react so violently that the product is carbonised. Good results were obtained as follows :—1 part of quinone was dissolved in 300 parts water and an aqueous solution of 1 part hydroxylamine hydrochloride added; the dark-coloured liquid was allowed to stand until all odour of quinone had disappeared (about 12 hours), then shaken with animal charcoal, filtered, and extracted with ether. The ethereal solution was evaporated, and the liquid residue, after further treatment with animal charcoal, placed in a vacuum, when long colourless needles separated. These proved to be identical with the paranitrosophenol of Baeyer and Caro (this Journal, 1875, 84). As this method of formation throws some doubt on the constitution assigned to this compound, experiments are being made to ascertain its true nature.

β-Naphthaquinone, when treated with hydroxylamine hydrochloride in manner similar to that described above, yields the β-nitroso-α-naphthol described by Fuchs (this Journal, 1876, 248). This substance, when heated in alcoholic solution with hydroxylamine hydrochloride and a few drops of hydrochloric acid in sealed tubes at 130°, yields a substance of the formula  $C_{10}H_6\langle\begin{smallmatrix}N\\N\end{smallmatrix}\rangle O$, which crystallises in fine pale yellow needles, and melts at 78°. That this substance is an anhydride and does not contain hydroxyl, is shown by its insolubility in alkalis. Of the two formula  and  that may be assigned to Fuchs' compound, the author regards the second as best explaining its reaction with hydroxylamine. He hopes soon to be able to settle the question.

A. J. G.

Azoparacresol. By C. LIEBERMANN and ST. v. KOSTANECKI (*Ber.*, **17**, 130—132).—Liebermann previously pointed out the incorrectness of the view that in the formation of the azophenols, the azo-group always assumes the para-position to the hydroxyl (*Ber.*, **16**, 2858), and he alluded to the formation of an azo-derivative of paracresol by Mazzara (*Gazzetta*, **9**, 424, and Abstr., 1880, 163). The authors have followed Mazzar's instructions in the preparation of the azo-derivatives of phenol and of the cresols, and they find that two compounds are almost always simultaneously produced, of which one is soluble and the other insoluble in dilute alkali. The two products are not isomerides, neither are the insoluble compounds always diazo-derivatives. *Phenylazoparacresol*, $PhN_2.C_6H_3Me.OH$, was prepared according to Mazzara's instructions, and the product dissolved in dilute alkali instead of in ammonia, and the solution precipitated with acetic acid. After repeated crystallisation from dilute alcohol, it was obtained in scales of a golden lustre melting at 108°; it can be volatilised almost unchanged by careful heating. It dissolves completely in cold alkali, forms a brownish-red solution with concentrated sulphuric acid, and is readily soluble in cold alcohol. It colours animal fibre pale canary-yellow. On dissolving the portion insoluble in alkali, in sodium ethylate and adding water, it is obtained in brown needles, which may be purified by crystallisation from dilute alcohol. *Phenylazorthocresol* is prepared in the same way as the para-compound, and forms needles or scales of golden lustre melting at 128—130°. It is completely soluble in cold alkali, dyes wool yellow, and forms a brown solution with sulphuric acid. A substance insoluble in alkali is also produced. *Cumylazoresorcinol*, $C_6H_2Me_3.N_2.C_6H_3(OH)_2$ (from liquid cumidine), has also been prepared, and here again dilute alkali separates a soluble from an insoluble product. The soluble compound, $C_{15}H_{16}N_2O_2$, forms small red needles, dissolves in concentrated sulphuric acid with a greenish yellowish-brown coloration, and melts a little above 200° with decomposition. The insoluble compound is possibly *cumylazoresorcinolazocumyl*, $(C_6H_2Me_3.N_2)_2C_6H_2(OH)_2$.

A. K. M.

Constitution of Resocyanin. By A. MICHAEL (*Am. Chem. J.*, **5**, 434—440).—After alluding to papers by Wittenberg, W. Schmid, and H. v. Pechman and C. Duisberg, the author describes his independent observations made some time ago.

The body was obtained by heating together equal weights of ethylic acetoacetate, resorcinol, and zinc chloride, and pouring the product into cold water. Analyses of this preparation and also those analyses made by Pechmann and Duisberg would seem to point to the formula $C_{10}H_8O_3$, while the determinations of Schmid and of Wittenberg agree better with the formula $C_{20}H_{16}O_6$. Resocyanin is fluorescent. When heated with acetic anhydride and sodium acetate, acetyl-resocyanin is formed. The methyl-derivative was obtained by adding sodium methylate and methyl iodide to a solution of resocyanin in methyl alcohol. With hydrogen an addition-product is formed, and this, treated with acetic anhydride and sodium acetate, yields a crystalline monacetyl-derivative. An acetic acid solution of bromine gives with resocyanin a crystalline precipitate, $C_{10}H_5Br_3O_3$. Potassium permanganate oxidises resocyanin completely in the cold; fused with zinc chloride, a red mass, a zinc-derivative of resocyanin is obtained; phosphorous pentachloride acts on resocyanin. A few analyses are given, which are not however sufficient to decide the composition of resocyanin. Further work is required. H. B.

1 : 2 : 4 Orthoxylidine. By O. JACOBSEN (*Ber.*, **17**, 159—162).—Wroblewsky has described (Abstr., 1881, 433) a xylidine which, without stating his evidence, he assumes to be the orthoxylidine 1 : 2 : 4. As from the method by which it was prepared it seemed probable to the author that it was a somewhat impure paraxylidine, he has prepared the 1 : 2 : 4 orthoxylidine, and finds it to be a substance entirely different from that described by Wroblewsky.

Nitro-orthoxylene, $C_6H_3MeMe.NO_2$ [1 : 2 : 4], is prepared by slowly adding pure orthoxylene to 8 or 10 times the quantity of fuming nitric acid, the mixture being kept well cooled. After purification, orthoxylidine is obtained as a yellowish heavy oil, which solidifies on cooling. It crystallises from alcohol in long clear yellow prisms, and melts at 29°. It boils with slight decomposition at 258° under the ordinary pressure, and without decomposition at 248° under 580 mm. pressure. Its sp. gr. is 1·139 at 30° (water at 30° = 1). It is the only nitroxylene produced in appreciable quantity by the reaction.

Orthoxylidine, $C_6H_4Me_2.NH_2$ [Me : Me : NH_2 = 1 : 2 : 4], is best prepared from nitro-orthoxylene by reduction with tin and hydrochloric acid; it crystallises in forms belonging to the monoclinic system, has scarcely any odour, melts at 49°, and boils at 226°. Its sp. gr. at 17·5 = 1·0755. It is sparingly soluble in cold water, moderately in light petroleum, readily in alcohol and ether. Pure orthoxylidine remains colourless when exposed to air and light.

Orthoxylidine hydrochloride, $C_8H_{11}N,HCl + H_2O$, crystallises in long thin prisms, is readily soluble in water, sparingly soluble in hydrochloric acid. It begins to volatilise at a little above 100°.

Acetoxylide, $C_8H_9.NH\overline{Ac}$, prepared by heating orthoxylidine with glacial acetic acid and acetic chloride, or by several hours' heating with glacial acetic acid alone, crystallises in brilliant long thin prisms, melts at 99°, is sparingly soluble in cold water, readily in alcohol.

The constitution of orthoxylidine was proved by its conversion into 1 : 2 : 4 orthoxylenol. This latter substance melts at 62·5°, not 61° as previously stated by the author (Abstr., 1878, 412).

A. J. G.

Paramidobenzyl Cyanide. By P. FRIEDLÄNDER (*Ber.*, **17**, 236—238).—A base of the formula $C_8H_8N_2$ was observed by the author and Mähly (Abstr., 1883, 918) to occur as a bye-product in the reduction of ethyl paranitrophenyl-nitroacrylate, and was erroneously supposed by them to have the constitution $NH_2.C_6H_4.CH.CH$. Further investigation has, however, shown the substance to be *paramidobenzyl cyanide*, $NH_2.C_6H_4.CH_2.CN$, so that in the reaction the group,

$$—C—NO_2$$

$$NH_2.C_6H_4.\underbrace{CH.CH}_{N}$$

must have been reduced to the cyanogen-group; a reaction that has not been previously noticed. The true nature of the substance was clearly shown by treatment with hydrochloric acid, when it yielded an acid agreeing in all particulars with those given for paramidophenylacetic acid by Radziszewski (*Ber.*, 2, 209), and by Bedson (Trans., 1880, 92), and further by comparison with paramidobenzyl cyanide, prepared by reduction of paranitrobenzyl cyanide. In similar manner, by the reduction of ethyl metanitrophenylnitroacrylate,

$$C_6H_4(NO_2).CH : C(NO_2).COOEt,$$

with tin and hydrochloric acid, it yields metamidobenzyl cyanide.

A. J. G.

Behaviour of Diamines towards Nitrous Acid. By A. LADENBURG (*Ber.*, 17, 147—150).—The author has shown that the condensation-products obtained by the action of nitrous acid on the diamines differ according to the position of the amido-groups; the reaction product from the orthodiamines (the azimido-compounds) being derived from 1 mol. of the diamine only, whilst in the meta- and para-compounds the product is derived from 2 mols. (this Journal, 1876, 933; 1877, 302). Biedermann and Ledoux have, however, stated (*Ber.*, 7, 1531) that the nitrophenylenediamine melting at 195°, from which Hofmann prepared the first known azimido-compound, is identical with nitroparaphenylenediamine. The author therefore thought it necessary to reinvestigate the question. Paraphenylenediamine was converted into the acetyl-compound, and then nitrated; the resulting *nitro-diacetylparaphenylenediamine* crystallises in golden-yellow needles, and melts at 184°. On gently heating it with dilute soda solution, *nitromonacetylparaphenylenediamine*, $C_6H_3(NO_2)(NH_2).NH\overline{Ac}$, is obtained, crystallising in red needles and melting at 186°. By boiling either the mono- or di-acetyl-compound with concentrated hydrochloric acid for 15 minutes, diluting and supersaturating with ammonia, *nitroparaphenylenediamine*, $C_6H_3(NO_2)(NH_2)_2$, is obtained; it crystallises in nearly black needles, having a strong green lustre, and melts at 137°, dissolves readily in dilute acids, and forms well characterised salts. Its non-identity with ordinary nitrophenylenediamine, melting at 195°, is therefore certain. Dissolved in sulphuric acid, and treated with sodium nitrite, it yields a brown powder, which was not further investigated.

When a solution of paraphenylenediamine hydrochloride is treated with potassium nitrite, it yields a brown powder, insoluble in all ordinary solvents, the figures obtained on analysis approximating to those required for the formula $C_{12}H_{12}N_2O_3$.

With regard to the constitution of the nitrophenylenediamines, the new body from paraphenylenediamine must have the positions

$$[NH_2 : NO_2 : NH_2 = 1 : 2 : 4];$$

whilst the compound melting at 195° has been obtained from the dinitroaniline in which the nitro-groups are in the meta-position to one another, its nitro- and amido-groups must occupy the positions $[NH_2 : NH_2 : NO_2 = 1 : 2 : 4]$. This latter body yields an acetyl-derivative, $C_6H_3(NO_2)(NH\overline{Ac})_2$, crystallising in colourless needles.

A. J. G.

Action of Hydroxylamine on the Imidoethers and Amidines. Acidoximes. By A. PINNER (*Ber.*, 17, 184—186).—The imide-group in the imidoethers and amidines is readily converted into the oximido-group (:N.OH) by the action of hydroxylamine. *Benzoximidoether*, CPh(OEt) : N.OH, is prepared by dissolving hydroxylamine hydrochloride in water, adding an equivalent quantity of benzimidoether, together with as much alcohol as is necessary to give a clear solution; after standing for some days, the mixture is diluted with water and shaken with ether. On evaporation of the ethereal solution benzoximidoether is left as a colourless liquid, which cannot be distilled without decomposition.

Benzoxamidine, NH_2.CPh : N.OH, is prepared by mixing equivalent quantities of the aqueous solutions of the hydrochlorides of benzamidine and hydroxylamine with addition of sufficient soda to decompose the latter salt, the mixture being allowed to stand some days; the like quantity of soda is again added, and the liquid extracted with ether. The residue from the evaporation of the ethereal solution is crystallised from alcohol, when large transparent plates of benzoxamidine are obtained melting at 80°. The substance shows great similarity in properties, except in melting point, with the addition-product of hydroxylamine and benzonitril melting at 70°, described by Tiemann (this vol., p. 734). A. J. G.

Possible Number of Homologous and Isomeric Rosanilines. By A. ROSENSTIEHL and GERBER (*Compt. rend.*, 98, 433—436).—The actual number of rosanilines already obtained is 9, 6 of which are homologues, the remainder being isomerides. It has been shown that the amines can be divided into three groups, according to their capability of forming rosanilines. Class (1) includes paratoluidine, α-metaxylidine, mesidine, and amidopentamethylbenzene, which furnish the carbon of the methane nucleus. In this class one of the CH_3-groups is in the para-position with respect to the NH_2-group, whilst the position of the other CH_3-groups is immaterial. Of the 20 known amidomethylbenzenes, only 10 fulfil these conditions. Class (2) includes aniline, orthotoluidine, γ-metaxylidine, and other derivatives in which methyl is *not* in the para-position with respect to NH_2, but, in the case of homologues of aniline, *is* in the ortho-position. Class (3) includes those derivatives which do not contain methyl in the para- or ortho-position, and consequently yield no rosanilines.

There is no experimental evidence to show whether the presence of CH_3 in the meta-position as well as in the ortho-position in a derivative of class 2 prevents the formation of a rosaniline. If it does not, the highest member of this class will be amidotetramethylbenzene (1 : 2 : 3 : 5 : 6), and the highest rosaniline will be $C_{31}H_{43}N_3O$, formed by the action of 1 mol. amidopentamethylbenzene on 2 mols. amidotetramethylbenzene, and amongst the 20 known amidomethylbenzenes there are 8 ortho-derivatives and 10 para-derivatives, which together may form 80 homologous and isomeric rosanilines.

If, however, the presence of CH_3 in the meta-position in a member of class 2 does prevent the formation of a rosaniline, no tri-methylbenzene can be in this group, since 1 of the 3 CH_3-groups must be in the meta-position. The highest member of this class will therefore be γ-metaxylidine, and the total possible number of homologous and isomeric rosanilines will be 30, the number of homologues being 9, the highest of which will be $C_{27}H_{35}N_3O$. To distinguish between these various homologues and isomerides will probably be very difficult. C. H. B.

Colouring Matters formed by the Simultaneous Oxidation of Paradiamines and Monamines. By R. NIETZKI (*Ber.*, **17**, 223—227).—By the oxidation of an acid solution of tetramethyldiamidodiphenylamine with ferric chloride, in presence of hydrogen sulphide, dimethylphenylene-green, $C_{16}H_{20}N_3Cl$, is first formed, and it is only after long standing and renewed addition of ferric chloride and of hydrogen sulphide that methylene-blue is obtained. The very small yield obtained, only 5 per cent. of the theoretical, points to its formation as due to some indirect process.

By oxidation of a mixture of equal molecular weights of paraphenylamine and diphenylamine, or of para-monamidodiphenylamine either alone or in presence of aniline, a substance, $C_{15}H_{15}N_3$(?), is obtained closely related to aniline-black, and is probably identical with "emeraldine," the incompletely oxidised aniline-black.

The formula of phenosafranine is $C_{18}H_{12}N_4$, as stated by Bindschedler (*Ber.*, **16**, 864), and not $C_{18}H_{16}N_4$, that previously given by the author. The author cannot confirm Bindschedler's statement that 4 atoms of hydrogen are necessary to convert 1 mol. of safranine into the leuco-bases; by titration of a strongly acid safranine solution with stannous chloride it was found that only 2 atoms of hydrogen were required. A. J. G.

Methylene-blue. By R. MÖHLAU (*Ber.*, **17**, 102—103).—On repeating the analysis of the double salt of methylene-white with zinc chloride, the numbers obtained indicate that this base has the formula $C_{16}H_{19}N_3S$, in accordance with the view held by Bernthsen (*Ber.*, **16**, 2896), and not $C_{16}H_{21}N_3S$, as previously assumed by the author (*Ber.*, **16**, 2728). He believes, with Bernthsen, that methylene-white is a tetramethyldiparamidothiodiphenylamine, and that the hydrochloride of methylene-blue has the constitution

$$Me_2N.C_6H_3\left\langle\begin{matrix} S.C_6H_3 \\ | \\ N \end{matrix}\right\rangle NMe_2Cl.$$

The atomic grouping assigned by Erlenmeyer to Bindschedler's dimethylphenylene-green (*Ber.*, **16**, 2857) more probably represents the base, $C_{16}H_{19}N_3$, obtained by the author from nitrosodimethylaniline and dimethylaniline. A. K. M.

Blue Colouring Matter from Pyrroline. By G. CIAMICIAN and P. SILBER (*Ber.*, **17**, 142—143).—The independent discovery of this substance by V. Meyer (this vol., 587), has obliged the authors to publish their researches on this subject, although still incomplete.

The best yield is obtained by dissolving 2 parts of isatin in 50 parts of glacial acetic acid, and adding 1 part of pyrroline to the boiling solution. The dark blue liquid is poured into water and nearly neutralised with sodium carbonate, when the colouring matter is precipitated. After purification, it forms a black microcrystalline powder, which assumes a metallic lustre when rubbed, has the composition $C_{24}H_{16}N_4O_3$, is insoluble in ether, soluble in glacial acetic acid, phenol, boiling alcohol, and concentrated sulphuric acid. Its formation is represented by the equation $C_{16}H_{10}N_2O_4 + 2C_4H_5N - H_2O = C_{24}H_{18}N_4O_3$. A. J. G.

Ethyl Derivatives of Anhydrobenzodiamidobenzene. By J. L. Howe (*Amer. Chem. J.*, 5, 418—424).—When anhydrobenzodiamidobenzene is heated with ethyl iodide at 120°, it yields a mass consisting approximately of equal parts of the iodide of the diethyl derivative and the hydriodate of the anhydro-base. From the aqueous solution of these iodides hot sodic hydrate completely precipitates the anhydro-base, whilst from the filtrate caustic potash precipitates *diethylanhydrobenzodiamidobenzene hydroxide*,  $C_6H_4\left\langle\begin{matrix}\text{——N}\\ \text{NEt}_2(\text{OH})\end{matrix}\right\rangle\text{CPh}$, a crystalline solid, melting at 136°. The following salts of this base are described: the iodide, $C_{13}H_9N_2 : Et_2I,H_2O$; the chloride,

$$C_{13}H_9N_2 : Et_2Cl,2H_2O;$$

a second chloride containing one molecule of hydrochloric acid and several of water, crystallises imperfectly from a very concentrated acid solution; the platinochloride, $(C_{13}H_9N_2Et_2Cl)_2,PtCl_4$, and the sulphate, $C_{13}H_9N_2Et_2,HSO_4,H_2O$; all crystalline salts. When the chloride is heated above 200°, it gradually decomposes, and a thick oil distils over, which slowly becomes crystalline after purification; it is *ethylanhydrobenzdiamidobenzene*, and is formed thus,

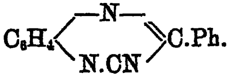
$$C_{13}H_9N_2 : Et_2Cl = C_{13}H_9N_2Et + EtCl.$$

This process could undoubtedly be applied to similar dialkyl anhydro-bases as a definite method of forming the monalkyl compounds which have hitherto been the result of no known conditions. The salts of this base are much less stable and less soluble in water than those of the diethyl base; boiling with dilute acid converts them into a salt of the anhydro-base. The hydrochloride, $C_{13}H_9N_2Et,HCl,3H_2O$; the platinochloride, $[C_{13}H_9N_2Et]_2,H_2PtCl_6$; and the nitrate

$$C_{13}H_9N_2Et,HNO_3,H_2O,$$

are described. A table showing the formulæ and general properties of all the derivatives of anhydrobenzdiamidobenzene, as described in the present paper, and previous ones by Hübner, C. S. Merrick, and F. Rinne is appended. H. B.

A Nitrile of Anhydro-benzodiamido-benzene. By J. L. Howe (*Amer. Chem. J.*, 5, 415—418).—When anhydro-benzodiamido-benzene (benzenyl-phenylene-amidine of Beilstein),  $C_6H_4{<}\substack{-N-\\ NH}{>}Ph$, is heated in a closed tube with an excess of cyanogen iodide, and a considerable quantity of benzene at about 100°, dark red crystals of the tri-iodide,  $C_6H_4{<}\substack{-N-\\ NH.HI}{>}CPh,I_2$ are formed, whilst the benzene contains a substance, $C_{13}H_9N_2.CN$, forming pale-yellow crystals. When this is boiled with caustic potash, the original anhydro-base is regenerated, and ammonia and potassium carbonate are formed. It was not possible to replace the cyanogen-group by carboxyl by heating with water at 250°, nor by treatment with very concentrated hydrochloric acid in a freezing mixture. On attempting to convert the cyanogen-group into the methyleneamine group by the use of sodium-amalgam and water, the anhydro-base alone was obtained. It is therefore probable that the cyanogen group is not united to a carbon-atom, so that its constitution may be represented by the formula



$$C_6H_4{<}\substack{-N-\\ N.CN}{>}C.Ph.$$

The compound is probably a cyanamide, anhydro-benzdiamido-benzene cyanamide, but it shows no tendency to polymerise. H. B.

Orthamidoazo-compounds. By E. NÖLTING and O. N. WITT (*Ber.*, **17**, 77—82).—The authors prove the incorrectness of the view that the formation of amidoazo-compounds from diazo-compounds and an amine only takes place when the para-position in the latter is free to the entrance of the azo-group. Hofmann and Geyger, and also Nietzki, could obtain no amidoazo-derivative from paratoluidine, a diazoamido-compound alone being formed, whilst orthotoluidine yields directly amidoazotoluene, according to Nietzki, without the intermediate production of the diazoamido-derivative. The authors find that perfectly pure orthotoluidine does yield a well-crystallised pale-yellow diazoamido-derivative; also that amidoazoparatoluene may be obtained if diazoamidoparatoluene (1 mol.) be added to 5—6 parts of melted paratoluidine, then dry paratoluidine hydrochloride (1 mol.), and the mixture heated for 10—12 hours at 65°. It crystallises in splendid orange-red lustrous needles, melting at 118·5°, is readily soluble in hot alcohol and ethyl acetate, very readily in benzene. Its salts are pale-yellow in the solid state, green in solution; the hydrochloride crystallises in slender, whitish-yellow needles, the acetyl-derivative, $C_6H_4Me.N_2.C_6H_3Me.NH\overline{Ac}$, in yellow needles, melting at 157°, and the benzoyl-derivative in orange-yellow needles, melting at 135°. Amidoazoparatoluene hydrochloride yields a disulphonic acid with fuming sulphuric acid, which is a yellow dye; by the action of nitrous acid on this and on amidoazoparatoluene, diazo-derivatives are produced, which yield red dyes with β-naphthol and its sulphonic acids. By the action of reducing agents on amidoazoparatoluene, paratoluidine and orthotoluylenediamine are obtained, proving the constitution , and thus showing that the diazo-group is capable of assuming the ortho-position when the para-position is occupied. The reaction also takes place with other substances, such as paraditolylamine.

On heating amidoazoparatoluene with paratoluidine hydrochloride dissolved in paratoluidine at 90—100°, a substance is produced resembling azophenine (Trans., 1883, 115). The *azophenine of paratoluidine*, $C_{42}H_{41}N_5$, crystallises in flat red needles, which melt at a high temperature, with decomposition. It dissolves in concentrated sulphuric acid, with reddish-violet coloration, and is insoluble in alcohol and ether. It is probably related to the substance obtained by Barsilowski (*Annalen*, **207**, 105) by the direct oxidation of paratoluidine. Dyes of the indulin series can be obtained from amidoazoparatoluene and the salts of primary bases. A. K. M.

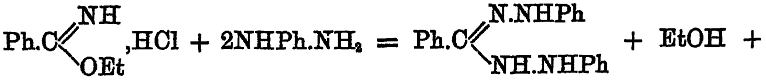
Indulines. By O. N. Witt (*Ber.*, **17**, 74—76).—In the ordinary method of producing the indulines, ammonia is produced, together with complicated secondary products, as previously shown by Witt and Thomas (Trans., 1883, 115). The author finds that this is not the case if phenylated amidoazobenzene be employed in the place of amidoazobenzene. On heating phenylamidoazobenzene (*Ber.*, **12**, 259) with aniline hydrochloride, no ammonia, and apparently no complicated secondary products are obtained, the reaction taking place more readily than when amidoazobenzene is used. The same applies to the higher homologues of phenylamidoazobenzene. The product of the action of diazoparatoluene on diphenylamine forms yellow plates, melting at 109—110°, and soluble in concentrated sulphuric acid with green coloration; the corresponding derivative of 1 : 2 : 4 metaxylidine forms scales of golden lustre, melting at 142—143°, and yielding a yellow solution with concentrated sulphuric acid. On substituting other secondary aromatic amines for diphenylamine, amidoazo-derivatives are obtained, which yield a whole series of new induline-like dye-stuffs with the salts of primary bases. A. K. M.

Indophenoles. By O. N. Witt (*Ber.*, **17**, 76).

Action of Phenylhydrazine on the Imido-ethers. Azidines. By A. Pinner (*Ber.*, **17**, 182—184).—*Benzenyldiphenylazidine*,

$$CPh(NH.NHPh) : N.NHPh,$$

is formed by the action of 2 mols. phenylhydrazine on 1 mol. benzimido-ether hydrochloride, both in alcoholic solution, the mixture being allowed to stand for 24 hours. It crystallises in tufts of deep red needles, having a golden-yellow metallic lustre, and melts at about 170°. It is sparingly soluble in cold alcohol, readily soluble in hot alcohol and in benzene, the solutions having an intense red colour. The formation of the substance is represented by the equation



$$Ph.C\genfrac{}{}{0pt}{}{/NH}{\backslash OEt},HCl + 2NHPh.NH_2 = Ph.C\genfrac{}{}{0pt}{}{/N.NHPh}{\backslash NH.NHPh} + EtOH +$$

NH_4Cl, although in all probability the reaction occurs in two stages.

A. J. G.

Preparation of Orthonitrobenzaldehyde. By A. EINHORN (*Ber.*, 17, 119—122).—This method depends on the oxidation of sodium ortho-nitrocinnamate by means of permanganate solution, and the removal of the resulting aldehyde at the moment of its formation from the oxidising liquid. It is carried out thus: 50 grams of crude orthonitrocinnamic acid are suspended in 2·5 litres water, neutralised with sodium carbonate solution, and filtered. The liquid is introduced into a large stoppered bottle, a litre of benzene added, and then little by little 1225 c.c. of a cold saturated solution of permanganate (6 per cent.), the mixture being vigorously agitated after each addition, and the whole kept cool by the introduction of ice. When the oxidation is finished, a warm solution of sodium sulphite (150 grams) is added, and then hydrochloric acid until the manganese dioxide is dissolved, when two layers are obtained, the lower of which is separated by means of a syphon. On distilling the benzene solution a liquid residue of orthonitrobenzaldehyde is obtained, crystallising on cooling. The yield by this method amounts to 50—53 per cent. of that required by theory, and in some experiments in which more dilute solutions were employed, and also more ice, the yield amounted to over 75 per cent., showing that the method is still capable of improvement.

A. K. M.

Lactones. By R. FITTIG (*Ber.*, 17, 201—203).—Phenylbutyrolactone unites with great readiness with hydrochloric, hydrobromic, or hydriodic acid when shaken with the aqueous acid saturated at 0°, yielding substitution-derivatives of phenylbutyric acid, identical with those obtained by similar treatment of isophenylcrotonic acid. They are reconverted into the lactone by the action of sodium carbonate.

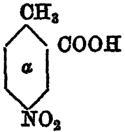
An alcoholic solution of phenylbutyrolactone, when saturated with gaseous ammonia and evaporated over sulphuric acid, yields large colourless monoclinic crystals of a compound having the formula $C_{10}H_{13}NO_2$; this melts at 85—86°, and at about 170° decomposes into lactone and ammonia. If crystallised from water, it can be obtained with 1 mol. H_2O. It dissolves in concentrated hydrochloric acid, but if excess of hydrochloric acid is added, a white crystalline precipitate of the hydrochloride is obtained; this redissolves on addition of a few drops of water, and after a few seconds the lactone precipitates. The hydrochloride dissolves completely in alcohol, but on spontaneous evaporation of the solution, is resolved into lactone and ammonium chloride. By gently heating the compound $C_{10}H_{13}NO_2$ with alkalis, ammonia is evolved. The very ready decomposibility of this compound renders it doubtful whether it should be regarded as an amido-acid, $CHPh(NH_2).CH_2.CH_2.COOH$, or as an acid amide,

$$CHPh(OH).CH_2.CH_2.CONH_2.$$

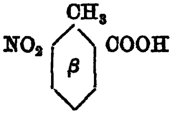
A. J. G.

Nitro-orthotoluic Acids. By O. Jacobsen (*Ber.*, **17**, 162—164).—The 1 : 2 : 4 nitro-orthoxylene described in the Abstract, p. 737, yields a mixture of two nitro-orthotoluic acids, by oxidation with dilute nitric acid; these can be separated by conversion into the barium salts, the crystals differing so widely in form that a mechanical separation is readily effected. Of these acids, the one melting at 179° is identical with the α-nitro-orthotoluic acid obtained by the nitration of orthotoluic acid; the other, γ-nitro-orthotoluic acid, melts at 152°, and is not identical with either of the acids obtained by the nitration of orthotoluic acid.

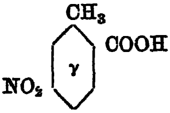
Of the four possible formulæ for orthonitrotoluic acids, the fourth



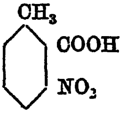
I.



II.



III.



IV.

cannot belong to any of the three known acids, as none of them yield the hydroxy-acid. The γ-acid alone yields a hydroxy-acid (metahomoparahydroxybenzoic acid) that can be split up by hydrochloric acid; it is therefore represented by formula III. The α-acid is obtained both by nitration of orthotoluic acid and by nitration of 1 : 2 : 4 nitro-orthoxylene; it therefore must have the constitution shown by the first formula. The hydroxy-acid obtained from it agrees in all properties with parahomometahydroxybenzoic acid. (The author's earlier statement (*Ber.*, **16**, 1958) on this subject is erroneous.) There remains for the β-acid the second formula.

The properties of the three orthonitrotoluic acids are compared in the following table:—

α-Nitro-orthotoluic acid, [Me : COOH : NO_2 = 1 : 2 : 4], obtained together with the β-acid by nitration of orthotoluic acid; together with the γ-acid by oxidation of nitrorthoxylene, melts at 179°.	β-Nitro-orthotoluic acid, [Me : COOH : NO_2 = 1 : 2 : 6], obtained, together with the α-acid, by nitration of orthotoluic acid, melts at 145°.	γ-Nitro-orthotoluic acid, [Me : COOH : NO_2 = 1 : 2 : 5], obtained, together with the α-acid, by oxidation of orthonitroxylene, melts at 152°, crystallises in long lustrous needles, and is readily soluble in hot water and alcohol.
The barium salt forms a soft opaque mass, composed of minute needles.		The barium salt, $(C_8H_6NO_4)_2Ba + 5H_2O$, crystallises in large transparent flat prisms.
α-Amido-orthotoluic acid melts at 196°, and on treatment with nitrous acid yields parahomometahydroxybenzoic acid melting at 172°.	β-Amido-orthotoluic acid melts at 191°.	γ-Amido-orthotoluic acid melts at 165°, crystallises in long flat needles, and on treatment with nitrous acid yields metahomoparahydroxybenzoic acid melting at 179°. This latter, on heating at 200° with hydrochloric acid, is resolved into carbonic anhydride and metacresol.

A. J. G.

Action of Chlor- and Brom-acetone, Acetophenone Bromide, and Phenylbromacetic Acid on Ethyl Acetoacetate. By A. Weltner (*Ber.*, **17**, 66—73).—Bromo- and chlor-acetone react readily with ethyl acetoacetate, but the author has not succeeded in obtaining any definite results; on saponifying the oily product ($CH_2\overline{Ac}.CH\overline{Ac}.COOEt$?) with cold dilute potash and acidulating, a brown oil is obtained, which becomes resinified on warming with dilute alkalis or by treatment with baryta-water. The preparation of ethylic acetophenone-acetoacetate from acetophenone bromide and ethyl acetoacetate has been described by Paal (this vol., 598). On reducing it with sodium-amalgam (the solution being kept neutral or slightly alkaline by the addition of acetic acid), a hydroxylactone,  $OH.CHMe.CH<\overset{CH_2-}{\underset{COO}{}}>CHPh$, is produced; it forms a thick yellow oil, insoluble in alkaline carbonates, soluble in alkalis and in baryta-water. When ethylic acetophenoneacetoacetate is boiled with dilute hydrochloric acid, much resinous matter is formed, together with a substance of the formula $C_{11}H_{12}O_2$; it is obtained as a brownish-yellow oil, insoluble in dilute alkali, and decomposed on distillation in a vacuum. It is doubtful whether it is the diketone,

$$C_6H_5.CO.CH_2.CH_2.CO.CH_3,$$

or the isomeric lactone. By the action of sodium-amalgam on an alcoholic solution, a deep brown-red colour is gradually produced, which disappears as the action continues, and on acidulating the colourless liquid, an acid ($C_{12}H_{10}O_3$ or $C_{12}H_{12}O_3$) is precipitated in white crystalline flakes; it crystallises from dilute alcohol in slender white lustrous needles melting at 179°. It is a well-characterised acid, dissolves readily in dilute alkalis, alkaline carbonates, and baryta-water; the sodium salt forms readily soluble lustrous needles, the silver salt a white insoluble precipitate. Boiled with acetic anhydride, it yields a compound insoluble in alkalis, sparingly soluble in alcohol, and crystallising from it in lustrous needles melting at 139°. Ethyl phenylacetosuccinate obtained from ethyl phenylbromacetate and ethyl acetoacetate has been prepared by Rügheimer (Abstr., 1881, 600). It forms colourless lustrous scales melting at 75—76°, the free acid forming clusters of large plates melting at 120—121°; the sodium salt crystallises in needles readily soluble in water. The monethyl-derivative, $COOH.CH\overline{Ac}.CHPh.COOEt$, forms slender needles melting at 132·5°. The ketonic acid, $CH_2\overline{Ac}.CHPh.COOH$, is produced on boiling the mon- or di-ethyl-derivative with dilute hydrochloric acid or baryta-water; it is readily soluble in alcohol and ether, and crystallises in clusters of plates melting at 126°; with nitric acid, it yields solid oxidation-products soluble in alkalis; a diketone has not yet been obtained from it. The zinc salt of the ketonic acid crystallises from hot water in long white needles; the silver salt forms a white flocculent precipitate; the copper salt, which is green, is insoluble in water, soluble in alcohol; the calcium and barium salts are readily soluble and do not crystallise. The lactone,  $\begin{matrix} CHPh.CO- \\ | \\ CH_2.CHMe \end{matrix}\!\!>O$, is produced by the action of sodium-amalgam on the ketonic acid, and forms an oil non-volatile (or nearly so) in steam. The calcium salt, $(C_{11}H_{13}O_3)_2Ca,H_2O$, of the corresponding hydroxy-acid is readily soluble; the silver salt forms a white precipitate.

A. K. M.

Derivatives of Orthonitrocinnamic Acid. By J. M. MORGAN (*Ber.*, **17**, 219—223).—Sodium orthonitrocinnamate (2 mols.) and sodium carbonate (1 mol.) are dissolved in water, and a stream of air saturated with bromine passed through the liquid. Orthonitrophenylbromolactic acid is the main product, but there is also formed an acid of the formula $C_9H_9NO_6$, crystallising in colourless transparent rectangular prisms, melting at 94°, and soluble in alcohol and ether. On dissolving it in hot anhydrous chloroform, water separates, and orthonitrophenyloxyacrylic acid is deposited on cooling.

On adding the acid $C_9H_9NO_6$ to fuming hydrobromic acid, there are formed orthonitrophenylbromolactic acid, indigotine, and a substance which crystallises from hot glacial acetic acid in silky needles, is sparingly soluble in ether, alcohol, and water. The addition of the least excess of alkali to its solution causes the formation of a deep indigo-blue precipitate, whose colour is destroyed by acids. On diluting the filtrate, a yellow precipitate is obtained; it can be crystallised from acetone or acetic ether, and then forms brilliant scarlet rectangular prisms of the formula $C_8H_6NO_2Br$ or $C_{16}H_{10}N_2O_4Br_2$, melts at 255°, and can be sublimed in long red needles on careful heating. It is sparingly soluble in chloroform, ether, and carbon bisulphide, more readily in alcohol.

A. J. G.

Tetramethylbenzidine. By W. MICHLER and H. PATTINSON (*Ber.*, **17**, 115—119).—By the action of concentrated sulphuric acid on dimethylaniline, Michler and Salathé (*Ber.*, **12**, 1171) obtained a base which was assumed to be either a tetramethyldiamidodiphenylmethane or tetramethylbenzidine, $Me_2N.C_6H_4.C_6H_4.NMe_2$. The following experiments show that the latter view is the correct one:—A substance having the same properties is obtained by oxidising dimethylaniline dissolved in sulphuric acid, by means of lead dioxide; the reaction probably takes place thus: $2C_6H_5NMe_2 + PbO_2 = NMe_2C_6H_4.C_6H_4.NMe_2 + PbO + H_2O$. When benzidine dissolved in benzene, or better in methyl alcohol, is heated with methyl iodide in sealed tubes for some hours at 120°, the compound $Me_2N.C_6H_4.C_6H_4.NMe_3I$ is obtained. It melts at 263°, crystallises in needles, and is sparingly soluble in water and alcohol. On distilling it, tetramethylbenzidine is obtained, agreeing in melting point (195°) and all other properties with the above base and with that previously obtained by Michler and Salathé. The compound $Me_2N.C_6H_4.C_6H_4.NMe_3Cl$ is prepared by boiling the corresponding iodine-derivative in aqueous solution with freshly-precipitated silver chloride; it is readily soluble in water and alcohol, and crystallises from the former in yellowish crystals melting at 228°; the platinochloride has the formula

$$Me_2N.C_6H_4.C_6H_4NMe_3Cl,HCl,PtCl_4.$$

Dinitrotetramethylbenzidine, $C_{16}H_{18}N_2(NO_2)_2$, is obtained as a yellowish-red precipitate on adding sodium nitrite to a solution of tetramethylbenzidine in dilute hydrochloric acid. It crystallises from alcohol in needles melting at 188°. On reduction, it yields *diamidotetramethylbenzidine*, $C_{16}H_{18}N_2(NH_2)_2$. This crystallises from alcohol in scales of silvery lustre, melts at 168°, and is readily soluble in hot, sparingly in cold alcohol, and insoluble in water. With ferric chloride and hydrochloric acid, it yields a violet coloration, which remains unaltered on dilution with water; and with potassium dichromate and sulphuric acid a brownish-red coloration, which becomes red on dilution; whilst permanganate and hydrochloric acid produce at first no change, the solution assuming a red coloration on standing.

A. K. M.

New Method for producing Acridine. By O. Fischer and G. Korner (*Ber.*, **17**, 101—102).—This consists in heating a mixture of chloroform (1 part), diphenylamine (1 part), zinc chloride (1 part), and zinc oxide (½ part) for 7—8 hours at 200—210°. The product is boiled with concentrated hydrochloric acid, the filtrate poured into water, and the acridine precipitated by alkali. The reaction, $NHPh_2 + CHCl_3 + ZnO = C_{13}H_9N,HCl + ZnCl_2 + H_2O$, is analogous to the formation of acridine from diphenylamine and formic acid (Abstr., 1883, 1133), but the yield is considerably better. The base obtained by the authors melted at 110—111°. Aluminium chloride may be substituted for the zinc chloride with advantage. A. K. M.

Acridine. By L. Medicus (*Ber.*, **17**, 196—197).—Acridine nitrite, $(C_{26}H_{18}N_2,NO_2H,H_2O)2H_2O$, obtained by mixing solutions of potassium nitrite with an acridine salt, as a yellow flocculent precipitate, crystallises from hot water in long silky yellow needles, melts at 150—151°, is sparingly soluble in cold water and in ether, more readily soluble in hot water, soluble in alcohol. The solutions show the fluorescence of acridine salts. A. J. G.

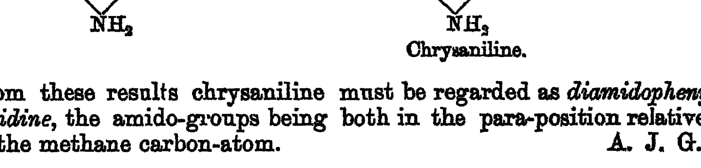
Chrysaniline. By C. Fischer and G. Körner (*Ber.*, **17**, 203—209).—Very little more is known of this substance than was published by Hofman in 1862 and 1869 (*Compt. rend.*, **55**, 817; *Ber.*, **2**, 379). From its close resemblance to flavaniline, which has been recently shown by Fischer, Rudolph, and Besthorn (Abstr., 1882, 1066; 1883, 600) to be a quinoline derivative, it appeared highly probable that chrysaniline would have a somewhat similar constitution: this view is now shown to be correct, as the authors' results prove chrysaniline to be the diamido-derivative of phenylacridine.

Chrysophenol, $C_{19}H_{15}N_2O$.—This substance was discovered and partly investigated by W. Claus, and further examined by the authors. By heating chrysaniline with 3—4 times its amount of concentrated hydrochloric acid at 180°, an amido-group is eliminated and replaced by hydroxyl, $C_9H_{15}N_3HCl + H_2O = C_9H_{15}N_2O + NH_4Cl$. Chrysophenol is separated from any unaltered chrysaniline by treatment with dilute soda in which it dissolves to a clear yellow solution, and is separated on neutralisation of the liquid as a yellowish-red precipitate. It crystallises from dilute alcohol in small red needles containing 1 mol. H_2O. It is sparingly soluble in water, benzene, and ether, very readily in alcohol. It is readily soluble in caustic alkalis, but insoluble in alkaline carbonates. It still possesses strong dyeing powers and, like chrysaniline, forms sparingly soluble salts with acids. On oxidation, it yields a crystalline acid, and this when distilled with lime gives an intense odour of pyridine bases.

Phenylacridine from Chrysaniline.—10 grams chrysaniline is dissolved in a mixture of 50 grams sulphuric acid and 4—5 grams water, and the well-cooled solution treated with a stream of nitrous anhydride until distinct excess of the latter is apparent. The resulting diazo-compound is then added in small portions to 600 grams of boiling alcohol, when an intensely yellowish-green fluorescing liquid is obtained. The greater part of the alcohol is distilled off, water added, followed by excess of caustic soda, when reddish-coloured flocks separate, and without further purification are mixed with excess of soda, heated on an oil-bath at 200°, and distilled by aid of a current of steam, whilst the temperature of the bath is slowly raised to 250°. Phenylacridine distils over, and, after purification, shows all the properties described by Bernthsen and Bender (Abstr., 1883, 1133). The formation of phenylacridine from chrysaniline shows clearly that the formula of this latter must be $C_{19}H_{15}N_3$, and not $C_{20}H_{17}N_3$, that previously adopted.

With regard to the formation of chrysaniline in the rosaniline process, three views are possible. 1. That chrysaniline is a condensation-product from 2 mols. of aniline and 1 mol. of paramido-benzaldehyde obtained by oxidation of paratoluidine. 2. That it is a condensation-product from orthotoluidine and aniline. 3. That amidophenylamine is formed, and reacts with amidobenzoic acid to form chrysaniline in a manner similar to that in which diphenylamine and benzoic acid yield phenylacridine.

Of these views the second is the most probable, as it is found that by heating orthodiparatriamidotriphenylmethane prepared from orthonitrobenzaldehyde and aniline (Renouf, Abstr., 1883, 981) with arsenic acid at 180—200°, chrysaniline is formed:—



Chrysaniline.

From these results chrysaniline must be regarded as *diamidophenylacridine*, the amido-groups being both in the para-position relatively to the methane carbon-atom. A. J. G.

Violet Derivatives of Triphenylmethane. By O. Fischer and G. Körner (*Ber.*, 17, 98—101).—The authors describe a new synthesis of hexamethylparaleucaniline which lends support to their views on the violet derivatives of rosaniline, and also indicates a method for the preparation of a whole series of methyl- and ethyl-derivatives of leucaniline. It consists in heating ethyl orthoformate (1 part) with dimethylaniline (3—4 parts) and zinc chloride (2 parts) for some hours on a water-bath, the zinc chloride being added gradually: $CH(OEt)_3 + 3NPhMe_2 = CH(C_6H_4.NMe_2)_3 + 3EtOH$.

The paper also contains a reply to Wichelhaus (*Ber.*, **16**, 3044).

A. K. M.

Kynuric Acid. By M. Kretschy (*Monatsh. Chem.*, **5**, 16—32).—The author now finds that the above acid (Abstr., 1883, 674) is identical with carbostyrilic acid, and not isomeric therewith as he formerly believed. The discrepancies previously observed in the behaviour of the two acids were due to inaccuracies in the published description of the properties of carbostyrilic acid. The kynuric acid used in the present research was prepared by the oxidation of kynurenic acid with an alkaline solution of potassium permanganate. The quantity of oxygen used in the oxidation was estimated and was always found to be about 6 atoms for every molecule of kynurenic acid oxidised. Small quantities of oxalic acid were usually formed, but scarcely any other bye-products. The most favourable results were obtained under the following conditions:—20 grams of kynurenic acid and 10 grams crystallised potassium hydroxide ($KOH + 2H_2O$) were dissolved in 3 litres of water, and 64 grams potassium permanganate in about one-fifth normal solution (*i.e.*, 3·5 grams $K_2Mn_2O_8$ in 100 c.c.) added. The whole was kept at 60—70° for four days, and the acid was then precipitated with hydrochloric or nitric acid. Unchanged kynurenic acid was removed by treating the mixed acids with boiling ether, in which kynurenic acid is almost insoluble, kynuric acid being easily soluble. About 70 per cent. of the theoretical quantity of kynuric acid was thus obtained. The acid must be crystallised from lukewarm water only, as hot water causes partial decomposition.

Kynuric acid crystallises in slender needles soluble in ether and alcohol, sparingly so in cold water (1 : 890 at 10°). The acid is dibasic, and forms acid and neutral salts. Its amido character is not very marked, but it forms double salts with platinum chloride, with iron chloride, and with silver and mercurous nitrates. It yields aniline when heated with a mixture of potassium hydroxide and carbonate. *Ammonium kynurate*, $C_9H_5NO_5(NH_4)_2$, crystallises in slender needles. *Hydrogen potassium kynurate* crystallises with $\frac{1}{2}H_2O$, and is sparingly soluble in water. *Hydrogen barium kynurate*, $(C_9H_6NO_5)_2Ba + H_2O$, is precipitated from a solution of the acid potassium salt by barium chloride, and crystallises in needles. *Barium kynurate*, $C_9H_5NO_5Ba + H_2O$, obtained from the neutral ammonium salt, forms microscopic needles, and gives up its water of crystallisation at 100°. *Calcium kynurate*, $C_9H_5NO_5Ca + 2\frac{1}{2}H_2O$, is precipitated in the form of microscopic needles which do not give up their water of crystallisation at 100°. A basic *copper* salt, $2(C_9H_5NO_5Cu),CuO + 4H_2O$, is precipitated from solutions of the neutral ammonium salt by copper acetate as a blue crystalline powder, which loses $2H_2O$ at 100°.

When heated for some time at 189—191°, kynuric acid decomposes, giving off carbonic anhydride and water, and leaving a bitter residue, sparingly soluble in benzene, ether, alcohol, and water. Alkalis dissolve it readily, and hydrochloric acid reprecipitates it from these solutions in a flocculent form. This residue seems to be a mixture of various bodies, and was not further examined. Kynuric acid cannot be crystallised from boiling water, as partial decomposition takes place. If its aqueous solution be maintained for some time at about 100°, or hydrochloric acid be added, and the solution be evaporated, the decomposition is complete, *orthamidobenzoic* and *oxalic* acids being produced. Friedländer and Ostermaier have already noticed this decomposition of carbostyrilic acid by hydrochloric acid. The formula of kynuric acid is therefore

$$C_6H_4(COOH)(NH.CO.COOH)[COOH : NH.CO.COOH = 1 : 2],$$

and the decomposition takes place according at the equation:—

$$C_6H_4(COOH)(NH.CO.COOH) + H_2O = C_6H_4(NH_2).COOH + (COOH)_2.$$

The author has succeeded in synthesising kynuric acid by heating together an intimate mixture of dry orthamidobenzoic and oxalic acids in an oil-bath at 115—135°, and finally at 145—150°. The acid thus obtained is identical with kynuric acid.

The formation of oxalyl-orthamidobenzoic acid by the oxidation of carbostyril, acetotetrahydroquinoline, kynurenic acid, and kynurin, and that of acetoanthranilic acid from quinaldine, shows the tendency of quinoline-derivatives to form anilido-compounds when the pyridine-ring is oxidised. The author intends to investigate the causes of potassium permanganate attacking the pyridine-ring in kynurenic acid and kynurin, and not the benzene-ring. From the results obtained by the oxidation, it is clear that the carboxyl and hydroxyl radicles in kynurenic acid are present in the pyridine-ring.

L. T. T.

Derivatives of Naphthalene. By E. LELLMANN (*Ber.*, **17**, 109—114).—By the action of nitric acid on α-acetonaphthalide, the author obtained a nitro-product melting at 171° in accordance with the results obtained by Liebermann (*Annalen*, **183**, 229) and by Andreoni and Biedermann (*Ber.*, **6**, 342), and by the action of potassium hydroxide on this, α-nitronaphthylamine was produced. By the action of benzoic chloride on α-nitronaphthylamino melting at 190°, the α-nitrobenzonaphthalide, melting at 224° (Hübner and Ebell, *Annalen*, **208**, 324) is obtained, yielding naphthylenediamine (m. p. 186°), on reduction. On reconverting α-nitronaphthylamine into the acetyl-derivative by means of acetic anhydride, *α-nitroacetonaphthalide* is obtained melting at 187°, and crystallising in long yellow needles; also a small quantity of a second substance (*δ-nitroacetonaphthalide*) melting at 142°. The mother-liquors from the preparation of α-nitronaphthylamine gradually deposit crystals containing β- and γ-nitronaphthylamines which can be separated by crystallisation from alcohol. The β-compound forms small yellow needles, melting at 198°, and yields a benzoyl-derivative, melting at 175°, identical with Hübner and Ebell's benzoylorthonitronaphthalide obtained by nitrating benzoylnaphthalide. By the action of acetic anhydride on β-nitronaphthylamine, *β-nitracetonaphthalide* is obtained, melting at 115°. *γ-Nitronaphthylamine* melts at 144° and crystallises from alcohol in splendid prisms of the colour of potassium dichromate and of greenish lustre. It yields an *acetyl-derivative*, melting at 194°, and by the action of alkali on this, *γ-nitronaphthol* is produced, melting at 116°. The author has examined Liebermann's γ-nitroacetonaphthalide, melting at 190°, and finds it to be identical with α-nitracetonaphthalide, melting at 187°. It is not yet understood whether the four isomeric nitro-derivatives of α-acetonaphthalide are formed during the nitration and exist together in the product melting at 171°, or whether a molecular change occurs in the splitting off or introduction of the acetyl-group; a product melting at 171° could not be obtained from a solution containing α- and β-nitracetonaphthalide. Nothing is known of the constitution of the γ- and δ-derivatives; the α-compound is without doubt

$$C_{10}H_6(NH_2)(NO_2),[NH_2 : NO_2 = 1 : 2],$$

whilst the constitution of the β-derivative cannot yet be decided owing to the apparently contradictory nature of the necessary data. By the further nitration of β-nitroacetonaphthalide a dinitro-derivative, melting at 247°, is produced identical with the compound obtained by Liebermann by the direct nitration of acetonaphthalide, and the constitution of which is

$$C_{10}H_5(NH\overline{Ac})(NO_2)_2[NH\overline{Ac} : NO_2 : NO_2 = 1 : 2 : 4].$$

α-Nitroacetonaphthalide appears to yield a different dinitro-derivative.

A. K. M.

Derivatives of β-Dinaphthylamine. By C. RIS and A. WEBER (*Ber.*, **17**, 197—198).—β-Dinaphthylamine is now obtainable in considerable quantities as it is a bye-product in the manufacture of β-naphthylamine. *Dinitro-β-dinaphthylamine* is obtained by adding the base to a well-cooled mixture of fuming nitric acid and glacial acetic acid. It crystallises from cumene in yellowish-red needles or fine prisms, and melts at 224—225°. *Tetranitro-β-dinaphthylamine* is obtained together with the above, and is formed exclusively if the temperature rises during the reaction. It is very sparingly soluble in benzene or cumene, readily soluble in boiling nitrobenzene, from which it separates on cooling in yellow crystalline granules of melting point 285—286°.

A. J. G.

Derivatives of Hydrindonaphthene. By A. BAEYER and W. H. PERKIN, Jun. (*Ber.*, **17**, 122—125).—On treating orthoxylylene bromide with ethyl sodomalonate according to Perkin's method (*Ber.*, **16**, 208, 1787, 2136), the ethyl dicarboxylate of a hydrocarbon,

$$C_6H_4{<}{\begin{matrix}CH_2\\CH_2\end{matrix}}{>}CH_2,$$

is produced, which the authors name *hydrindonaphthene*, indonaphthene being  $C_6H_4{<}{\begin{matrix}CH\\CH_2\end{matrix}}{>}CH$, and bearing the same relation to indol that naphthalene does to quinoline: $C_6H_4<\begin{matrix}CH_2Br\\CH_2Br\end{matrix}$ + $Na_2C(COOEt)_2$ = $C_6H_4<\begin{matrix}CH_2\\CH_2\end{matrix}>C(COOEt)_2$ + 2NaBr. The *orthoxylylene bromide* obtained by the authors must be isomeric with the compound described by Radziszewski and Wispeck (Abstr., 1882, 1284), since it melts at 93° and dissolves in 5 parts of ether. *Hydrindonaphthenedicarboxylic acid*, $C_6H_4<\begin{matrix}CH_2\\CH_2\end{matrix}>C(COOH)_2$, is best prepared as follows:—Sodium (2 atoms) is dissolved in 8 times its weight of alcohol, and the semi-solid mass obtained mixed with 3 times its weight of ether; a solution of the bromide (1 mol.) in 5 parts ether is next added, and then a solution of ethyl malonate (1 mol.) in the same quantity of ether. After standing three hours, the ether is decanted from the precipitate, and this, together with the residue from the evaporation of the ether, boiled with alcoholic potash until the addition of water no longer produces turbidity; the alcohol is evaporated, the residue dissolved in water, the solution filtered, acidulated with dilute sulphuric acid, and extracted with ether. Hydrindonaphthenedicarboxylic acid is moderately soluble in hot water from which it crystallises in rhombic plates melting at 199°, and then decomposing into carbonic anhydride and *hydrindonaphthenemonocarboxylic acid*,  $C_6H_4<\begin{matrix}CH_2\\CH_2\end{matrix}>CH.COOH$. This melts at 130°, distils without decomposition, dissolves in 120 parts of boiling water, and very sparingly in cold water. A. K. M.

Synthesis of Dimethylanthracene Hydride and Diphenylethane from Benzene and Ethylidene Chloride. By A. ANGEBLIS and R. ANSCHÜTZ (*Ber.*, 17, 165—167).—By the action of benzene on ethylidene chloride or bromide in presence of aluminium chloride, there are formed unsymmetrical diphenylethane and dimethylanthracene hydride. Diphenylethane boils at 150° under 16 mm. pressure, is quite colourless, and has a blue fluorescence, its other properties are well known. Benzophenone boils at 170° under 15 mm. pressure.

Dimethylanthracene hydride (diphenylene-diethylidine), $C_{16}H_{16}$ = $C_6H_4<\begin{matrix}CHMe\\CHMe\end{matrix}>C_6H_4$, crystallises from solvents in pale yellow transparent plates, melts at 178—179°, and sublimes readily in transparent clear yellow broad needles. It is readily soluble in ether, benzene, carbon bisulphide, boiling glacial acetic acid and hot alcohol. On oxidation with chromic acid, it yields anthraquinone and carbonic anhydride approximately in the ratio of 1 mol. of the former to 2 mols. of the latter. On distillation over nearly red hot zinc-dust the hydrocarbon readily yields anthracene. The picric acid compound, $C_{16}H_{16},C_6H_2(NO_2)_3.OH$, crystallises in dark reddish-blue needles, and melts at 170°. A. J. G.

Action of Aluminium Chloride on a Mixture of Benzene and Vinyl Bromide and of Benzene and Vinyl Tribromide. By A. ANGEBLIS and R. ANSCHÜTZ (*Ber.*, 17, 167—168).—By passing a regular stream of vinyl bromide vapour into a mixture of benzene and aluminium chloride gently heated on the water-bath, there is obtained a mixture of ethylbenzene, diphenylethane, and dimethylanthracene hydride. The formation of ethylbenzene instead of cinnamene is an instance of the nearly general rule that in this reaction instead of an unsaturated, the corresponding saturated aromatic hydrocarbon is formed. With regard to the formation of the other two hydrocarbons, which are the same as those described in the preceding abstract as obtained by the action of benzene on ethylidine chloride, &c., it appears to the authors to be most probable that during the reaction an addition of HBr to vinyl bromide takes place with consequent formation of ethylidine bromide, which then reacts as already described.

By the reaction of benzene on vinyl tribromide in presence of aluminium chloride, dibenzyl was obtained in moderate quantity.

A. J. G.

Remarks on the Preceding Communications on Synthesis by Means of Aluminium Chloride. By R. Anschütz (*Ber.*, **17**, 169—170).—In the syntheses of hydrocarbons from benzene and the halogen-derivatives of fatty hydrocarbons by aid of aluminium chloride, four kinds of condensation-products may be distinguished:—1. Those in which phenyl replaces the halogen in one molecule of the halogen-derivative of the fatty hydrocarbon. 2. Those in which more than one hydrogen-atom of one and the same benzene molecule is replaced by alkyl-groups. 3. Those in which two phenylene-groups are united to two carbon-atoms, which are also united to one another. 4. Those in which two phenylene-groups are united to two carbon-atoms not in union with one another. A. J. G.

Paramidofluorene. By J. Strasburger (*Ber.*, **17**, 107—108).—In a previous paper (this vol., 329) the author mentioned the formation of paramidofluorene by the distillation of the hydrochloride of paramidodiphenic acid with lime. He now confirms this by comparing the substance so obtained with paramidofluorene prepared from fluorene. He prepares *paranitrofluorene*,  $\begin{matrix} C_6H_3(NO_2) \\ | \\ C_6H_4 \end{matrix} > CH_2$, by adding nitric acid (sp. gr. 1·4) to a cold saturated solution of fluorene in glacial acetic acid, and then heating to the boiling point. It melts at 154°, and on oxidation yields nitrodiphenylene ketone melting at 217—218°. On reduction, it yields paramidofluorene crystallising from dilute alcohol in grey or brown crystals melting at 124—125°; the somewhat lower melting point (123°) previously given is explained by the imperfect purification of the small quantity of the substance obtained from the amidodiphenic acid. Paramidofluorene from both sources yields an *acetyl-derivative* melting at 187—188°.

A. K. M.

Borneol from Camphor. By J. Kachler and F. V. Spitzer (*Monatsh. Chem.*, **5**, 50—54).—Jackson and Menke (*Amer. Chem. J.*, 1883, 270) state that if camphor (10 grams) be dissolved in ten times its weight of alcohol and one-third more (4 grams) than the theoretical quantity of sodium be gradually added, the camphor is converted into borneol, 9·4 grams of the latter, or 94 per cent., being obtained. The authors have repeated these experiments, but can *not* confirm the results. Mixtures of camphor and borneol were obtained, the unchanged camphor always largely predominating.

As the separation of borneol from camphor is impracticable, this reaction does not form a means of preparing borneol. The product, analysed by treatment with phosphoric chloride (when borneol yields $C_{10}H_{17}Cl$, and camphor $C_{10}H_{16}Cl_2$) was proved to contain 22·8 per cent. borneol, and 77·2 per cent. camphor. L. T. T.

Isomeric Campholurethanes. By HALLER (*Compt. rend.*, **98**, 578—580).—The author has previously described (*ibid.*, **92**, 1511, and **94**, 86 and 869) a dextrogyrate campholurethane obtained from dextrogyrate borneol, and crystallising in dextrohemihedral crystals. By the same method, he has prepared a campholurethane from lævogyrate Ngaï borneol from Shanghai. This borneol has the same melting point, 198°, as dextroborneol, and its rotatory power $[\alpha]_D = -32° 30'$. The lævocampholurethane thus obtained melts at 126—127°, and its alcoholic solution has a lævorotatory power $[\alpha]_D = -29·9$. It is deposited from its aqueous solution in lævohemihedral crystals, the dominant form being a rhomboidal prism of 82° 32′, modified on the angles *o* and *e*, and on the face *g*. The angles of these crystals correspond exactly with those of the right-handed form, but the crystals of dextrocampholurethane never have the face *e* on angles to the left, and the crystals of lævocampholurethane never have this face on angles to the right, and on most of the crystals the inverse law holds good for the face *g′*.

Dextroborneol yields a campholurethane which forms dextrohemihedral crystals, and is dextrogyrate, whilst lævoborneol yields a campholurethane which forms lævohemihedral crystals, and is lævogyrate. This dissymmetry is strictly analogous to that observed by Pasteur in the case of the sodium ammonium tartrates.

In the preparation of lævocampholurethane, a lævogyrate borneol carbonate is also obtained, and this compound is formed in much higher proportion than is dextrogyrate borneol carbonate from dextroborneol, in fact, the Ngaï borneol is often almost entirely converted into the carbonate. It would seem, therefore, that the isomerism of this borneol with ordinary borneol is not purely physical, and this supposition is supported by the fact that in the preparation of lævocampholurethane a substance slightly soluble in alcohol and ether is formed, which is not formed in the preparation of the dextrocompound. Moreover, dextrocampholurethane melts at 115°, whilst the isomeric lævocampholurethane melts at 126—127°. The two borneol carbonates have, however, the same melting point, 215°.

C. H. B.

Oxidation of Menthol by Potassium Permanganate. By G. ARTH (*Compt. rend.*, **98**, 576—577).—8 grams of potassium permanganate, 500 c.c. of water, and 5 c.c. of dilute sulphuric acid (1 : 4) are placed in a stoppered flask, 4 grams of finely powdered menthol added, the mixture agitated and allowed to stand in a warm place.

After 24 hours a further quantity of 2 grams of menthol is added, and the addition is repeated at the end of 48 hours. When the permanganate has been decolorised, the liquid is neutralised with sodium carbonate and concentrated by evaporation. The sodium salt is then decomposed by dilute sulphuric acid, and the liquid agitated with ether, which on evaporation leaves a brown syrupy liquid, which does not distil at a fixed temperature, has a somewhat powerful odour slightly resembling that of valeric acid, and is only slightly soluble in water, to which it imparts a strongly acid reaction. This brown liquid seems to be a mixture of two distinct acids. It dissolves with effervescence in sodium carbonate solution, and if the excess of carbonate is removed by means of alcohol, and silver nitrate is added, two distinct precipitates are obtained. One of these dissolves in boiling water, and on cooling the solution deposits nacreous lamellæ of the composition $C_{10}H_{17}AgO_3$; they are the silver salt of an acid $C_{10}H_{18}O_3$, which is liquid at ordinary temperatures. The other precipitate is not soluble in boiling water, but is gradually decomposed by prolonged ebullition. It is probably the silver salt of a more highly oxidised acid intermediate between the acid, $C_{10}H_{15}O_3$, and carbonic and oxalic acids. C. H. B.

Contributions to the Constitution of Brazilin. By M. WIEDEMANN (*Ber.*, **17**, 194—195).—By heating brazilin with amorphous phosphorus and hydriodic acid of sp. gr. 1·5 for some hours in a vessel provided with a reflux condenser, it yields *brazinole*, $C_{16}H_{14}O_4$, as a dark-brown amorphous powder, readily soluble in alcohol and alkalis, insoluble in benzene and chloroform, sparingly soluble in ether, water, and dilute acids. By heating brazilin or brazinole in sealed tubes with phosphorus and hydriodic acid of sp. gr. 1·9 at 150° for 8—12 hours, a substance of the formula $C_{16}H_{28}O_3$ or $C_{16}H_{24}O_3$ is obtained as a red-brown amorphous powder, resembling brazinole in its solubilities.

On distilling brazinole with zinc-dust in a stream of carbonic anhydride, nearly complete decomposition ensues, very minute quantities only of a crystalline substance, apparently a hydrocarbon of the formula $C_{16}H_{14}$ or $C_{16}H_{16}$, being obtained.

By fusing brazilin with potash, Liebermann and Burg (*Ber.*, 9, 1883) obtained resorcinol; in the products of the fusion at 240—250°, the author found formic and acetic acids, at higher temperatures (310—330°) formic acid and resorcinol. A. J. G.

Quinoline and Quinaldine. (*Dingl. polyt. J.*, **250**, 533—542.)—When an aqueous solution of orthamidobenzaldehyde is treated with a small quantity of acetaldehyde and a solution of caustic soda, quinoline is produced. Friedländer and Gohring have found that this reaction is not limited to acetaldehyde, but that a large number of aldehydes and ketones give quinoline when treated with orthamidobenzaldehyde in a similar manner. Aqueous solutions of orthamidobenzaldehyde and pure acetone when treated in the cold with soda-ley combine together, producing *α-methylquinoline* or *quinaldine*, a colourless oil of pleasant odour boiling at 240°.

According to the "Chemische Fabrik," formerly E. Schering of

Berlin, quinaldines are obtained on warming acetaldehyde with the salts of primary aromatic amines. The resulting bases can be converted into hydro- or hydroxy-derivatives, which may be used in dyeing or as antiseptic and antipyretic agents.

The simplest substitute of these bases, *i.e.*, quinaldine obtained from aniline and aldehyde is formed, according to the equation—

$$C_6H_7N + 2C_2H_4O = C_{10}H_9N + 2H_2O + H_2.$$

For the preparation of quinaldines, a mixture of 100 parts aniline (115 toluidine or 130 xylidine) 150 paraldehyde, 200 fuming hydrochloric acid, and 2—5 aluminium chloride, is boiled for 4 to 6 hours. The product is then poured into water, and the filtered solution saturated with soda-ley. The base produced is distilled with steam and purified by fractionation.

Aldehyde, acetal, crotonaldehyde, aldol, or lactic acid, may be employed in the place of paraldehyde, and hydrobromic, sulphuric, phosphoric, or other acids in the place of hydrochloric acid.

Quinaldine, $C_{10}H_9N$ (from aniline), is a liquid resembling quinoline in smell. It boils at 240°. *Orthomethylquinaldine*, $MeC_{10}H_8N$, is liquid, and boils at 249—251°. *Paramethylquinaldine* is isomeric with the former, but is solid, forming colourless crystals which melt at 59—60°.

When a mixture of aniline and ethyl acetoacetate is heated nearly to the boiling point, alcohol escapes. On interrupting the reaction when the mass becomes dark yellow, treating the product with concentrated sulphuric acid, diluting with water and adding alkali, *hydroxymethylquinoline*, $C_{10}H_9ON$, is precipitated (m. p. 222°). D. B.

Paradibromoquinoline. By S. Metzger (*Ber.*, **17**, 186—191).—*Paradibromoquinoline* is prepared by heating paradibromaniline with nitrobenzene, glycerol, and sulphuric acid. It crystallises in long white needles, can be distilled with steam, melts at 127—128°. It is nearly insoluble in water, readily soluble in acids, ether, alcohol, benzene, light petroleum, &c. The *hydrochloride*, $C_9H_5Br_2N,HCl$, crystallises in small broad needles; it is decomposed into free base and hydrochloric acid by cold water. The *picrate* crystallises in long yellow needles, and is also decomposed by water. The *chromate*, $(C_9H_5Br_2N)_2,H_2Cr_2O_7$, forms a microcrystalline orange-red powder. The *platinochloride*, $(C_9H_5Br_2N)_2,H_2PtCl_6$, crystallises in minute yellow needles, and is readily decomposed by water. A comparison of the α-dibromoquinoline obtained by La Coste (Abstr., 1881, 741) by direct bromination of quinoline, showed its identity with parabromoquinoline. A. J. G.

Paraquinolinesulphonic Acids. By J. Happ (*Ber.*, **17**, 191—193).—Ortho- and meta-quinolinesulphonic acids have been obtained by the action of sulphuric acid on quinoline (Lubavin, *Annalen*, **155**, 313; Bedall and A. Fischer, Abstr., 1882, 869).

Paraquinolinesulphonic acid, 
, is obtained by heating

a mixture of sulphanilic acid, nitrobenzene, glycerol, and sulphuric acid. It crystallises in strongly refractive, hard, brilliant, colourless needles of the formula $C_9H_6N.SO_3H + 1\frac{1}{2}H_2O$, is sparingly soluble in cold water or cold alcohol, more readily soluble in hot water or alcohol. It does not melt at 260°. The barium salt, $(C_9H_6SO_3N)_2Ba$, forms crystalline scales; the potassium salt, $C_9H_6NSO_3K$, crystallises in brilliant plates; the sodium salt, $C_9H_6NSO_3Na$, crystallises in lance-shaped needles; the silver salt, $C_9H_6NSO_3Ag$, forms slender white needles; an acid silver salt, $2C_9H_6NSO_3Ag + C_9H_7NSO_3$, also crystallises in needles. On fusing the sulphonic acid with potash, a hydroxyquinoline of melting point 193° is obtained, apparently identical with Skraup's parahydroxyquinoline. A. J. G.

Relation between Benzene and Pyridine. By C. Böttinger (*Ber.*, 17, 144).

Pyridine-derivatives. By C. Böttinger (*Ber.*, 17, 92—95).—This paper contains the analytical data omitted in previous communications (Abstr., 1881, 181 and 612). Picolinecarboxylic acid crystallises with 1 mol. H_2O, which it gradually loses in dry air, rapidly when heated at 100°. It forms a very readily soluble barium salt, $(C_7H_6NO_2)_2Ba,11H_2O$, crystallising in broad lustrous needles, which effloresce on exposure to the air. The calcium salt, $(C_7H_6NO_2)_2Ca,H_2O$, is readily soluble in water, and crystallises in colourless transparent four-sided prisms, which do not lose their water at 120°. The sulphate and oxalate of picolinecarboxylic acid are readily soluble in water; the platinochloride crystallises in scales, readily soluble in water and alcohol.

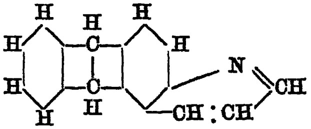
Pyridinedicarboxylic acid crystallises with 1 mol. H_2O, which it readily loses at 100°: it dissolves readily in sulphuric and hydrochloric acids, but on evaporating the hydrochloride on a water-bath, the acid becomes dissipated. The barium salt, $C_7H_3NO_4Ba,1\frac{1}{2}H_2O$, is sparingly soluble, and the calcium salt, $C_7H_3NO_4Ca,\frac{1}{2}H_2O$, almost insoluble in water. Pyridinemonocarboxylic acid, obtained by heating the above, yields a very characteristic copper salt,

$$(C_6H_4NO_2)_2Cu,4H_2O,$$

crystallising in bluish-green irregular six-sided scales. Tricarbopyridinic acid (trimesitinic acid) yields a barium salt of the formula $(C_8H_2NO_6)_2Ba_3,7H_2O$, and a calcium salt, $C_8H_3NO_6Ca,2\frac{1}{2}H_2O$, insoluble in water and in dilute acetic acid; the copper salt, $C_8H_3NO_6Cu,3H_2O$, forms an insoluble greenish-blue precipitate, and the silver salt, $C_8H_2NO_6Ag_3,H_2O$, a gelatinous precipitate. Ethyl uvitonate may be obtained by heating the potassium salt of the acid with alcoholic ethyl iodide at 130°; it is insoluble in dilute ammonia, soluble in hydrochloric acid. When heated rapidly, it can be distilled in small quantity, but is decomposed by continued heating. A. K. M.

Condensation to Pyridine-derivatives. By C. Böttinger (*Ber.*, 17, 53—54).—The author refers to a previous paper (*Annalen*, 208, 122) in which he showed that the formation of uvitonic acid from pyruvic acid is only possible by the separation of hydrogen, which, however, does not become free, but reduces a portion of the pyruvic acid. The author has made many experiments with the view to avoid this loss of pyruvic acid, and to improve the yield of uvitonic acid. On treating ammonium imidopyruvate with bromine-vapour, a violent reaction takes place with evolution of carbonic anhydride. When the bromine is in excess uvitonic acid separates as a pale-yellow powder, which becomes colourless when washed, whilst the liquid contains formic acid, bromoform, and probably bromine-derivatives of aldehyde. The formation of these compounds shows that only a portion of the pyruvic acid has been converted into uvitonic acid. A. K. M.

Synthesis of Anthraquinoline. By C. Graebe (*Ber.*, **17**, 170—171).—By heating anthramine with nitrobenzene, glycerol, and sulphuric acid the author has obtained anthraquinoline. This substance is identical with that previously prepared by him by heating alizarin-blue with zinc-dust (Abstr., 1880, 262), thus further confirming the accuracy of the constitution—



assigned to anthraquinoline. A. J. G.

Bases of the Pyridine and Piperidine Series. By A. Ladenburg (*Compt. rend.*, **98**, 516—518).—The bases of the pyridine series are tertiary bases, and they combine with alcoholic iodides forming quaternary iodides. When these iodides are heated in sealed tubes at about 290°, they are partially converted into hydriodides of tertiary bases homologous with the pyridine employed. By this reaction, two isomeric bases are always obtained: one, which is formed in largest proportion, belonging to the γ-series, whilst the other, obtained in smaller quantity and having a higher boiling point, probably belongs to the α-series.

When the compound of pyridine with ethyl iodide is treated in this way, it yields two lutidines, one of which boils between 153° and 154°, and yields isonicotianic acid on oxidation, whilst the other boils at about 166°, and on oxidation yields traces only of an acid which has not yet been isolated. The compound with propyl iodide yields two collidines, one of which, γ-propyl-pyridine, boils at 163°, and yields isonicotianic acid on oxidation, whilst the other boils at 174°, and is characterised by its slightly soluble and distinctly crystalline platinochloride. The compound with methyl iodide seems to behave in a precisely similar manner, but the products have not yet been isolated. If these quaternary iodides are heated at a still higher temperature, ammonia and a considerable proportion of aromatic hydrocarbons are formed. Ethylbenzene was obtained in this way from the compound with ethyl iodide.

The conversion of pyridine bases into piperidine bases is effected by the action of sodium on a hot alcoholic solution, practically the theoretical yield being obtained, and in this way a whole series of homologues of piperidine can be prepared. Pyridine yields a piperidine, which seems to be identical with the piperidine obtained from piperine. Crude methyl-pyridine from Dippel's oil, however, yields a methylpiperidine entirely different from that described by Hofmann. It is a transparent, strongly alkaline liquid, which boils at 122°, and has the odour of piperidine. It dissolves in water with development of heat, but separates from a very strong solution on heating. It yields a crystalline and non-deliquescent hydrochloride, a very soluble crystalline platinochloride, and a much less soluble aurochloride, which melts in slightly warm water. The crude methyl-pyridine from which this base was obtained contained β-methyl-pyridine, together with a larger proportion of α-picoline.

γ-Ethylpiperidine is obtained in the same way from the γ-ethylpyridine prepared by the method described above. It boils at 143°, forms a crystalline hydrochloride, has an odour resembling that of conicine, and behaves like this latter compound in contact with water.

C. H. B.

Piperethylalkine Bromide. By A. LADENBURG (*Ber.*, 17, 154—155).—The hydrobromide of piperethylalkine is heated with 1 mol. bromine in sealed tubes for six hours, first at 100°, then at 120°: the solid product is evaporated several times with water to remove hydrobromic acid, and finally crystallised from absolute alcohol.

Piperethylalkine bromide, $C_7H_{13}NBr_2$, so obtained crystallises in brilliant, colourless, thin prisms; it is sparingly soluble in alcohol, very readily in hot water. It can be regarded as the hydrobromide of *bromovinylpiperidine*, $C_5H_{10}:N(HBr)C_2H_2Br$. Treated with silver chloride, it yields the corresponding *hydrochloride*, $C_{17}H_{13}NBrCl$, forming colourless needles; the *platinochloride*, $(C_{17}H_{13}NBrCl)_2,PtCl_4$, crystallises in orange-coloured prisms; the *aurochloride*,

$$C_7H_{13}NBrCl,AuCl_3,$$

forms needles, which are sparingly soluble and melt in hot water. By treating it with silver oxide, all the bromine is removed from piperethylalkine bromide; several bodies are produced, but these have not as yet been separated. By treatment with sodium-amalgam, the bromide is converted into ethylpiperidine and ethenylpiperyldiamine, the reaction being represented by the equations $C_5H_{10}:N.C_2H_2Br + 2H_2 = NEtC_5H_{10} + HBr$ and $2C_5H_{10}:N.C_2H_2Br + 3H_2 = N_2(C_5H_{10})_2C_2H_4 + 2HBr + C_2H_4$.

A. J. G.

Synthesis of Piperidine. By A. LADENBURG (*Ber.*, 17, 156).—Pyridine cannot be converted into piperidine by the action of tin and hydrochloric acid, but by the action of sodium on an alcoholic solution of pyridine the hydrogenisation can be effected, although only in small part. The separation of the bases was effected by nitrous acid, the resulting nitrosopiperidine being afterwards decomposed by hydrochloric acid. The platinochloride prepared from the base showed a complete agreement in properties with those of piperidine platinochloride. A. J. G.

Methyltropidine. By C. F. ROTH (*Ber.*, **17**, 157—159).—*Methyltropidine* is obtained by the action of freshly precipitated silver oxide on an aqueous solution of tropidine methiodide. It is a colourless syrupy oil of distinctly tropylene-like odour; cannot be distilled without decomposition; it is soluble in ether and chloroform. The *platinochloride*, $(C_9H_{15}N)_2,H_2PtCl_6$, crystallises well, and is readily soluble in water; it melts at 120°. The *picrate*, $C_9H_{15}N,C_6H_2(NO_2)_3.OH$, crystallises from hot water in golden-yellow silky plates. The *hydrobromide*, $C_9H_{15}N,HBr$, forms brilliant colourless crystals.

A. J. G.

Belladonine. By A. LADENBURG and C. F. ROTH (*Ber.*, **17**, 152—153).—When this alkaloïd or mixture of alkaloïds is boiled with alkalis, it readily dissolves, and is decomposed into tropine and an *oxytropine*, which gives a platinochloride, $(C_8H_{15}NO_2)_2,H_2PtCl_6$, crystallising in large red quadratic prisms, readily soluble in water; the acids formed at the same time are tropic acid, and its decomposition-products, atropic and isatropic acids. It is therefore possible that "belladonine" is a mixture of atropine and oxyatropine, $C_{17}H_{23}NO_4$; further investigations are in progress. A. J. G.

Hyoscine. By A. LADENBURG and C. F. ROTH (*Ber.*, **17**, 151—152).—Ladenburg has shown that on boiling hyoscine with alkalis or baryta, it is resolved into tropic acid and pseudotropine, a base isomeric with tropine (Abstr., 1881, 56). *Pseudotropine* crystallises in rhombohedrons, melts at 106°, and boils at 241—243° (tropine crystallises in the rhombic system, and melts at 62°); it is less hygroscopic than tropine, is very readily soluble in water, readily soluble in chloroform, sparingly in ether. Its aurochloride melts at 198°. By the action of methyl iodide on an aqueous solution of pseudotropine at 100°, *pseudotropine methiodide*, $C_8H_{15}N,MeI$, is obtained in colourless rhombohedrons, readily converted into the periodide by iodine. By shaking the iodide with freshly precipitated silver chloride, and adding platinic chloride to the solution, the platinochloride, $(C_{19}H_{18}N)_2,H_2PtCl_6$, is obtained in fine brilliant reddish-yellow plates. Proof of the identity of the tropic acid from hyoscine with that from other sources was obtained by its conversion into atropine when treated with tropine and hydrochloric acid. A. J. G.

Physiological Chemistry.

Milk. By E. Duclaux (*Compt. rend.*, **98**, 438—441, and 526—528).—The albuminoïd matter in milk may be divided into *colloidal caseïn*, *caseïn in suspension*, and *soluble caseïn*, the latter being capable of passing through biscuit earthenware. Small battery cells give good results, but the larger cells do not yield a filtrate of constant composition, even from the same milk, in consequence of inequalities in the earthenware. This method of filtration separates those substances which are in suspension, *i.e.*, fat, caseïn, &c., from those which are in solution, *i.e.*, sugar, inorganic salts, &c. The original milk and the filtrates were examined by the methods described in the author's memoir (*Ann. de l'Institut Agronomique*, 1879—1880). The following results were obtained with a sample of Cantal milk:—

	In suspension.	In solution.
Fat	3·32	—
Sugar	—	4·98
Caseïn	3·31	0·84
Calcium phosphate	0·22	0·14
Inorganic salts	—	0·39
	6·75	6·35

In this case, the soluble caseïn is about one-fifth of the total caseïn, but the proportion is rarely so high: in Cantal milk, the amount of soluble caseïn varies between 4 and 6 grams per litre; this proportion remains approximately constant, and does not sensibly change, even when the milk is kept for a considerable time. It is only slightly affected by the action of heat; the filtrate becomes turbid on boiling, but the precipitate is very slight, and gradually redissolves. The action of heat on the other two varieties of caseïn causes them to agglomerate, and the deposit inside the porous cell after filtration is always more compact if the milk has been boiled. Slight acidity causes a portion of the colloidal caseïn to pass into the suspended condition, and slight alkalinity converts some of the suspended caseïn into the colloidal form, but neither of these conditions has any effect on the soluble caseïn. The proportion of soluble caseïn in normal milk is not only approximately constant, but seems to be independent of the nature of the milk, and is sensibly the same in the milk of cows from various districts, in goats', asses', and human milk. The proportion of soluble caseïn is increased to a slight extent by the addition of water, and to a much greater extent by the presence of the diastase to which the author has previously given the name *casease*. In one case the proportion of soluble caseïn was 0·61 per cent., but under the influence of casease it increased in 8 hours to 1·80, and in 24 hours to 2·20 per cent., after which it remained constant, one-third of the total caseïn being still in the colloidal condition. The destruction of the equilibrium thus established required a very much longer time, or the addition of a further quantity of casease. The caseïn can be more quickly converted into the soluble form by addition of some of those microbes which produce casease (*loc. cit.*), and which continually secrete this substance, whilst at the same time they use up the caseïn already existing in the soluble form for their own nourishment. The secretion of the casease is in fact the means by which these microbes prepare their own food at the expense of the suspended and colloidal caseïn, and is strictly analogous to the action of the pancreatic juice in the higher animals.

Hammarsten supposed that the action of rennet on milk is to split up the caseïn into two new albuminoïds, one of which is insoluble in presence of the calcium phosphate contained in the milk, and carries down a portion of this phosphate with it, whilst the other, corresponding to lacto-proteïn, and called *whey-proteïn* by Hammarsten, remains in solution. The author treated milk with rennet free from casease, care being taken to prevent the access of bacteria as far as possible, and examined the resulting liquid by the filtration method. The results of one out of a number of experiments are given in the following table:—

	In suspension.		In solution.	
	Milk	Whey.	Milk.	Whey.
Fat	4·30	0·85	—	—
Sugar	—	—	5·37	5·73
Caseïn	3·53	0·46	0·37	0·36
Calcium phosphate	0·23	—	0·17	0·17
Inorganic salts	—	—	0·40	0·43
	8·06	1·31	6·31	6·69

The proportion of soluble caseïn and of dissolved calcium phosphate is the same in both the milk and the whey. The suspended calcium phosphate is, however, carried down together with the fat and the caseïn in the curd. Hammarsten's supposition is, therefore, not confirmed by experiment, since the amount of soluble caseïn is not increased, and the calcium phosphate plays no active part in the formation of the curd.

From the above table, it appears that 0·46 of the colloidal caseïn has not been converted into the solid form, and it is found that the whole of the coagulable caseïn is never precipitated, although the amount remaining in solution diminishes if the proportion of rennet is increased. Milk may be regarded as a system in which the three forms of caseïn are in equilibrium, this equilibrium being disturbed by the addition of minute quantities of inorganic salts, ferments, &c. Coagulation corresponds to the slow and regular production in a liquid mass of a state of equilibrium which requires the solidification of a dissolved substance, but there is no evidence to show why part of the caseïn should be precipitated in presence of rennet. The explanation is not to be sought in any specific properties of rennet, for other substances produce the same effect, nor in the specific properties of caseïn, since other bodies, such as oxide of iron, can exist in the same three states. Coagulation, in fact, appears to be simply a problem in molecular mechanics which cannot be solved in the present state of our knowledge. C. H. B.

Observation on a Note by Calmels "On the Poison of Batrachians." By A. Gautier and Étard (*Compt. rend.*, **98**, 631). —Calmels stated (*Compt. rend.*, **98**, 536) that the carbylamines are produced by the splitting up of the isocyanacetic acid and its homologues which pre-exist in the poison, and he considers that these same carbylamines must be present amongst the products of putrefaction, and be closely related to the ptomaïnes. The authors have observed the presence of carbylamines amongst the products of the bacterial fermentation of albuminoïds, more especially in the chloroform extract which contains the ptomaïnes (this vol., 89). C. H. B.

Poisons and Drugs which Act on Hæmoglobin, especially those which convert it into Met-hæmoglobin. By G. Hayem (*Compt. rend.*, **98**, 580—583).—Dissolved hæmoglobin is much more sensitive to the action of substances, such as amyl nitrite, potassium ferricyanide, and sodium nitrite, which can convert it into met-hæmoglobin, than is the hæmoglobin existing in blood corpuscles, and when once the former has been converted into met-hæmoglobin, it remains in that condition, whereas the latter after some time resumes its original condition and properties. Substances which, like amyl nitrite in moderate doses, do not destroy the corpuscles, do not produce any sensible anæmia, whilst those which have that effect, *e.g.*, sodium nitrite, cause somewhat rapid anæmia. The resistance which the hæmoglobin in the corpuscles offers to the action of substances which tend to convert it into met-hæmoglobin explains why these substances can be introduced into the blood even in considerable quantity without producing any sensible effect on it. This resistance is assisted by the rapid elimination of these substances, and by the changes which some of them, *e.g.*, ferricyanides, rapidly undergo in the organism. C. H. B.

Chemistry of Vegetable Physiology and Agriculture.

Influence of Salicylic Acid on Alcoholic Fermentation. By G. Heinzelmann (*Bied. Centr.*, 1883, 503).—The author's experiments show that the vitality of yeast is completely destroyed by the presence of 0·15 gram of salicylic acid per 400 c.c. of sugar solution, whilst the addition of 0·01 per cent. favours its greatest activity, and although the yeast plant does not propagate, nevertheless the cells developed in the presence of salicylic acid are stronger and larger than those produced in a solution free from that acid. Moreover under similar circumstances the production of alcohol in a given time is greater.

The addition of 0·1 gram of salicylic acid per litre of "mashing" favours fermentation, especially with pure sugar solutions.

D. A. L.

Bacillus Butylicus. By Fitz (*Bied. Centr.*, 1883, 503).—This bacillus is capable of yielding other products of fermentation than butyric acid. In the author's experiments, the following results were obtained:—

Product of fermentation.	100 glycerol.	100 mannitol.	100 invert-sugar.
Butyl alcohol	8·1	10·2	0·5
Butyric acid	17·4	35·4	42·5
Lactic acid	1·7	0·4	0·3
Succinic acid	—	0·01	trace
Trimethylene alcohol	3·4	—	—

Milk-sugar is not attacked.

D. A. L.

Chemistry of Plants. By M. Ballo (*Ber.*, **17**, 6—12).—The author previously showed that in aqueous solutions of carbonic anhydride, the latter exists as hydroxide (Abstr., 1883, 574), and he concludes therefore that this is the form in which it becomes assimilated by plants. He finds that the reduction of carbonic anhydride to formic acid can be effected not only by the action of potassium on the moist gas, but also by the action of an energetic reducing agent (sodium-amalgam) on alkaline hydrogen carbonates, and on calcium hydrogen carbonates, this being of interest in connection with plant chemistry through the wide distribution of the latter salt in water. Glycollic acid, which has been shown to occur in unripe grapes, and also tartaric acid have been obtained by the reduction of oxalic acid (*Bull. Soc. Chim.*, **27**, 3; *Annalen*, **166**, 124). Tartaric acid has likewise been shown by Liebig and others to be an oxidation-product of most of the carbohydrates, and by reversing the process (*i.e.*, by reduction) it might therefore be better suited to the formation of these substances than carbonic acid. Whilst a portion of the oxalic acid of plants serves to decompose calcium sulphate, by far the greater portion must give rise to the production of glycollic and tartaric, or of malic and succinic acids. The conversion of formic acid (which is assumed to be the first reduction-product of carbonic acid) into oxalic acid in plants, is probably brought about by nitric acid; it is found that nitric acid does effect this conversion if the reaction be stopped when red fumes begin to be evolved. The author believes that this is the reason why nitrogen must be presented to plants in the form of nitrates; a portion of this is no doubt reduced to ammonia, a second portion probably to nitrous acid, whilst the greater part is reduced to nitric oxide, which, by the action of oxygen and water, becomes reconverted into nitric acid.

The reduction of oxalic to tartaric acid may be assumed to be effected by the coalition of two oxalic acid molecules or of one molecule oxalic acid with one molecule glycollic acid; whilst the production of acids containing an uneven number of CH OH-groups can be explained by formic acid taking part in the reaction. By the further reduction of the acids, alcohols are produced. It is not yet understood in what way the salts act in the vegetable and animal organisms, but the author thinks it possible that they assist in bringing about the formation of the more complicated products.

By the action of sodium on an ethereal solution of chlorhydrin, a hexyl alcohol, $C_6H_{10}(OH)_4$ (*glycerythrol*), is obtained, homologous with erythrol. It is soluble in water and alcohol, insoluble in ether, and forms a thick yellowish syrup of bitter taste. A. K. M.

Action of Rain, Dew, and Watering on Plants. By J. WIESSNER (*Bied. Centr.*, 1883, 471—472).—The moistened leaves of plants transpire more freely than when they are dry, consequently a larger quantity of water is withdrawn from the soil by the roots; if then there is plenty of moisture in the ground, the plant flourishes, but if otherwise it drops and languishes. Plants should not be watered on the loaf unless the soil is likewise moist. The small amount of extra transpiration induced by dew can do no harm, as it is almost certain that the ground will be sufficiently moist to supply the requisite amount of water. The action of rain is more beneficial still, for then the supply of plant food is most rapid. E. W. P.

Studies on Ripe Cherries and Currants. By C. AMTHOR (*Bied. Centr.*, 1883, 499—500).—The following conclusions are deduced from numerous determinations. Some of the experiments lasted six weeks, terminating with the maturity of the fruit under investigation. With cherries, both water and dry matter showed a constant increase throughout the period of experiment, and at the termination the water amounted to 398, and the dry matter to 295 per cent. of the original. The rate of increase of these matters is not, however, always in the same proportion; for instance, four weeks previous to ripening, the increase in water is behind that of the dry matter, but afterwards matters are reversed. In ripe cherries, the ash increases 204 per cent., the phosphoric acid 195 per cent., therefore these constituents do not increase to the same extent as the dry matter and water, and consequently appear to suffer diminution when compared with the latter. Ripe kernels contained 19·1 per cent. ash, and 20 per cent. phosphoric acid; thus showing an increase in both constituents. As currants ripen, various constituents increase in quantity; during the six weeks of experiment, both water and dry matter increased by 62 per cent., whilst the percentage of ash in some berries rose by 50, of phosphoric acid by 47, and of sulphuric acid by 126 per cent. D. A. L.

Distribution of Sugar in Beet, and the Position in the Beet of the Mean Amount of Sugar. By G. MAREK (*Bied. Centr.*, 1883, 480—482).—For the determination of absolute weight, dressed roots were divided from top to root-end into eight cross-sections, but to study the distribution of sugar, the beets were cut lengthwise into halves, one set being employed for the determination of sugar in the various cross-sections, from top to root-end, whilst in the other set similar determinations were made in peripheric zones from the centre to the outside. With regard to the absolute weight, the uppermost portion contains 30·87, the lowest, or tail or root-end, 1·33 per cent. of the entire weight of the root (comp. Abstr., 1883, 124, and this vol., 356). The amount of juice obtained from each separate part is in the same relation. The sap of highest sp. gr is found in the second and third eighth from top, then follows the first, and finally the others in succession, the sp. gr. diminishing towards the root-end. The rotatory power is greatest in the second section from the top, then sinks as the sections get nearer the root-end; that of the top section lies between five and six. For the determination of lateral distribution, the upper portions (from the neck of the root) only were employed, and these were carefully divided into seven semicircular pieces. The absolute weight increases from centre to the outside, the centre being lighter. Sp. gr., amount of sugar, and purity coefficient are comparatively low in the centre portions, then increase to the sixth part, and are lowest in the exterior layer. The position of the mean amount of sugar lies between the first and second eighth in large and medium beets, but is somewhat higher in small roots. D. A. L.

Effect of Drying, of Remoistening Dry Beets, of Frost, and of Winter Storage on the Constitution of Sugar-beet. By G. Marek (*Bied. Centr.*, 1883, 484—487).—The first series of experiments were made to determine if the loss of water could be made up and polarisation readjusted by the addition of moisture to dry tested beets. Loss of water occasions concentration of the sap, and therefore more or less noteworthy changes in the polarisation and purity. The loss of water is greatest during the first two days' exposure of the roots, the quantity varying greatly with the prevalent temperature and the mode of covering the roots. When the loss of water is small, it can be restored by simply wrapping the roots in a damp cloth, or sprinkling them with water. When, however, the loss is great, it cannot be renewed in that manner. The most effectual way of compensating for evaporation is to lay the roots in soak, which method is of doubtful practical utility on account of its effect on the soundness of the root.

The cells of thawed frozen roots are clear and transparent, whilst the sap is difficult to filter, and very prone to mucous fermentation. It contains a calcium salt, which is not decomposed by carbonic anhydride; these defects of the thawed sap cannot be rectified by mixing with good extract. Roots may freeze when they are in the ground, or when they lie uncovered, or insufficiently covered on the ground, or during transport. The first case rarely happens, as the beet can withstand — 7° without freezing, provided it remains undisturbed, it is therefore advisable not to pull roots while the ground is frozen. The second case can be prevented by covering them with a sufficiently thick layer of earth. Roots frozen during transport should be used at once. In order to ascertain the time of the initial change in the internal composition of frozen roots, the author proceeded as follows:—20 beets were each divided into 8 equal parts, and subjected to experiments in different stages: (1), fresh; (2), after 24 hours at — 3°; (3), after 48 hours at from — 3° to — 4°; (4), after 5 days' storage of the frozen beet at 5°; (5), after 14 days; (6), after 30 days' storage. The sap testings were as follows:—

Stages.	Sp. gr.	Per cent.			
		Dry matter.	Polarisation.	Not sugar.	Purity.
1	1·0630	15·371	13·429	1·942	88·36
2	1·0650	15·837	13·109	2·728	82·77
3	1·0810	19·497	16·518	3·979	84·72
4	1·0650	15·837	13·725	2·112	86·66
5	1·0615	15·721	13·860	1·861	88·16
6	1·0585	14·309	9·690	4·619	67·71

The decomposition which interferes with the manufacturing processes commences about 20 days after freezing.

From another series of investigations, the author shows that the spontaneous changes of beet which take place during the winter were variable during the seasons 1880–81 and 1881–82, and therefore the exact period at which the greatest amount of sugar is to be found has not been definitely fixed. Thus the diminution in sugar from December, 1880, to March, 1881, was 4·44 per cent.; whilst from November, 1881, to February, 1882, it was 2·691 per cent. The loss of sugar commenced in 1880–81 in January, in 1881–82 in December.

D. A. L.

Poisonous Action of Ammonium Thiocyanate on Plant Life. By M. Märcker (*Bied. Centr.*, 1883, 497).—Experiments prove that superphosphate may be mixed with 1 per cent. of ammonium thiocyanate without injurious effect; whilst with oats as much as 100 kilos. of this salt per hectare does not act prejudicially (comp. Abstr., 1883, 495—496). D. A. L.

Influence of Thick and Thin Sowing, and of the Manuring on the Yield of Oats. By O. Bessler and M. Märcker (*Bied. Centr.*, 1883, 472—488).—The quantity of seed sown was 22 lbs. per morgen, distance 23·5 cm. between the drills, and 38 lbs. distance 17 cm. In the former case, even with the assistance of manures, the yield obtained did not reach that of the 38 lbs. per morgen. Addition of phosphate produced no great increase, but advantage was gained by the use of Chili saltpetre, and then the increase was proportional to the increase of nitrogen; with small quantities of nitrate, the addition of phosphates was productive of good results, but this was not so when much nitrate was used. These manures equally raised the yield of grain and straw, which were in the ratio of 1 : 1·3 with thick sowing, and 1 : 1·22 with thin sowing. Plants growing closely together were poorer in albuminoïds than those at a greater distance apart, and the presence of extra phosphates did not raise the percentage of these compounds; neither did nitrogen manures in addition to phosphates. Seeing that the higher the yield was, the higher was the percentage of albuminoïd matter, the conclusion is drawn that the larger the crop the better is its quality, and that moderate manuring renders a crop better in quantity and in quality. E. W. P.

Cultivation of Peruvian Rice (Chenopodium Quinoa) in Austria. By E. v. RODICZKY (*Bied. Centr.*, 1883, 487—488).—The author has conducted some successful experiments in this direction in Hungarian Altenburg during the seasons 1879 and 1882. Sowing on 16th March in a loamy soil poor in humus, the plants appeared on the 26th; on 1st June they were hoed, they flowered at the commencement of July, and were ripe for harvest in the middle of September; in another case the sowing was on 5th April, the plants came up on 20th, were in flower on 12th July, but on account of unfavourable weather did not ripen until the middle of October. 7—9 kilos. of seed were sown per hectare in rows 50—60 cm. apart, the crop was hoed once, and at a later date thinned to stand 25 to 30 cm. apart in the rows. The yield is very good, 17 grams (even 87 grams) per plant, 2700 kilos. per hectare. The percentage composition of the grain, according to Voelker, is as follows:—Dry matter 83·90, starch 58·22, extractive matter 5·12, fat 4·81, albuminoids 11·71, ash 4·25. It is a very hardy plant, withstanding both frosts and drought. In Peru, it is eaten green as a vegetable, whilst the grain is used in soups, &c., like sago. It does not appear to be fitted for fodder, but as it produces an abundance of leaf and stem, the author considers it adapted for green manuring. D. A. L.

Cultivation of Vicia villosa and of Pisum arvense. By MÄRCKER and others (*Bied. Centr.*, 1883, 488—491).—The Vicia is best sown as soon as the ground is free from frost, in March, using 10 kilos. of vetch and 20 kilos. of summer rye per morgen. It is advisable to harvest when the rye is ripe, then the partially ripe vetch dries easily without losing its vitality. Perfectly ripe vetch does not scatter, unless it is bound and carried in hot dry weather, when the seed pods break off, and are left in the field. Dry soil of Class 7 or 8, as free from weeds as possible, is the most suitable for this plant; it thrives, however, on deep moist soils, but does not produce much seed, it is therefore advisable to feed off with sheep in such cases.

On poor land the following rotation is recommended:—(1), Potatoes (manured); (2), *Vicia villosa* (sand vetch), with summer rye; (3), winter rye. Kainite and phosphate are probably favourable manures. For better wheat and root land the following: 1, Roots or potatoes manured; 2, barley, half with clover; 3, half clover, *V. villosa* as fodder; 4, wheat. *V. villosa* is winter-proof, therefore for early green fodder it may be sown in the autumn along with winter rye or else a mixture of oats, and this vetch may be sown at intervals of three or four weeks, so that there will be green fodder always at hand until late in the autumn. To prevent the *V. villosa* becoming a permanent weed, the stubble should be pulled up twice, or it may be used as forerunner of manured potatoes in rotation.

Heinrich has cultivated *V. villosa* and *Pisum arvense* on light sandy soil, with marly subsoil in some places. Both varieties of seed were mixed with one-third their weight of summer rye, and were dressed with 5 kilos. blood manure per plot of 2 ares. The yield of vetch was small, 26·7 centners of straw and 3·2 centners of grain per hectare. Peas yielded per hectare, on the land with marly subsoil, 69·5 centners straw, &c., 22·2 centners grain; on the other soil, straw, &c., 47·5 centners, and grain 15·4 centners.

Troschke has cultivated "white pea," "grey pea," and "sand pea" (*P. arvense*), in order to investigate and compare the relative composition at various stages of growth. The harvest results were lost owing to unfavourable weather; but the plants at the beginning of blossoming, and subsequently the ripe seed, have been submitted to chemical examination, with the following results; figures are per cent.:—

Constituent.	Plant at beginning of blossoming.			Ripe seed.		
	White pea.	Grey pea.	Sand pea.	White pea.	Grey pea.	Sand pea.
Water	16·0	16·0	16·0	16·0	16·7	16·2
Ash	6·9	7·8	7·2	2·6	3·8	4·1
Albuminoids	22·7	21·9	20·8	23·3	22·7	21·4
Fibre	24·9	23·1	21·8	6·2	7·2	7·0
Extractive matter	26·8	28·7	30·8	50·2	47·8	49·5
Fat	2·7	2·5	3·4	1·7	1·8	1·8

Two samples of "sand" pea had the following composition per cent.:—

	Grain		Straw	
	From Gr. Warbelin.	From Melln.	From Gr. Warbelin.	From Melln.
Water	16·8	14·7	15·0	16·0
Ash	2·3	2·5	4·0	3·9
Albuminoids	21·8	23·3	7·3	6·8
Fibre	5·8	6·0	38·5	43·5
Extractive matter	51·8	52·1	33·6	28·7
Fat	1·5	1·4	1·6	1·1

It will be seen that in composition this variety of pea somewhat resembles other varieties; it, however, differs from the latter in yielding better harvest and economising the soil. Von Borcke has investigated the cultivation of this pea (*P. arvense*) on various soils, and has found sandy soil to be the most favourable. D. A. L.

Composition of Silage. By A. Smetham (*Jour. Roy. Agri. Soc.*, 1884, 380).—The silage from Tatton Park was made from fresh grass mown in July; the grass was cut into chaff, and about 8 parts of salt added per 1000 of grass. The composition of the grass and of the resulting silage is given below. The silage from Wilmslow was made from grass mown in October; the grass was not chaffed, no salt was added. The silage from Hayton was made from chaffed clover and rye-grass mown early in September. The sample was taken for analysis in March.

	Tatton Park.				Wilmslow.	Hayton.
		Silage from grass.				
	Original grass.	1½ ft. to 2 ft. from bottom.	1 ft. to 1½ ft. from bottom.	Bottom layer.	Silage from grass.	Silage from clover and rye-grass.
	In 100 parts of fresh substance.					
Water	70·48	68·74	65·84	78·65	81·38	78·10
	In 100 parts of dry substance.					
Insoluble albuminoïds	6·94	3·65	3·75	3·84	6·12	6·53
Soluble albuminoids	3·06	6·08	6·06	5·90	7·09	5·20
Fat (ether extract)	2·80	7·52	5·39	4·31	3·98	6·66
Soluble carbohydrates	11·65	5·69	8·61	2·81	1·18	7·85
Digestible fibre	36·24	29·81	36·24	33·72	36·63	25·80
Indigestible fibre	32·33	31·67	26·64	34·42	31·10	36·76
Soluble mineral matter	5·24	13·98	11·47	12·51	7·35	6·17
Insoluble mineral matter	1·74	1·60	1·84	2·49	6·55	5·03
Acidity as acetic acid	—	0·99	1·02	2·34	0·97	1·51

The central layer of silage from Tatton Park contained in the fresh state 0·34 per cent. of alcohol; in the bottom layer only a trace of alcohol was found. The amount of free acid increased greatly towards the bottom; the liquid occurring there contained 0·89 per cent. The acid is reckoned as acetic, but in fact includes both butyric and lactic. The marked increase in the quantity of ether extract is probably due to the presence of acids soluble in ether. The albuminoïds are merely calculated from the nitrogen present. The soluble nitrogenous compounds were clearly not wholly albuminoïd (see this Journal, Trans., 122), a part apparently were amines. The most considerable changes resulting from ensilage are apparently in the albuminoïds, resulting in the formation of simpler soluble bodies, and in the soluble carbohydrates, which suffer loss by fermentation.

R. W.

Changes which take Place in the Conversion of Hay into Silage. By F. J. LLOYD (*Chem. News*, 49, 210).—Taking the analysis of grass, and of silage made from it at Tatton Park (see preceding abstract), the author finds that the proportion of nitrogen in dry organic matter in the two substances is as 100 : 106, and concludes that 106 of organic matter as grass have yielded 100 as silage. He then compares the composition of these two quantities, and concludes, in addition to the deductions given above, that there is no increase in the amount of digestible fibre during ensilage.

R. W.

Heaping Potatoes. By SCHLEH (*Bied. Centr.*. 1883, 483—484).—Experiments were made with "Red Heidelberg," "Sieberhauser," and Dabersche potatoes; heaping increased the total yield in the latter case only. In all cases it produced more large tubers, but did not prevent disease, and on the whole favoured extension of the stolons. In conclusion, the author considers heaping on dry sandy and light soils not only superfluous, but, under certain circumstances, even detrimental.

D. A. L.

Digestibility of Wheat Chaff, and the Changes which it undergoes by different Methods of Preparation, &c. By G. KÜHN and others (*Bied. Centr.*, 1883, 455—471).—As it was first necessary to determine the digestibility of the hay used for fodder in addition to the chaff, seven bullocks were put up and fed with three qualities of hay, both dry and moistened; afterwards they were fed with the hay to which was added chaff, dry, moistened, and boiled. Several tables show the result of these experiments, which may be summed up in the following sentences:—The digestibility of the hay is not affected by previous moistening with cold water or chaff tea; moistening of the hay has no influence on the digestibility of the chaff; steeping of chaff in cold water for 24 hours does not render either the chaff or the hay more easy of digestion; steeping the chaff renders its albuminoïd matters less easy of digestion, and the less so the higher the temperature of the water, and the longer the time during which the steeping is conducted.

E. W. P.

Amount of Easily Digestible Albuminoïds in Germinated Maize. By A. STUTZER (*Bied. Centr.*, 1883, 497).—Maize becomes less nutritious by germination, because the albuminoïds are decomposed into substances of lower nutritious value than albumin. The germinated samples examined contained only a few tenths or even as little as 0·1 per cent. of easily digestible albuminoïds.

D. A. L.

Effect of High Farming on the Amount of Nutritious Matter in Straw. By M. MÄRCKER (*Bied. Centr.*, 1883, 500).—Three years' experiments with oat-straw on the highly-cultivated soil of Saxony yielded unfavourable results, inasmuch as the straw frequently contained only 1 per cent. of albuminoïds, whereas, according to Wolf's mean, it should amount to 4 per cent. It is for this reason that oat-straw is only of small value in Saxony. Other experiments with grain show that the amount of albuminoïds diminishes with a limited application of nitrogenous manures and *vice versâ*. For example, by the use of 2 centners of sodium nitrate and 1 centner of superphosphate,* the amount of albuminoïds in oat-grain was raised from 7 to 11 per cent. (compare Abstr., this vol., 630).

D. A. L.

Fertility of a Soil which had been Removed from its Original Position and subsequently Replaced. By M. MÄRCKER (*Bied. Centr.*, 1883, 496).—The soil in question was a surface soil rich in humus; it was removed (in order to work the underlying lignite) and subsequently replaced; after which operation it was lightly manured with artificial manures and sown with barley, when a luxuriant crop of straw was obtained. The author suggests the following explanation: that by removal the soil becomes looser, and moreover during removal, more thorough contact with the air ensued, and consequently there was a more energetic decomposition of nitrogenous matter, accompanied by nitrification. The detrimental effect of the large quantity of nitric acid thus produced could be avoided by the abundant use of phosphatic manures, whilst the consistency of the soil might be improved by a dressing of kainite and by mechanical means. D. A. L.

Fermentation of Manure. By U. GAYON (*Compt. rend*, **98**, 528—530).—Fresh manure undergoes two entirely different kinds of fermentation, according as it is exposed to the air or is kept in a closed vessel. If exposed to the air, the temperature gradually rises until it attains a maximum of 74°, after which it gradually falls, because the mass has become much drier and ceases to oxidise. If, however, water is added, combustion recommences and the temperature again rises. The development of heat causes the evolution of large volumes of vapour, which carry off considerable quantities of ammonia. Microscopic examination shows that even in the most highly heated portions there are multitudes of torulæ, micrococci, bacilli, amœbæ, &c. Similar organisms have been observed in fermenting tobacco, even when the temperature has been as high as 80°.

If the manure is carefully protected from the air, there is at first a slight rise of temperature up to about 20°, due to absorption of the imprisoned oxygen, but afterwards the temperature gradually falls, until it is only one or two degrees above that of the surrounding air. Large quantities of carbonic anhydride and methane are given off, and the manure is found to be full of extremely minute anaerobic organisms, which can be cultivated in suitable fluids. When these cultivated organisms are brought in contact with cellulose, &c., carbonic anhydride and methane are given off. C. H. B.

Application of Artificial Manures in the Cultivation of Beetroot. (*Dingl. polyt. J.*, **250**, 553.)—According to Déhérain, ammonium sulphate has an injurious effect on the germination of beetroot when the soil does not contain a sufficient amount of organic matter. Ammonium sulphate reduces the yield of crop, whilst sodium nitrate diminishes the percentage of sugar. One hectare of unmanured soil yielded 46,600 kilos. roots with 16·24 per cent. sugar; after the addition of 1200 kilos. sodium nitrate, 57,400 kilos. roots with 9·97 per cent. sugar; and after treatment with 1200 kilos. ammonium sulphate, 37,200 kilos. with 13·38 per cent. sugar. Holdefleiss, on the other hand, recommends a judicious addition of farmyard manure mixed with a small proportion of sodium nitrate. Farmyard manure may be replaced by superphosphate and sodium nitrate. Too large a quantity of nitrogenous manures, however, impoverishes the soil. D. B.

---

* The extent of land is not mentioned; it is, however, most probably per morgen: 2 centners per morgen = 350 lbs. per acre.

Retrograde Phosphoric Acid. By J. Post (*Bied. Centr.*, 1883, 448—449).—The superphosphate was examined at various periods; the acid estimated by means of aqueous ammonium citrate at 40° and at 90°. During the first two months as much soluble phosphoric acid was reduced as during the succeeding four; the amounts of ferric and aluminium phosphates, soluble in water, were also reduced by keeping, but a larger amount of these compounds became soluble in citrate at 40°; whilst but little difference was shown by citrate at 90°. The reduction must have been occasioned by combination of the originally free acid with some of the insoluble portions of the superphosphate, probably alumina or iron, forming calcio-aluminic or calcio-ferric phosphate. E. W. P.

Comparison of Dissolved and Undissolved Phosphates. By B. Dyer (*J. Roy. Agri. Soc.*, 1884, 113).—The first experiments were made at Horsham in 1882; the soil was a stiff clay containing no calcium carbonate. Swedes were grown with 5 cwts. per acre of coprolite superphosphate, and with 6½ cwts. (the same money value) of very finely-ground Cambridge coprolite. The comparison was made both with and without dung, but the produce obtained was not large; in each case the better result was from the undissolved phosphate. In the following year, oats were grown on the same plots without further addition of manure; the produce was again, on an average, better where the undissolved phosphate had been employed. The experiments with swedes were repeated in 1883. On this occasion, 235 bushels of lime per acre were ploughed in before sowing the crop. The same quantities of manure were applied as before. Owing to the dryness of the season, the crops were very small. The produce was in this instance distinctly better where the dissolved phosphate had been applied. These results confirm earlier experiments, showing that dissolved phosphates are more effective than undissolved when the soil contains lime. In the above experiments, the ground coprolite supplied more than twice as much phosphate as the superphosphate. R. W.

Manuring with Potash. By F. Farsky (*Bied. Centr.*, 1883, 457—459).—Pure salts of potassium reduce the yield of the crop, and the more the nearer the salt is to the seed. Potassium chloride is less lowering. The Stassfurt salts were distinctly harmful to barley and rye, but the lowering effect is less the more moisture there is in the soil, which renders the solution of the salts dilute. Experiments with other crops showed that advantage was derived from the use of Stassfurt salt with most crops, excepting barley, oats, and, to some degree, rye and clover. Autumn manuring is better than spring.

E. W. P.

Action of Sulphuric Acid as a Manure. By F. FARSKY (*Bied. Centr.*, 1883, 447).—Strong sulphuric acid as well as sodium hydrogen sulphate in solution were applied to soil in boxes. The experiments were in duplicate, one set after the first moistening was not further wetted, but the other was kept moist with plain water.

The results were that the moistened sets brought no higher yield than a blank set, whilst the yields from the soils kept dry were lowered.

E. W. P.

Analytical Chemistry.

Apparatus for the Reduction of Measured Gas-volumes to Normal Condition. By U. KREUSLER (*Ber.*, 17, 29—34).—The author describes two forms of apparatus, the principle of which is the same as in Vernon Harcourt's apparatus (Abstr., 1883, 378).

A. K. M.

The Alkaline Reaction of Glass as a Source of Error in Analysis. By U. KREUSLER and O. HENZOLD (*Ber.*, 17, 34—40).—Whilst repeating Kjeldahl's experiments on the formation of ammonia by the action of sulphuric acid and potassium permanganate on organic compounds (this vol., 364), the authors made comparative experiments with pure ammonium salts, with the result that too high a percentage of ammonia was found. The same result was observed in blank experiments when no ammonia was present, the average alkalinity (estimated as ammonia) from three experiments being equal to 2·13 mgrms. nitrogen. The authors have traced this source of error to the decomposition of the glass employed in the experiments; they have also compared different sorts of glass, namely (1), readily fusible Thuringian glass; (2), less fusible Thuringian glass; (3), combustion tubing of very refractory Bohemian glass, and (4), more readily fusible Bohemian glass. Of these, the first is far the most readily attacked by water, the third being the least attacked, and yielding results which require no correction. The fourth is nearly as good as the third, whilst the second is much more readily acted on. The alkaline reaction of glass may be easily shown by boiling red litmus tincture in a test-tube, and by other such simple experiments.

A. K. M.

Test for Available Chlorine in Bleach Works and Similar Establishments. By R. BAUR (*Dingl. polyt. J.*, 251, 173—177).—The author considers that the simplest, quickest, and most accurate method of determining the available chlorine in the baths of bleach works, paper works, &c., is Dupasquier and Bunsen's modified iodine method, a detailed account of which is given in the original paper.

D. B.

Purification of Hydrogen Sulphide by Means of Hydrochloric Acid. By W. LENZ (*Ber.*, **17**, 209).—A reply to the criticisms of Otto (this vol., 638) on the method of purification of hydrogen sulphide from traces of arsenic as described by the author (this vol., 215).

A. J. G.

Titration of Sulphurous Acid and its Salts. By G. LUNGE (*Dingl. polyt. J.*, **250**, 530—533).—Formerly it was assumed that an aqueous solution of sulphurous acid could be titrated with litmus exactly as the strong mineral acids are; that is, that the change of colour takes place when 2 mols. sodium hydroxide have been added to 1 mol. sulphurous acid. This, however, is not the case, as $NaHSO_3$ is neutral to litmus. Litmus has been recently replaced in many cases by methyl-orange, which presents greater advantages for titrating carbonates or sulphides. The orange cannot, however, be employed with organic acids.

Thomson's experiments (*Chem. News*, **47**, 136) having brought forward the important fact that the salts of sulphurous acid present have different kinds of neutrality towards indicators, the author repeated his experiments in order to confirm Thomson's results: in the course of this investigation, the author made a series of interesting experiments on the titration of bisulphites and of free sulphurous acid. He concludes that litmus and phenacetolin should be entirely rejected for the titration of sulphurous acid, for totally different results are obtained according as the change of colour is taken at a decided blue or a decided red. Methyl-orange, phenolphthaleïn, and rosolic acid are equally well serviceable; in the case of the orange, however, it must be noted that 1 mol. SO_2 is saturated by 1 mol. KHO, and in the case of phenolphthaleïn and rosolic acid, by only half a molecule, *i.e.*, one equivalent of SO_2 to one of KOH. A further confirmation of these results was obtained by some experiments with sulphites.

The novelty of the author's experiments is the abnormal behaviour of litmus and phenolphthaleïn.

D. B.

Action of Soda Lime and Magnesia on the Salts of Ammonia and Organic Amines, and on the Titration of Aniline. By G. LUNGE (*Dingl. polyt. J.*, **251**, 36—41).—The author has made a series of experiments in order to ascertain which of the above-named three bases is the best adapted for liberating ammonia in analytical operations. The following conclusions were arrived at:—

1. Lime, magnesia, and soda in excess liberate all the ammonia contained in ammonium chloride equally well. The distillation should not, however, occupy much less than three hours, otherwise even lime or soda fail to expel all the ammonia.

2. In the presence of fatty (ethylamine) or aromatic amines (aniline), these are liberated under the same conditions as ammonia,

so that the assumption that magnesia avoids the decomposition of the organic amines originating in coal-tar and possibly contained in commercial ammonium salts, is erroneous, the employment of magnesia offers no advantage in respect of estimating the ammonia alone without the other amines. Quinoline was found to behave like aniline.

3. Lime and soda when distilled for three hours with an excess of ammonium chloride, liberate their full equivalent of ammonia; magnesia, however, on distilling for 3 to 5 hours, expels only about 85 per cent. of the theoretical quantity of ammonia (probably owing to the formation of a basic magnesium chloride difficult to decompose). Hence magnesium must always be employed in excess, whilst this is not necessary in the case of lime or soda.

Referring to the titration of aromatic amines, the author has found that methyl-orange when employed as indicator, is not changed by aniline salts, whilst aniline itself shows the reaction of a base. The same is the case with ortho- and para-toluidine, xylidine, meta- and para-phenylenediamine. Experiments have been made with these bases in the hope of being able to estimate the relative proportions of aniline and toluidine in commercial aniline oils, taking advantage of the difference of molecular weights, and although it was possible to titrate very small quantities of aniline mixed with ammonia salts with sufficient accuracy by methyl-orange, it was impossible to quantitatively estimate aniline along with toluidine in this way; owing to the fact that a slight difference in the test acid consumed (1 c.c. = 0·093 gram aniline or = 0·109 toluidine) will indicate a considerable difference in the proportion of the amines. D. B.

Estimation of Lead as Lead Dioxide by Means of the Electric Current. By F. Tenney (*Amer. Chem. J.*, 5, 413—415).—Luckow, May and Riche have previously used this method. Using a solution of known strength of pure lead nitrate, very good results were obtained, when about 10 per cent. of nitric acid was added. A solution containing about 12 parts of copper to one of lead, allowed of an accurate separation and determination of the two metals, when from 1½ to 10 per cent. of nitric acid was present. In presence of iron the separation is also accurate. If large amounts of lead are present, either an aliquot portion must be taken, or a platinum dish may be made the positive pole and the dioxide washed by decantation. In the analysis of slags and mattes, the copper and lead are best precipitated by sulphuretted hydrogen, and the solution of the sulphides in nitric acid electrolysed. H. B.

Qualitative Separation of Tin, Antimony, and Arsenic. By E. Berglund (*Ber.*, 17, 95—98).—The solution of the sulphides in ammonium sulphide obtained in the usual way is acidulated with hydrochloric acid, the precipitate well washed, boiled with water, and sodium sulphide added. The solution is then boiled with copper oxide, when copper sulphide is formed and a colourless liquid obtained, containing sodium stannate, antimoniate, and arsenate; when cold, alcohol (¼—⅓ vol.) is added to the filtrate, producing a white precipitate containing the antimony. The filtrate is boiled to expel the alcohol, ammonium chloride added in excess, and then (whether a precipitate has been produced or not) a few drops of ammonia. Hydrogen sulphide is passed through the liquid, and if a precipitate forms, the passage of the gas is continued until the latter is dissolved. The arsenic is then thrown down as ammonium magnesium arsenate by the addition of ammonia ($\frac{1}{3}$ vol.) and magnesia mixture, and the filtrate treated with hydrochloric acid, which precipitates the tin as stannic sulphide. A. K. M.

Testing Grape-sugar, and some Reactions of Sugars. By Worm-Müller and others (*Bied. Centr.*, 1883, 492—495).—A great many of the publications referred to in this memoir have already appeared in this Journal (Abstr., 1883, 38, 624, 829, 1176; 1884, 502). Pure dextrose has been prepared from cane-sugar in the following way:—About 300 grams of finely powdered cane-sugar are mixed gradually in course of some weeks with 600 c.c. of 80 per cent. alcohol and 20 c.c. of fuming hydrochloric acid. The sugar dissolves, and after some time dextrose separates in beautiful white crystals, which are washed with alcohol and dried at 100°; they are easily recrystallised either from methyl or absolute ethyl alcohol. 50 per cent. of the raw sugar is converted in this manner. The description of Vivien's method (this vol., 502) is not quite accurate. The solution of 10 grams of sugar in 200 c.c. of water is mixed with diluted Fehling's solution of various strengths of which 10 c.c. represent respectively 0·01, 0·009, and 0·001 gram of glucose. To determine the amount of starch-sugar in sugar cane, Geissler makes use of the powerful reducing action which the former exerts on Fehling's solution, whereas the latter is inactive until "inverted." Starch-sugar has been detected in a commercial raspberry-juice. D. A. L.

Salicylic Acid in Beer and Wine. By J. A. Barral (*Bied. Centr.*, 1883, 495—496).—In two series, each of three experiments, Ladureau employed (1) beer alone, and beer mixed respectively with (2) 4 and (3) 8 grams of salicylic acid per hectolitre. The three beers were exposed to the air (during spring in one case, and in the second series during summer) for two weeks and subsequently closed up for a month, after which period they were examined:—beer (1) was very sour; beer (2) only slightly; beer (3) not at all. To complete the investigation, the salicylated beer was employed for dietetic purposes for several weeks without any deleterious effect on the health of the experimenter. Therefore the addition, at most, of 10 grams of salicylic acid per hectolitre preserves the beer without affecting its use as a beverage. 50 to 80 milligrams of salicylic acid per litre is sufficient to prevent wine turning sour. The author therefore defends the use of salicylic acid, and maintains that a prejudicial amount would never be added owing to the facility with which salicylic acid may be accurately estimated. D. A. L.

Method of Testing Butter for Foreign Fats. By H. Beckurts (*Dingl. polyt. J.*, **251**, 240).—The author has tested butter in accordance with Reichert's method. 2·5 grams of the dried fat were saponified with 1 gram of potassium hydroxide and 20 grams of 80 per cent. alcohol. The mixture was heated on a water-bath to expel the alcohol; it was then diluted with 50 c.c. of water, and, as soon as the soap had dissolved, 20 c.c. of dilute sulphuric acid (1 acid to 10 vols.) were poured in and the mixture distilled, a platinum spiral being introduced to avoid bumping. The distillation was continued until exactly 50 c.c. were obtained. In the case of genuine butter, Reichert found that 14 c.c. of decinormal soda-solution were required to neutralise the distillate, but the author had to employ from 15·6 to 17·5 c.c., and concludes therefore that Reichert's numbers were too low. He also states that in order to obtain concordant results it is necessary to adhere strictly to the above proportions. D. B.

Analysis of Beeswax. By O. Hehner (*Dingl. polyt. J.*, **251**, 168—170).—The author dissolves 3 to 5 grams of beeswax in about 50 c.c. of methyl alcohol and titrates the cerotic acid with phenolphthaleïn and a solution of alcoholic potash, 1 c.c. corresponding with 0·3—0·4 c.c. of normal sulphuric acid. Having added potash in excess, the myricin is saponified and calculated from the quantity of potash required for the complete saponification, assuming that 1 c.c. normal alkali neutralises 0·41 gram cerotic acid and decomposes 0·676 gram myricin. The author obtained the following results:—

	Cerotic acid.	Myricin.	Total.

The English wax contained an average of 14·4 per cent. cerotic acid and 88·09 per cent. myricin. The foreign kinds were mostly coloured, and some had been adulterated with fat. The organic adulterants are either acids, palmitic or stearic acid; inert or saponifiable substances, stearin, palmitin, Japanese wax, spermaceti and carnauba wax; or substances which are not acted on by alcoholic potassium hydroxide, paraffin. 1 part stearic acid = 1·443 cerotic acid; 1 part palmitic acid = 1·601 cerotic acid, whilst 1·518 of the latter is equal to 1 of a mixture of these fatty acids. 1 part of a mixture of palmitin and stearin is equal to 2·391 myricin. Japan wax contained 6 21 per cent. palmitic acid and 94·12 per cent. palmitin. Spermaceti being as costly as beeswax is sometimes used as a substitute. Carnauba wax yielded 6 09 per cent. cerotic acid and 92·18 per cent. myricin. It is added to beeswax when the latter has been treated with fat. When paraffin is employed, the percentage of acid and saponifiable matter is reduced in proportion to the quantity of paraffin present, and can be calculated by difference unless other adulterants have been used, in which case it is necessary to determine the paraffin. If A is the percentage of free acid calculated as cerotic acid, and B the unsaponifiable substances calculated as myricin, we obtain the following equation, assuming x to represent the unknown quantity of cerotic acid, y that of the fatty acids, z of myricin, and w of the remaining substances:—$x = 25{\cdot}649 - (0{\cdot}1689\mathrm{A} + 0{\cdot}1073\mathrm{B})$. $x + 1{\cdot}518y = \mathrm{A}$; $z = 6{\cdot}117\,x$, and $z + 2{\cdot}391w = \mathrm{B}$. On multiplying the quantity of cerotic acid by 6·117, we obtain the amount of myricin which when added to the former gives the percentage of wax. A mixture of 79·98 per cent. wax and 20·02 fat gave 11·30 per cent. cerotic acid, 69·12 myricin, 0·46 fatty acids, and 19·07 fat corresponding with 80·42 per cent. wax and 19·53 per cent. fat.

The sp. gr. of beeswax varies from 0·9625 to 0·9675. Paraffin and fat are lighter than beeswax, whilst the fatty acids and resin increase the sp. gr. of beeswax. D. B

Technical Chemistry.

Consumption of Fuel for Heating Boilers. By SCHEURER-KESTNER (*Dingl. polyt. J.*, **251**, 278—283).—A reply to Bunte, who criticised the author's results on the heat of combustion of coal.

P. P. B.

Self-purification of Peaty Waters. By W. N. HARTLEY (*Bied. Centr.*, 1883, 433—435).—Tidy refers the loss of organic matter which peaty water suffers to oxidation. The author quotes experiments made by himself which corroborate the statements of others, that the amount of organic matter which is oxidised is but small. With the theory that the organic matter is carried down by suspended mineral matter, the author cannot fully concur, for although sandy clay and sand did not decolorise the water, yet magnesia and chalk had some action. Good results were obtained by the use of very hard spring-water, still better with aluminium sulphate, and the best by employing aluminic, ferric, and manganic hydroxides. E. W. P.

Analysis of a Pit-water. By O. ARCHE and C. HASSACK (*Dingl. polyt. J.*, **251**, 132—135).—This water was drawn from the lignite mines at Wolleschnick in the domain of Frauenburg in Bohemia. The object of its examination was to ascertain whether it was serviceable as a feed-water for fish-ponds. The water had a dark-brown colour from the presence of much suspended matter. After filtration its colour was a pale yellow. 100,000 parts yielded 55·8 suspended matter composed of 24·4 inorganic and 31·4 organic matters. The former contained silicic acid, alumina, ferric oxide, lime, magnesia, sodium, and potassium silicates. The organic matter consisted mainly of coal.

100,000 parts of this water contained:—

Solid residue	20·51 parts
Residue after ignition	16·80 „
Total hardness	4·57°
Permanent hardness	1·78
Temporary hardness	2·79

From the results of the analysis given in the original paper, the authors are of opinion that the water is not suitable for the above purpose; a large proportion of organic matter is objectionable, since it would absorb the oxygen dissolved in the water and deprive the fish of this essential constituent. D. B.

Preparation of an Antiseptic Compound. By C. ASCHMANN (*Dingl. polyt. J.*, **251**, 143).—For the preparation of this substance, called "antibacteride," the author heats 338 parts borax with 198 glucose, in the presence of a small amount of water. When the fusion is complete, he adds 124 parts boric acid, whilst constantly stirring, until it has been dissolved, and causes the liquor to evaporate at a gentle heat until a sample of it solidifies when run on a cold plate. The resulting mass is soft and translucent, forming an antiseptic suitable for the preservation of provisions. Its composition is represented by the formula $C_6H_{12}O_6,Na_2B_4O_7,3H_3BO_3$. D. B.

Use of Boric Acid for Preserving Food. By J. FORSTER (*Dingl. polyt. J.*, **251**, 170—172).—From a series of experiments made with a view to determine the action of boric acid on the animal system, the author draws the following conclusions: The admission of boric acid as addition to food, even in very small doses, is injurious to the digestive organs. This injurious action depends on the circumstance that boric acid acts so as to materially increase the proportion of solid matters and nitrogen in the fæces separated. It is also a remarkable coincidence that the action of boric acid on the intestinal discharge is well marked, even by the exhibition of as little as 0·5 gram per diem. Moreover, this action is in direct relation to the quantity of acid taken, and is maintained for some time after the doses of acid have ceased. The action described is perceptible, not only with vegetable or animal foods, which contain a large proportion of indigestible ingredients, but also when highly digestible food, such as milk and eggs, is taken. Food to which boric acid has been added tends to cause an increase in the secretion of gall during assimilation. Its most important action, however, is the increase which it causes in the discharge of albuminous substances from the intestinal canal. From this it is evident that its use as a food preservative is not as beneficial as hitherto assumed. D. B.

Process for Converting Liquid Mineral Acids into a Solid Form by the Addition of Kieselguhr. (*Dingl. polyt. J.*, **251**, 96.) According to an invention patented by Vorster and Grüneberg, acids are mixed with kieselguhr or asbestos with a view to facilitate their transport. A mixture of 4 parts acid and 1 of kieselguhr forms a paste, which can be used for some operations without re-separation, *e.g.*, sulphuric acid for the purification of paraffin and the preparation of carbonic anhydride for mineral water making. D. B.

Utilisation of Phosphatic Slags. By C. Scheibler (*Dingl. polyt. J.*, **251**, 191).—In order to oxidise the ferrous and manganous oxides in the slags from the basic process into ferric and ferrosoferric, manganic and manganosomanganic oxides, and effect the decomposition of the sulphides, the author subjects the slag in pieces of fist-size to a careful roasting process in the presence of an abundant supply of air. The slag is then treated with water or steam, when, owing to the conversion of calcium oxide into calcium hydroxide, an extremely fine powder is obtained. By this treatment the slag is obtained in a more finely divided state than by mechanical means, *i.e.*, pulverisation in disintegrators or other grinding machines.

D. B.

Process for Preparing Dichromates. By T. Roemer (*Dingl. polyt. J.*, **251**, 192).—100 parts chrome ore are fused with 150 lime, 40 potash, and 30 soda. The melt is lixiviated with water, and the resulting liquor of potassium and sodium chromate treated with sulphuric or hydrochloric acid, the requisite amount of acid being calculated in accordance with the equation $K_2Na_2Cr_2O_8 + H_2SO_4 = K_2Cr_2O_7 + Na_2SO_4 + H_2O$. Potassium dichromate is formed, together with sodium sulphate, which is separated by evaporation.

D. B.

Utilisation of the Waste Waters from Wool Washing Works. (*Dingl. polyt. J.*, **251**, 230.)—Referring to Fischer's process for lixiviating wool with water, and evaporating the resulting liquors for the recovery of potash, it is stated that 100 kilos. of wool produce 80 liters of liquor of 10° B. 100 liters of this liquor give 6·5 kilos. residue by evaporation containing about 70 per cent. potash.

Delattre evaporates the liquors to a density of from 10 to 12° B., and fuses the residue. The resulting crude potash contains

K_2CO_3.	K_2SO_4.	KCl.	Na_2CO_3.	Insoluble.	Loss.
80	6	4	3	5	2

After the extraction of the suint the wool is washed, the resulting soap waters being treated with hydrochloric acid and ferric chloride for the recovery of the fatty acids.

According to Braun, the separation and purification of suint is effected by treating the sweat of wool with water. Thus a compound called "lanoline" is obtained, which when heated splits up into suint and water. Suint is suspended in the wool washings in the form of lanoline, and is separated by passing the wash waters through hydro-extractors. The mass is purified by washing it with water, heating and decanting the fat; by rinsing the latter with water, white lanoline is obtained. With water, commercial suint forms sodium carbonate or hydroxide, soap, and a milky substance from which lanoline is obtained when the mixture is subjected to the above treatment.

Lortzing precipitates the suint from wool wash-waters with lime and ferrous sulphate, and utilises the resulting sludge for the preparation of bituminous cement. The pressed sludge is dried, ground, mixed with 15 per cent. suint, and heated to 200°, after which it is treated with an equal weight of calcium carbonate. D. B.

Influence of Titanic Acid on the Fusibility of Refractory Earths. By H. Seger (*Dingl. polyt. J.*, **251**, 94).—100 parts of Zettlitz kaolin of 98·5 per cent. purity were mixed with from 5 to 10 per cent. of silicic acid on the one hand, and an equivalent amount of titanic acid on the other hand. The mixture was formed into small cones and exposed in Deville's blast furnace to a temperature between those at which wrought iron and platinum melt. Treated in this manner, the kaolin gave a white hard mass of well-defined form, translucent at the edges, and with a dull surface. 100 parts kaolin mixed with 5 parts silicic acid gave a well-defined form, snow-white in colour, somewhat porous, translucent at the edges, dull surface, and giving on fracture a porcelain-like appearance. A mixture of 100 parts kaolin with 10 parts silicic acid gave a similar result, but a more porous product on fracture resembling porcelain still more closely. The cone composed of a mixture of 100 parts kaolin with 6·65 titanic acid had a bluish-grey glazed surface, and proved on fracture to have thoroughly sintered together. 100 parts kaolin, mixed with 13·3 titanic acid, fused completely to a dark bluish-grey bead of enamel.

Hence the presence of titanic acid has an influence on the fusibility of refractory clays which is exactly the reverse of that which silicic acid exerts, the conditions of temperature being the same. It is therefore important to take into consideration the amount of titanic acid present in earths to be employed as refractory materials. It is not improbable that the bluish-grey colour which some clays develop when heated very strongly is due to the presence of titanic acid.

D. B.

Process for Preparing Ochre Colours. By S. H. Cohn (*Dingl. polyt. J.*, **251**, 240).—The author obtains ochre pigments by treating a mixture of lead oxide and chloride with nitric acid, aluminium sulphate, and potassium dichromate. He then adds water, and introduces sulphuretted hydrogen into the mixture until the desired tint is obtained. D. B.

Application of Electricity in Chemical Industry. By F. Fischer (*Dingl. polyt. J.*, **251**, 28—32).—The practical difficulty of utilising electricity for metallurgical purposes has been its cost of production, although since the introduction of dynamo-machines the application of electricity in metallurgy has made more progress.

According to Kohlrausch, a current of 1 weber deposits 6·779 mgrms. of silver per minute, whilst 1 ampère (= 10 webers) corresponds to 3·96 grams silver per hour in a cell. For practical purposes it may be assumed that a current of 100 ampères deposits 1 mgrm.-equivalent of the various substances per second. Thermochemical researches have, however, given different values to the various compounds, *e.g.*:—

Reaction.	Heat of formation of the compound.	Heat of solution of the compound.	Heat of formation in aqueous solution.
$Zn.Cl_2$	97,210	+15,630	112,840
$Cd.Cl_2$	93,240	+ 3,010	96,250
$Cu_2.Cl_2$	65,760	—	—
$Cu.Cl_2$	51,630	+11,080	67,710
$Hg.Cl_2$	63,160	− 3,300	59,860
$Au.Cl_3$	22,810	+ 4,450	27,260
$Sn.Cl_2$	80,790	+ 350	81,140
$Sn.Cl_4$	127,240	+29,920	157,160
$Zn.O.SO_3.Aq$	—	—	106,090
$Cu.O.SO_3.Aq$	—	—	55,960
$Ag_2.O.N_2O_5.Aq$	—	—	16,780

Kiliani is of opinion that the electromotive force of a Daniell's element is equivalent to the difference of the thermal values corresponding with the chemical processes involved therein, *i.e.*, 106,090 − 55,960 = 50,130 cal. Assuming that the E.M.F. of a Daniell's element is equal to 1·12 volts, 1 volt would be equal to 44,760 cal., and it would therefore be possible to calculate the E.M.F. from the thermal units, *e.g.*:—

Compound.	Calorific value.	E.M.F. calculated therefrom.
$Ag_2.O.N_2O_5.Aq$	16,780	0·37 volt.
$Ag_2.O.SO_3.Aq$	20,390	0·46 „
$Cu.O.N_2O_5.Aq$	52,410	1·17 „
$Cu.O.SO_3.Aq$	55,960	1·25 „

The deposition of pure silver from a mixed solution of the sulphates or nitrates of silver and copper would be effected by the use of an E.M.F. of 1·17 and 1·25 volts respectively. Braun has, however, shown that a part only of the heat of combination is transformed into current energy; whilst Jahn found that in spite of the different amounts of chemical work which must be supplied by the current for the decomposition of, *e.g.*, zinc and copper sulphates, the entire loss of energy in the circuit is the same in both cases, for in the deposition of 1 kilo. copper and 1 kilo. zinc, 1807 and 977 cal. are developed, corresponding with—

	Free heat.		Chemical work.		
$ZnSO_4$....	63,216 cal.	+	106,090 cal.	=	169,306 cal.
$CuSO_4$....	114,744 „	+	55,960 „	=	170,704 „

The total amount of electricity abstracted from the battery during the decomposition was equal to 170,000 cal. (approximately). When no chemical work is done, that is, when the platinum electrodes are replaced by zinc and copper electrodes, the amount of heat liberated in the decomposition of $CuSO_4$ is equal to 78,994 cal., and in the case of $ZnSO_4$ to 79,916 cal.

According to Kiliani, the following ores are good conductors of electricity:—Tin ore, silver glance, red silver, galena, copper glance, purple copper, copper pyrites, sulphuretted ores of nickel and cobalt, and iron pyrites. The following are bad or non-conductors:—Grey antimony ore, tin pyrites, white lead ore, red copper ore, malachite, lasurite, grey copper ore, blende, and calamine. D. B.

Investigations on the Welding of Iron. By E. P. BOEHME (*Dingl. polyt. J.*, **251**, 71—77).—In 1880 the German Society for Promoting Technical Industry appointed a commission to inquire into the capacity of different kinds of iron for welding. The author now gives an account of the experiments which were made, and of the results which were obtained. The samples of iron experimented with were prepared from the same material (ingot iron from the Gutehoffnungs Hütte), and consisted of a series of unwelded and welded round bars. Experiments were made also with bars from ordinary Silesian iron.

The subjoined table (p. 787) gives the results of the investigation.

In comparing these results with the chemical constitution, the following conclusions are arrived at:—The molecular adjustment of iron has a much greater influence on its capability of being welded than the amount of carbon present. This property of iron increases with the amount of silicon, and decreases with that of the manganese present. This is due to the fact that during the oxidation in the welding operation the silicon produces a slag which dissolves the resulting ferrosoferric oxide. In the case of ingot iron, it was found that the amount of silicon was the same before and after welding, and it is not improbable that the modified condition in which this element is present in ingot iron explains this want of influence on the welding property. Whilst Ledebur supposes that the total amount of foreign constituents in unwelded iron is about 70 per cent. greater than in welded iron, the results of the present investigation show that the percentage of silicon, phosphorus, carbon, and manganese in the harder kinds of ingot is 0·717, in the softer kinds 0·423, and in weld iron 0·520. According to Reiser the welding of iron is influenced by the chemical constitution, inasmuch as its molecular condition, that is, the property of crystallising, depends thereon.

Properties.	Hard ingot iron.		Soft ingot iron.		Silesian weld iron.	
	Not welded.	Welded.	Not welded.	Welded.	Not welded.	Welded.
Tensile strength (kilos. per sq. mm.)	50·7	29·4	45·4	32·2	40·7	33·1
Expansion in per cent., calculated—						
1. On 100 mm., *i.e.*, 50 mm. on each side of the fractured place	24·6	3·7	29·9	5·8	26·1	8·1
2. On 200 mm., *i.e.*, 100 mm. on each side of the fractured place	20·8	3·2	25·1	5·1	22·2	7·7
Transverse contraction in per cent. of the original diameter.....	34·9	4·5	44·7	10·5	39·5	14·0

In conclusion, it is recommended to abstain from welding ingot iron, as it can be cast with ease into any form or size. D. B.

Evolution of Gas from Steel Castings. By F. MÜLLER (*Dingl. polyt. J.*, **251**, 83—91).—Contrary to Pourcel's assumption that the gas evolved from steel castings consists of carbonic oxide, the author found only hydrogen and nitrogen in the occluded gases given off from steel ingots. Pourcel has, however, recently shown that the gas evolved during the solidification of steel contains the more hydrogen the richer the metal is in manganese. The author is of opinion that the rising of steel in the mould is due to the presence of hydrogen, whilst the frothing and crackling is attributed to the absorption of carbonic oxide, which escapes in the form of bubbles of gas when the fluid metal has been reduced to the solidifying temperature. The basic metal, without any addition, contains mainly hydrogen and nitrogen, and small quantities of absorbed carbonic oxide, hence it is more quiescent in the mould, although it shows a great tendency to rise. Carbonic oxide is formed on adding spiegeleisen or ferromanganese, and the steel being saturated with the gas, then froths up, and emits gas bubbles until it begins to solidify, when hydrogen is again evolved. When silicide is added steel may be formed without the evolution of carbonic oxide. Whilst the author assumes that silicon augments the solubility of the gases in steel, and Pourcel supposes that it diminishes or annuls it, Brustlein is of opinion that silicon and manganese render the steel more porous, so that the gases are better able to pass through the mass of cast metal.

In conclusion, it is stated that if the formation of bubbles is attributed to the presence of hydrogen, it is essential to conduct the final operation in connection with the casting of steel in dry air; on the other hand, if carbonic oxide is the gas evolved, the decomposition should be effected by silicon, which will destroy the bubbles.

D. B.

Zinc from Pyrites Residues. By M. J. Creutz (*Chem. News*, **49**, 62—63).—In one process for recovering the zinc from pyrites residues, the burnt ore is lixiviated, the lixivium concentrated to crystallising point, mixed with sodium chloride in quantity equal to the zinc sulphate dissolved, whereupon sodium sulphate is deposited. When the concentration reaches 50° B., various ferrous and sodium sulphates separate out, and zinc chloride remains in solution. None of these separations are sharply indicated, nor are the reactions as simple as they appear, and therefore the dry residue from the last solution contains about 85 per cent. zinc chloride and 15 per cent. sodium salts. It is for this reason unsuitable for the preservation of wood; it can, however, be used with advantage for the preparation of zinc hydroxide to be used in desulphuring alkaline lyes; for this purpose it is simply necessary to treat with milk of lime, and separate and wash the precipitated zinc oxide.

In another process, the burnt ores are exposed to the air in order to further oxidise the iron, manganese, and sulphurous acid; they are then systematically extracted in a series of tanks, so that the final solution is of 20° B., contains scarcely any iron and only traces of manganese and cobalt. This is mixed with calcium chloride solution 15° B., and the calcium sulphate separated; the filtrate (10° B.) is evaporated, chloride of lime added to precipitate the manganese and cobalt, and at 48° B. the whole of the calcium sulphate separates and the solution contains zinc chloride mixed with a small quantity of sulphate. This process yields a zinc chloride applicable to all purposes; but it has the drawback of being very dilute, and does not produce any saleable byeproduct like the sodium sulphate in the above process. The removal of zinc and sulphur from the burnt ore increases its value for subsequent metallurgical treatment.

Process for Preparing Hydrocarbons. By E. Heusser (*Dingl. polyt. J.*, **251**, 192).—For the preparation of low-boiling hydrocarbons, the author subjects coal to destructive distillation and the simultaneous action of gaseous chlorine and hydrochloric acid gas. High-boiling hydrocarbons are obtained by subjecting a mixture of coal and zinc chloride, or coal, coal-tar, and zinc chloride, or coal, coal-tar oil, and zinc chloride, to destructive distillation in a current of hydrochloric acid gas.

D. B.

Products of the Dry Distillation of Wood at Low Temperatures. By C. F. Mabery (*Amer. Chem. J.*, **5**, 256—263).—Three samples of crude methyl alcohol, prepared in the manufacture of acetic acid by the dry distillation of wood at low temperatures, were examined; they were collected (*a*) at the beginning of the distillation, (*b*) after several hundred gallons had distilled, and (*c*) when the distillation of methyl alcohol was well advanced. These samples were subjected to fractional distillation. The most volatile portion in each case was proved to be acetaldehyde. The fraction boiling at 25—40° from (*a*) was shown to contain methyl formate, which has not hitherto been recognised as a constituent of wood-spirit; the presence of methylal could not be determined. The fraction 50—54° from (*a*) gave reactions for aldehyde and acetone, and fractions 54—56° from (*a*) and from (*b*) were nearly pure methyl acetate. The bulk of the methyl alcohol was found in fraction 65—68° from (*c*). Dimethylacetal could not be detected. The amount of acetone—which affects the value of wood-spirit for preparing dimethylaniline—was determined in several portions by Kramer's method; the amount found varying from 1·04 to 3·41 per cent., is smaller than is usual in wood-spirit. Allyl alcohol could not be detected. For want of material, the high boiling oils were not completely examined; they contain furfuraldehyde, pyroxanthine in small quantity, as also methyl ethyl ketone and allyl acetate. H. B.

Pasteurising Barrelled Beer. By G. BEHREND (*Bied. Centr.*, 1883, 502).—The principal points to be observed are the following:—Filter off the albuminous matter, which separates while the beer is heating, and run the hot beer under pressure direct into the storage vessel, avoiding contact with the air, in order to prevent the introduction of deleterious germs. The author prefers to employ barrel-shaped glass carboys. The filling under pressure is an important factor, as the pressure subsequently increases in the closed vessel, and helps to preserve the beer. D. A. L.

Fermentation Experiments with Gluten instead of Diastase in the Mash. By G. HEINZELMANN (*Bied. Centr.*, 1883, 503).—150 grams of rye-groats were made up to 1 litre with water warmed at 60° C. for one hour, then cooled to 30°, and mixed with 20 grams compressed yeast containing starch, for fermentation. In almost all experiments, a large amount of acid was formed. In two cases, when sulphuric acid had been added, the quantity of acid produced was very small; the fermentation, however, was very weak. In fact, the action of gluten on starch was almost completely destroyed.
D. A. L.

Mashing Temperature and the Favourable Temperature for Yeast Sowing. By STENGLEIN (*Bied. Centr.*, 1883, 503).—The practical results of the author's experiments are in brief:—For mashing good malt, 61·25° is recommended, and for bad and injured malt 61·25—65°; the temperature should not systematically increase either during mashing or fermenting. A temperature of 61·25° kills globular bacteria, and consequently prevents formation of liquid acids. The most favourable temperature for the production of lactic acid is 45—61·25°, and the presence of a sufficient quantity of this acid in the yeast stops the development of butyric acid. The favourable temperature for sowing yeast is 50°. D. A. L.

Strong Yeast. By G. HEINZELMANN (*Bied. Centr.*, 1883, 502—503).—In this note, the following scheme is described for the preparation of a very active and durable yeast. For this purpose a large vat

(2900 litres capacity), 2 barrels (154 litres capacity), and a cask (34 litres capacity) of yeast are required. In the afternoon, a mash is prepared in one of the barrels from 25 kilos. of green malt and hot water: the following morning another mashing is made in the second barrel with 12·5 kilos. green malt, 2 buckets of the preceding mash, and hot water. The first mashing is continued until the following morning, when it is somewhat sour, the second until 1 o'clock (night). The former is thoroughly well mixed at 8 P.M. with the yeast, and the yeast-cask is refilled with the mixture, which in its turn is added to the contents of the second barrel at 4 A.M. The yeast is removed at 7 A.M. from the first barrel, the contents of both barrels are then mixed together, and distributed equally over it. The yeast then remains until the fresh mash is cooled for mixing.

D. A. L.

Utilisation of Malt Combings in the Manufacture of Pressed Yeast. By L. HAYDUCK (*Dingl. polyt. J.*, **251**, 287).—100 grams malt combings are boiled in water for half an hour, and filtered. The filtrate is treated with 100 grams sugar, and diluted to 1 litre. 10 grams pressed yeast (containing 78·35 per cent. moisture) are then added. The mixture is allowed to ferment at 17·5°. The nitrogen before fermentation was equal to 0·0947 per cent., whilst after fermentation it amounted to 0·0474 per cent., so that 50 per cent. had been assimilated by the yeast. The weight of yeast after fermentation was 39·7 grams, hence 29·7 grams had been newly formed.

D. B.

Nitrogenous Constituents of Barley and Malt. By C. LINTNER (*Dingl. polyt. J.*, **251**, 225—228).—The author is of opinion that the total amount of nitrogen in barley or malt bears no relation to the diastatic action. The quantity of soluble albumin, however, is of some value in determining this point. By assuming that the soluble albuminous nitrogen belongs to the diastase—an hypothesis which is quite justifiable—and that the diastase is closely related to the albuminoïds (so that on multiplying by 6·25 we obtain nitrogen corresponding to diastase), the quantity of diastase in malt amounts to about 2 per cent. on the dry substance. 1 part of diastase is capable of converting 400 parts of starch into sugar in 20 minutes. In practice the following proportions hold good:—100 parts dry malt substance corresponding to 166 green malt containing 40 per cent. moisture contain 2 parts diastase capable of saccharifying 800 parts starch in 20 minutes. 166 parts green malt convert 800 parts starch into sugar, or 0·2075 converts 1 of starch. When potatoes containing 18 per cent. starch are used, the saccharification of 18 kilos. starch from 100 kilos. potatoes would require the addition of $(18 \times 0{\cdot}2075) = 3{\cdot}735$ kilos. malt exclusive of the quantity necessary for the preparation of yeast.

D. B.

Refining of Sugar and Molasses by Means of Concentrated Acetic Acid. By A. WERNICKE (*Bied. Centr.*, 1883, 502).—Pure sugar scarcely dissolves in concentrated acetic acid, whilst all the impurities of cane-sugar are readily soluble in it. In the present process, dry cane-sugar is heated at about 70° in closed vessels with

50—70 per cent. of its weight of concentrated acetic acid or molasses concentrated to 45—50° B. with 75 to 90 per cent. When cool the acetic acid is poured off, and the sugar machined and dried, when it is ready for the market. The acetic acid is recovered by distillation.

D. A. L.

Loss in the Beet-sugar Manufacture. (*Bied. Centr.*, 1883, 491—492.)—In grating the beets previous to pressing, lumps and clots form, which are not sufficiently pressed in the subsequent operation. This occasions a loss of sugar of considerable monetary value. It is therefore advisable to rub the material from the press through a sieve, sprinkling water over it, repressing the portions which run through, and also to break up the lumps and repress them when disintegrated.

D. A. L.

Purification of Saccharine Juices. (*Dingl. polyt. J.*, **251**, 191.) Schott treats beet-juice with a solution of potash-water glass, and heats the mixture. He then adds sulphurous acid, and completes the neutralisation with dilute sulphuric acid. The filtrate is treated with 1·82 parts of gypsum to 1 part of potassium hydroxide contained therein; it is then evaporated to a syrupy consistence and filtered. After standing for some time, the sugar crystallises out completely from the solution.

Eachrau recommends the treatment of saccharine juices with from 0·5—6 per cent. manganous oxide, manganic dioxide, manganese sulphate, &c. Allow to settle, filter, add about 5 per cent. lime, remove the excess with carbonic anhydride or sulphurous acid, filter through animal charcoal, and evaporate. D. B.

The Working of a Sugar Refinery. By G. Stade (*Dingl. polyt. J.*, **251**, 127—132).—The author gives a detailed account of a year's working of a sugar refinery, which dealt with raw sugar from the district of Magdeburg and Brunswick. The total quantity of crude sugar which was worked up during that period amounted to 5777·3 tons, the average composition being:—

		In 100 parts of dry substance.	To 100 parts sugar.
Sugar	96·39	97·96	—
Water	1·60	—	—
Non-saccharine matter..	2·01	2·04	2·09
Ash contained therein ..	0·99	1·01	1·03

Of this quantity 1878·9 tons were worked up in the crude form, whilst 3898·4 tons were machined. The first and second products of the refinery were filtered through 10,583 tons of animal charcoal, 18 32 tons being used for 10 tons of crude sugar. The charcoal had the following composition:—

H_2O.	C.	Insoluble in HCl.	$CaCO_3$.	$CaSO_4$.	CaS.	Undetermined.
1·93	6·23	0·72	8·16	0·45	0·03	82·48

When heated with potash it yielded a solution having a pale yellow colour. After use it was boiled out on the filters with soda-ley, or a mixture of soda and ammonia. The boilers were worked with Westphalian coal, containing 1·9 per cent. of water and 10·8 per cent. ash. The consumption of fuel was 144·7 parts for every 100 parts of crude sugar passed through the works. This large amount is due to inferiority of the coal and defects in the plant and machinery.

The following statistics are given as to the actual working of the refinery:—

Candy, white and half white	975·579	tons or	16·98	p.c. on the	raw sugar.
Candy, yellow and dark yellow	87·981	,,	1·52	,,	,,
Lump sugar, in loaves of 12·5 k.	1424·615	,,	24·66	,,	,,
Lump sugar, crushed	1591·965	,,	27·55	,,	,,
Lump sugar, in cubes	1021·250	,,	17·68	,,	,,
Brown sugar	118·667	,,	2·06	,,	,,
Osmose water, concentrated	81·000	,,	1·40	,,	,,
Syrup	316·250	,,	5·47	,,	,,
Total mass	5617·307	,,	97·23	,,	,,

By deducting this sum from the total amount of raw sugar passed into the works, *i.e.*, 5777·3 tons, a loss of 159·993 tons, or 2·77 per cent., is obtained. In order to determine the loss of sugar and non-sugar, the following figures are given:—

	Sugar.	Ash.	Non-sugar.
Candy	1063·560 tons	—	—
Lump sugar	4037·830 ,,	—	—
Brown sugar	109·767 ,,	2·136 tons	3·560 tons
Osmose water	34·115 ,,	15·236 ,,	18·290 ,,
Syrup	179·029 ,,	30·961 ,,	53·320 ,,
Passed out of refinery	5424·300 ,,	48·333 ,,	75·170 ,,
Passed through works	5568·700 ,,	57·195 ,,	58·929 ,,
Difference	−144·400 ,,	−8·862 ,,	+16·241 ,,

The loss of pure sugar was—

In the charcoal	28·786 tons
In the sweet waste water	37·430 ,,
In other operations	78·222 ,,
Total loss	144·438 ,,

For every 100 parts of loss—

19·33 took place in the animal charcoal,
25·92 in the sweet waste water, and
54·15 in other stages of the process.

The loss in 100 parts of pure sugar was 2 59 or 2·50 in 100 parts of raw sugar. Of the mineral constituents, a loss of 8·862 tons took place, which amount passed out of the refinery in the processes of filtration.

The following numbers will give a clear idea of the actual yields obtained:—

Produced.

5101·390	tons	refined sugar	+ 97·900	tons from brown sugar.
81·000	„	osmose water	+ 3·314	„ „
316·250	„	syrup	+ 13·299	„ „
159·993	„	loss	+ 4·154	„ „

Yield.

Refined sugar	5199·290 tons,	or 90·00 per cent.
Osmose water	84·314 „	1·46 „
Syrup..............	329·549 „	5·70 „
Loss	164·147 „	2·80 „
Total weight of raw sugar converted	5777·300 tons.	

If the syrup and osmose water be brought under the one heading of syrup, we obtain 90·00 per cent. refined sugar, 7·16 per cent. syrup, and 2 84 per cent. loss.

Yield obtained from the pure sugar contained in the raw sugar passed into the works:—

5199·290 tons refined sugar at 100 per cent. pure sugar	5199·290 tons.
84·314 tons osmose water at 42·13 per cent. pure sugar	35·522 „
329·549 tons syrup at 56·61 per cent. pure sugar	186·558 „
Total obtained	5421·370 „
Pure sugar contained in raw sugar	5568·739 „
Loss of polarising substance......	147·369 „

Hence the yield for 100 parts of pure sugar was 93·366 refined sugar, 0·638 osmose water, 3·346 syrup, and 2·650 loss, or by calculating osmose water and syrup as syrup, 93·366 refined sugar, 3·984 syrup, and 2·650 loss, or by regarding the osmose water as loss, 93·366 refined sugar, 3·346 syrup, and 3·288 loss. D. B.

Bleaching Flax and Hemp Tissues. (*Dingl. polyt. J.*, 251, 228.)—According to Delabove, the threads or tissues are subjected to successive boilings in alkaline liquors to remove pectinic substances from the cellulose. They are then passed through a solution of chloride of lime and a solution of aluminium sulphate, saturated with aluminium hydroxide. If required perfectly white, they are boiled in soap solution and ammonia, and subjected to a second treatment.

D. B.

Contributions to the Chemistry of Mordants. By L. LIECHTI and W. SUIDA (*Dingl. polyt. J.*, 251, 177—185).—The authors have investigated the dissociation ratios of the most important salts of alumina and ferric oxide used as mordants. The normal and basic sesquioxide salts of one and the same acid, as well as various acids (*e.g.*, thioacetates), were experimented with, and in speaking of dissociation, the authors mean decomposition which is observed externally, and characterised by the separation of an *insoluble* compound. Two expedients were adopted to produce this result: Dilution with water, and heating the respective aqueous saline solutions. It is thought that the following data will be of great service to the dyeing and printing industry.

To study the behaviour of aluminium sulphates, the compounds $Al_2(SO_4)_2(OH)_2$ and $Al_4(SO_4)_3(OH)_6$ were examined, in addition to the normal sulphate. They were obtained by deoxidising the normal salt with Na_2CO_3 or $NaHCO_3$, so that sodium sulphate was simultaneously present in the solutions. Concentrated solutions were composed of 200 grams $Al_2(SO_4)_3$, whilst dilute solutions contained 150 grams of the normal salt. $Al_2(SO_4)_3$ is not altered by dilution with water or when heated. $Al_2(SO_4)_2(OH)_2$ in concentrated solutions remains unaltered when heated, whilst in dilute solutions it splits up after being boiled for half an hour, a permanent precipitate being formed. $Al_4(SO_4)_3(OH)_6$ is decomposed in concentrated solutions at 65°, and in dilute solutions at 55°, with the formation of permanent precipitates. At 100° both solutions are gelatinised. In mordanting, drying, and ageing the following quantities of alumina are retained in an insoluble form by the fibre: $Al_2(SO_4)_3$ 13 per cent., $Al_2(SO_4)_2(OH)_2$ 51 per cent., and $Al_4(SO_4)_3(OH)_6$ 58 per cent.

To investigate the behaviour of aluminium sulphacetates, the following salts were prepared from the normal sulphate:—$Al_2SO_4\overline{Ac}_4$ by means of lead acetate, $Al_2SO_4\overline{Ac}_3(OH)$ by means of lead acetate and sodium carbonate, $Al_2SO_4\overline{Ac}_2(OH)_2$ by means of lead acetate and sodium bicarbonate, and $Al_2SO_4\overline{Ac}(OH)_3$ by means of lead acetate and acetic acid. The salts are gelatinised at 100°. The first is decomposed at 89° in concentrated solutions, whilst the dissociation of the other salts depends on the extent of their basicity, the last salt decomposing at 48° in concentrated solutions, and at 40° in dilute solutions. In mordanting, drying, and ageing nearly the whole of the alumina contained in these salts is retained by the fibre in an insoluble form.

In the next place, the authors studied the action of aluminium acetates, the normal salts being prepared from aluminium sulphate and lead acetate. The basic salts were obtained by the addition of sodium bicarbonate to the normal acetate. The solutions contained 200 grams $Al_2(SO_4)_3 + 18H_2O$ in 1 liter. $Al_2\overline{Ac}_6$ is not decomposed when heated. $Al_2\overline{Ac}_5OH$ is split up when boiled for a short time, and at 100° yields a permanent precipitate. $Al_2\overline{Ac}_4(OH)_2$ is decomposed at 74°, $Al_2\overline{Ac}(OH)_3$ at 56°, and $Al_2\overline{Ac}_2(OH)_4$ at 44°. The salts are not altered when diluted with water. The compound,

$$Al_2\overline{Ac}_4(OH)_2,$$

when prepared from the normal sulphate by the addition of lead acetate and sodium carbonate, according to the equation—

$$[Al_2(SO_4)_3 + 18H_2O] + 2[Pb\overline{Ac}_2 + 3H_2O] + Na_2CO_3 + H_2O = 2PbSO_4 + Na_2SO_4 + CO_2 + 24H_2O + Al_2\overline{Ac}_4(OH)_2,$$

begins to decompose at 65°, and differs from the acetates described in the above by being split up when diluted with water. Dilution in the case of the other acetates raises the dissociation ratio. In mordanting, drying, and ageing, the normal acetate gives up half its alumina to the fibre; whilst the alumina of the salt, $Al_2\overline{Ac}_4(OH)_2$, obtained from aluminium sulphate by means of lead acetate and sodium carbonate, is completely deposited in the fibre.

In regard to the behaviour of aluminium thiocyanates, the following observations were made: The normal thiocyanate was prepared by double decomposition of $Al_2(SO_4)_3 + 18H_2O$ and $Ba(CNS)_2 + 2H_2O$, and from it the basic salts were obtained by deoxidation with sodium bicarbonate. The solutions of the normal salt corresponding with 200 grams aluminium sulphate per liter remained clear at all temperatures. The following salts were prepared:—

$$Al_2(CNS)_6,\ Al_2(CNS)_5OH,\ Al_2(CNS)_4(OH)_2,\ Al_2(CNS)_3(OH)_3,\ \text{and}\ Al_2(CNS)_2(OH)_4.$$

The compound, $Al_2(CNS)_5OH$, is not altered when heated; whilst the more basic compounds are decomposed on boiling. Dilution with water does not affect any of the thiocyanates. Only 33 per cent. of $Al_2(CNS)_6$ is fixed on the fibre.

The behaviour of aluminium chloride was then investigated. The normal salt was prepared by dissolving aluminium hydroxide in the theoretical quantity of hydrochloric acid. The basic compound,

$$Al_2Cl_4(OH)_2,$$

was obtained by heating Al_2Cl_6 with aluminium hydroxide, thus:— $2Al_2Cl_6 + Al_2(OH)_6 = 3Al_2Cl_4(OH)_2$. By carrying the deoxidation still further, *i.e.*, introducing more $Al_2(OH)_6$ than the quantity represented by the above equation, decomposition takes place, a solution being formed which contains free hydrochloric acid in addition to Al_2Cl_6, whilst alumina is deposited. When a solution of aluminium chloride, corresponding with 200 grams $Al_2(SO_4)_3 + 18H_2O$ in 1 liter, is treated with sodium carbonate, the deoxidation may be carried gradually from Al_2Cl_5OH, $Al_2Cl_4(OH)_2$ and $Al_2Cl_3(OH)_3$ to $Al_2Cl_2(OH)_4$. On heating it is possible to obtain even the compound $Al_4Cl_3(OH)_9$. The soluble aluminium chlorides are not altered when heated or diluted. The compound, $Al_2Cl_2\overline{Ac}_4$, is recommended by the authors as a mordant in printing with alizarin. It is prepared in accordance with the equation $Al_2(SO_4)_3 + 18H_2O + 2Pb\overline{Ac}_2.3H_2O + BaCl_2.2H_2O = BaSO_4 + 2PbSO_4 + 26H_2O + Al_2Cl_2\overline{Ac}_4$, corresponding with 200 grams of aluminium sulphate, 227·6 lead acetate, and 73·3 barium chloride for 1 liter of mordant of 7·8° B; the product can be heated or diluted without decomposition. In mordanting, drying, and ageing, only 3·26 per cent. of the alumina contained in this mordant is given up to the fibre in an insoluble form.

Aluminium nitrate, $Al_2(NO_3)_6$, is obtained from the normal aluminium sulphate and lead nitrate, and gives the following compounds when treated with sodium bicarbonate :—$Al_2(NO_3)_5OH$, $Al_2(NO_3)_4(OH)_2$, $Al_2(NO_3)_3(OH)_3$, and $Al_2(NO_3)_2(OH)_4$. By continuing the addition of alkali, a gelatinous precipitate was obtained. The behaviour of these mordants is analogous to that of the corresponding chlorides.

Referring to aluminium phosphate, the authors mention that sodium phosphate, Na_2HPO_4, does not produce a precipitate when treated with an excess of aluminium sulphate. They found that it requires 2 mols. of aluminium sulphate to keep 1 mol. of aluminium phosphate in solution.

Behaviour of Ferric Oxide Salts.—Normal ferric sulphate, $Fe_2(SO_4)_3$, can be deoxidised with sodium bicarbonate until the compound

$$Fe_2(SO_4)_2(OH)_2$$

is formed; the latter, however, decomposes in a few hours. The same applies to a solution of ferric sulphate corresponding with 200 grams aluminium sulphate per liter. By doubling the strength of the solution, the addition of alkali can be carried on to form the compound $Fe_4(SO_4)_3(OH)_6$, which is a very unstable salt. Fe_2Cl_6 can be deoxidised to $Fe_2Cl(OH)_5$.

Normal ferric acetate was prepared from $Fe_2(SO_4)_3$ and lead acetate. By the removal of acid by means of sodium carbonate, the solutions of the following compounds can be obtained :—$Fe_2\overline{Ac}_5OH$, $Fe_2\overline{Ac}_4(OH)_2$, $Fe_2\overline{Ac}_3(OH)_3$, and $Fe_2\overline{Ac}_2(OH)_4$. The normal ferric acetate can be heated or diluted without change. The solutions of the basic salts correspond with 100 grams $Al_2(SO_4)_3$ in 1 liter. The first salt,

$$Fe_2\overline{Ac}_5OH,$$

is decomposed at 86°, and the last, $Fe_2\overline{Ac}_2(OH)_4$, at 70°. D. B.

Substitute for Tartar Emetic in Dyeing. (*Dingl. polyt. J.*, **251**, 48.)—Tartar emetic is being gradually replaced in dyeing and printing by a new antimony preparation consisting of potassio-antimonic oxalate, $C_6O_{12}SbK_3 + 6H_2O$. It is obtained by saturating a boiling solution of hydrogen potassium oxalate (salt of sorrel) with freshly precipitated antimonious oxide, and filtering the mixture whilst hot. On cooling, potassio-antimonic oxalate crystallises out. This preparation is sold at a moderate price as a substitute for tartar emetic in fixing tannin colours. D. B.

Fixing Perthiocyanogen in Printing. By H. SCHMID (*Dingl. polyt. J.*, **251**, 41—44).—The fact that thiocyanic acid and its salts under the influence of oxidising agents yields yellow insoluble perthiocyanogen, $C_3HN_3S_3$, has long been known. Prochoroff of Moscow found that perthiocyanogen may be employed as a colouring matter, and has patented the preparation of this compound under the name of "canarin." Potassium thiocyanate, KCNS, is oxidised by potassium chlorate in the presence of hydrochloric and sulphuric acids. Bromine acts in a similar manner. The yield of colouring matter is about 40 per cent. of the weight of potassium thiocyanate employed. Canarin appears as an orange-yellow heavy powder, insoluble in water, alcohol, and ether, but soluble in strong sulphuric acid and in caustic leys. Prochoroff recommends this dye for printing wool, but makes no mention as to its application in calico-printing. Owing to its insolubility in the ordinary reagents, the only method of applying perthiocyanogen in cotton-printing is to produce it within the fibre. After making a number of trials, the author found that the best results were obtained when the printing was done with the following mixture:—

280 parts of thickening agent,
5–15 parts of solution of vanadious chloride,
100 parts of crystallised aluminium thiocyanate,
100 parts of aluminium chlorate, 40° B.

The solution of aluminium chlorate is prepared by mixing 7900 grams crystallised barium chloride dissolved in 8 litres of water with a solution of crystallised aluminium sulphate in 5·5 litres of hot water. The solution of vanadium is obtained by dissolving 20 grams of ammonium metavanadate in 100 grams of hydrochloric acid and 200 of water, and reducing the solution by means of 30 c.c. of commercial sodium bisulphite. The mixture is warmed, and when solution is complete and a blue colour has appeared, it is made up to 20 litres with water: 1 litre contains 1 gram ammonium vanadate, and is therefore the same as the solution employed in the production of aniline black. The new yellow dye rapidly develops in the oxidation or drying chambers, and with the same facility as aniline black. It gives a brilliant yellow colour without weakening the fabric. Perthiocyanogen yellow is remarkable for its great stability. Neither concentrated acids nor alkalis act on it, and its tint is merely rendered lighter by nitric acid. It is altered slowly by air and light, whilst chloride of lime and boiling soap solution have no action on it. It, moreover, has the property of acting as a mordant to the aniline colours, such as methylene-blue, aniline-green, red, violet, &c. This reaction cannot be attributed to the presence of sulphur in the fibre, as it still takes place after the sulphur has been extracted. Neither can it be due to the formation of hydrocellulose, since the fixation of the aniline colours takes place when the yellow dye has formed, whereas the rotting of the fabric due to the formation of hydrocellulose was observed in the blank spaces of the pattern. Wool cannot be printed with the above mixture. D. B.

Preparation and Dyeing of China Grass. (*Dingl. polyt. J.*, **251**, 135—140.)—Owing to the large amount of pectinic substances contained in China grass, it cannot be subjected to the steeping processes practised with hemp and flax, as the resulting fermentation of the pectin would destroy the texture. Hence the separation of the bast from the woody constituents must be effected by mechanical means.

The machines employed for the scutching operation separate the bast from the stem, and simultaneously remove the thin coloured upper skin from the bast. After this treatment the fibres which are still held together by the intercellular substances are separated individually by chemical means. The retting is effected by an immersion for 24 hours in warm water, boiling twice in soda-ley of 2° to 3° B. under pressure and washing. The strength of the fibres is not weakened by this treatment. The spinning is then commenced, and in some cases the fibres are bleached before spinning. To increase their lustre and elasticity, the fibres may be passed through a bath of glycerol or oil. The length of the fibre of China grass is from 6 to 25 cm. It is therefore the longest of all bast fibres. Its density is between that of flax and hemp, and its tearing length equal to 20 km. The distinctive property is its lustre.

China grass, like cotton, has little or no attraction for dyes, hence the methods in vogue for cotton are applicable also to the dyeing of China grass. The dyeing is, however, attended with more difficulty, inasmuch as its success depends on the maintenance of the lustre, smoothness and strength, which characterises the China grass fibre. Mineral colours, such as chrome-yellow and orange, destroy the silky lustre. The yellow dye obtained with cadmium sulphide, however, does not act on the fibre in this way. Alizarin mordanted with Turkey-red oil destroys the lustre, whilst aniline colours fixed with the same mordant, retain the silky appearance. Rosaniline-derivatives and the azo-colouring matters give good colours.

In conclusion, it is stated that the silky appearance which the China grass fibre possesses is not removed when it is dyed immediately after retting and before spinning. D. B.

Preparation of Blue Dye-stuffs. (*Dingl. polyt. J.*, 251, 240.)—Ochler obtains blue dyes from nitroso-derivatives of dimethyl-, diethyl-, or ethylmethyl-aniline, by treating their solutions in concentrated sulphuric acid or phosphoric acid with sulphuretted hydrogen gas or metallic sulphides.

Mülhauser prepares toluene-blue and anisoïl-blue by treating the sulphonic acids of the amidazo-derivatives of substituted toluene and anisoil with sulphuretted hydrogen, and subsequently oxidising the sulphuretted leuco-compounds.

Lembach and Schleicher obtain a blue colouring matter by the reduction of diethylanilineazobenzene-parasulphonic acid with zinc-dust and ammonia, and subsequent oxidation with ferric chloride in the presence of sulphuretted hydrogen. D. B.

Process for Preparing Dye-stuffs from Pyridine and Quinoline Bases. By E. Jacobsen (*Dingl. polyt. J.*, 250, 466—469).—By heating phthalic anhydride with pyridine and quinoline bases, yellow condensation-products are formed. Yellow colouring matters are obtained with pyridine, picoline, the pyridine bases from coal-tar boiling between 130° and 230°, and the quinoline bases from coal-tar boiling between 230° and 310°. Quinaldine discovered by Doebner and Miller, and its homologues obtained by treating toluidine or xylidine with paraldehyde and dehydrating agents, and naphthaquinaldine obtained from naphthylamine give similar dye-stuffs when subjected to the action of phthalic anhydride.

For the preparation of the dyes, 1 mol. phthalic anhydride is heated at 200—250° with 2 mols. of the respective pyridine or quinoline base and 1 mol. zinc chloride, and the resulting colouring matter is converted into the soluble sulphonic acid. Similar dye-stuffs are obtained if nitrophthalic acid or phthalimide is used instead of phthalic anhydride.

For the preparation of red colouring matters by the action of benzotrichloride on pyridine and quinoline bases, benzylene chloride or bromide, or benzylene chlorobromide may be employed in the place of the trichloride. Whereas most tertiary aromatic amines when treated with benzylene chloride give colourless compounds, the pyridine and quinoline bases produce dye-stuffs, which, although analogous in shade, are not identical with the reds yielded by benzotrichloride, differing in solubility and crystalline form.

The author claims as novelty the preparation of colouring matters by the action of quinoline, toluquinoline, or dimethylquinoline with additions of quinaldine, methylquinaldine, or dimethylquinaldine on benzotrichloride, benzylene chloride, &c. By treating coal-tar quinoline or synthetical quinoline with nascent hydrogen, hydroquinoline is obtained, which yields green dyes with benzotrichloride.

Process for Finishing Silken Goods with Amber. By O. Thümmel (*Dingl. polyt. J.*, **250**, 556).—One part of amber is dissolved in two parts of chloroform, and the solution is put on silken articles with a sponge or brush. The goods are then placed in a drying chamber, when the chloroform is recovered, and the articles dried. By this treatment the silk is said to acquire a peculiar softness and elasticity. D. B.

Method of Imparting the Appearance of Silk to Vegetable Fibres. (*Dingl. polyt. J.*, **250**, 476.)—Gedge has recently patented a process for bleaching vegetable fibres and animalising them in order to render them better able to receive colours, and to give them the appearance of silk. The bleaching consists in a successive treatment with soda-ley, hydrochloric acid, and sodium hypochlorite. The animalising is effected by steeping the material in a solution of sugar, drying, and subjecting it to the action of a mixture of nitric and sulphuric acids, whereby the sugar is converted into nitroglucose, and the cellulose into dinitrocellulose.

It is said that the application of nitroglucose is not novel, as it was patented by Bonneville in 1881. D. B.

Presence of Tin in Preserved Food. By E. UNGER (*Dingl. polyt. J.*, **251**, 192).—The author found that asparagus preserved in tinned boxes contained 0·019 to 0·033 per cent. tin near the sides, and from 0·021 to 0·033 per cent. in the centre of the boxes. The tin was present in the form of a proto-salt. The acid juice of pressed apricots and strawberries was found to be free from tin, whilst the fruit contained this metal. 100 grams of apricots gave 0·0185 per cent. tin, and 76·5 grams of strawberries 0·0175 per cent. D. B.

Methods employed by Fishermen for "Barking," and in other ways preserving Nets and Sails. By F. H. STORER (*Amer. Chem. J.*, **5**, 440—455).—On several foggy coasts the men annually "bark" their sails and nets to colour them and protect them from mildew. Oak-bark is boiled in water, and the nets are then kneaded and allowed to stand about two days, after which they are dried. Catechu is now, however, principally used instead of oak-bark. By the use of walnut-bark, *Chelidonium majus*, or young wheat plants, a "dead-leaf" colour, a dirty-orange or a green tint is imparted. In Nova Scotia, the bark of fir and spruce trees is employed, no mordant or fixing agent of any kind being employed. At Yarmouth, the nets are tanned in the beginning to preserve them from rotting, and the process is repeated at the close of the fishery to cleanse them thoroughly. A manufacturing firm in Boston fixes the catechu with potassium dichromate. An alkali—as soft soap—is also used in conjunction with bark; the alkali assists the oxidation and formation of colouring matter, and the oil probably serves much the same purpose as the emulsion of oil and alkali used in Turkey-red dyeing. In other localities, the fishermen use a mixture of bark, tar, and oil; and again others rub into the sail a mixture of tar and oil only. The sizing in new cloth is very liable to induce mildew; old sails are said to be comparatively exempt from mildew. H. B.

Process for Preparing Hop Extract. By W. S. FORSTER (*Dingl. polyt. J.*, **251**, 288).—The author distils hops by means of steam and recovers the ethereal oils. The residue is extracted with carbon bisulphide, and the extract, after expelling the carbon bisulphide, is neutralised with soda and evaporated in a vacuum. It is then treated with alcohol, filtered, and the residue dissolved in ether. From this solution, the lupulin is separated in the form of an alkaline salt by the addition of potash or soda. After treatment with carbon bisulphide, the hops are distilled with steam to remove the bisulphide; the tannin is then extracted with boiling water and the extract evaporated. In brewing with these substances, the tannin and lupulin extracts are added to the beer worts before boiling; whilst the hop oil is added after boiling, immediately before the commencement of the fermentation. D. B.

General and Physical Chemistry.

Spark-spectra Emitted by Metallic Elements under Varying Conditions. By E. WIEDEMANN (*Chem. News*, 49, 117).—In a recent paper (this vol., 137), Hartley stated that the short lines in some arc-spectra are lengthened by moistening the electrodes with water; and, moreover, it is suggested that this phenomenon is due to the cooling action of the water on the negative electrode, since heating the electrodes produces a reverse result. The author of the present note takes exception to this explanation, and offers the following:—When the electrodes are moistened, the discharge produces oxygen and hydrogen gases, which recombine at some distance from the electrode with great development of heat, consequently increasing the temperature of the metallic vapours, and also the length of the lines. By directly heating the electrodes, however, the potential available for the production of spark is lowered, with the result that the amount of matter dispersed at each discharge is diminished, as well as the temperature of the spark, the ultimate effect being shortened lines in the spectrum. D. A. L.

Spectroscopic Examination of Vapours Evolved on Heating Iron, &c., at Atmospheric Pressure. By J. PERRY (*Chem. News*, 49, 241—242).—It is an accepted fact that most metals when heated to high temperatures, give off fumes of the metals. With iron, however, even in the Bessemer converter, no iron has been detected by the spectroscope in the fumes given off. The author shows that even when easily volatile metals are heated, no spectroscopic indication of them is given in a flame without the electric spark is passed through it simultaneously. By subjecting several substances to such treatment, the following results have been obtained.

When heated in a crucible over a blowpipe, aluminium is volatile; thallium, copper, potassium, sodium, are easily volatile, and give spectra in flame and spark. The following, of which arsenic, cadmium, zinc, and antimony are easily volatile, and bismuth, tin, lead, and manganese are so with difficulty, give spectra with spark only. Silver, chromium and gold are not volatile, but give the copper spectrum with spark. Selenium and tellurium give spectra requiring further investigation. By slightly heating either phosphorus or sulphur on a hot iron plate just below the spark, good spectra of these substances are obtained.

Spiegeleisen, when heated in a crucible, evolves a fume in which zinc, copper, manganese, calcium and magnesium (?) were detected. In a similar manner, Bessemer pig evolved copper, manganese, calcium, lead or arsenic; whilst when burnt at a low red heat in a stream of oxygen, in addition to the above a carbon spectrum was observed. Spanish iron ore reduced with charcoal in a crucible at a temperature sufficient to fuse the metal, gave zinc, copper, and manganese. When the dry chlorides, obtained by treating Spanish ore with hydrochloric acid, are gradually heated in the blowpipe, copper, zinc, calcium, barium, lead, silver, and manganese lines are detected successively in the vapours. At the highest temperature, iron lines appear. In the same way, when spiegeleisen and steel or iron filings are treated with hydrochloric acid, or mixed with ammonium chloride and heated, the various substances volatilise much more easily and give bright successive spectra. Heated in a glass tube four inches long, the chlorides from steel gave vapours at the top of the tube in which were detected calcium, copper, and then manganese, finally only calcium and copper were observed; copper was detected in the vapour at the top of a 20-inch glass tube, at the bottom of which copper and ammonium chlorides were heated. Copper was evolved from all the metals tested. Lithium, strontium, calcium, copper, zinc, barium and magnesium chlorides give spectra when volatilised in an ordinary spirit lamp.

A Probable Cause of the Difference between the Observed Electromotive Force of Galvanic Couples and that Calculated from Thermochemical Data. By G. CHAPERON (*Compt. rend.*, 98, 729—732).—Amongst galvanic couples which have an actual electromotive force considerably different from that calculated from thermochemical data, there are several which seem to exhibit phenomena due to the polarisation of the dissolved metal, and although these couples have a positive electrode which cannot polarise, they yield a current, the electromotive force of which falls very rapidly to zero. The author has determined the E.M.F. of several couples of this kind, and finds that they constitute systems which are polarisable up to the point of decomposition of the electrolyte into its elements, the difference of potential between the two electrodes increasing between zero and the point of electrolysis, and even beyond the latter, in accordance with an uninterrupted law. If T*m*R, and T*m*H, represent the work or electric energy corresponding, at a given temperature and pressure, with the absorption or restitution of the elements R and H of an electrolyte, by an electrode of the polarisable metal *m*, then T*m*R and T*m*H are not constant, but vary between very wide limits, diminishing as the proportion of R and H absorbed increases. It follows that the chemical work corresponding with the electric energy given back by the two polarised electrodes will generally be—

$$\mathrm{TRH} - \mathrm{T}m\mathrm{R} - \mathrm{T}m\mathrm{H},$$

where TRH is the energy of formation of the electrolyte. When polarisation follows an uninterrupted law, this value of the chemical energy will vary from TRH to zero, between the point of electrolysis and the state of neutrality of the electrodes which is represented by the equation—

$$\mathrm{TRH} - \mathrm{T}m\mathrm{R} - \mathrm{T}m\mathrm{H} = 0.$$

Between the same limits, T*m*R and T*m*H will vary from zero to two positive values, each of which will, at the limit, be smaller than TRH, and it is the value of T*m*R satisfying equation (1) which ought to be used instead of the heat of combination in calculating the theoretical E.M.F.

C. H. B.

Heat of Hydration of Salts. By S. U. Pickering (*Chem. News*, **49**, 216).—It is pointed out, that in calculating the heat of hydration of a salt by taking the algebraic difference between the heat of solution of the anhydrous salt and that of the hydrated salt, the heat evolved by the conversion of a certain quantity of liquid water into solid water of crystallisation is not correctly accounted for. For instance, Thomsen's numbers for magnesium sulphate are:—

$$MgSO_4 + Aq = 20{,}280 \text{ cal.}; \; MgSO_4 7H_2O + Aq = -3800 \text{ cal.};$$

whence he deduces $MgSO_4 + 7H_2O = 24{,}080$ cal.; but the solidification of $7H_2O = 10{,}010$ cal., hence the actual heat due to the chemical action, $MgSO_4 + 7H_2O$, is only 14,070 cal. Such being the case, it is evident that similar corrections are required in other instances.

D. A. L.

Normal and Acid Sodium Sulphites. By de Forcrand (*Compt. rend.*, **98**, 738—741).—Normal sodium sulphite was prepared by saturating a known weight of sodium carbonate with sulphurous acid, adding an equal weight of the carbonate, and crystallising in an atmosphere of dry nitrogen. The salt crystallises with $7H_2O$, all of which is given off at 150°. The author was unable to obtain the decahydrate described by Muspratt. The heat of solution of the hydrated salt $Na_2SO_3 + 7H_2O$ at $+ 10°$ is $- 11·1$ cal., and that of the anhydrous salt $+ 2·5$ cal., from which it follows that—

Cal.

Na_2SO_3 solid $+ 7H_2O$ solid $= Na_2SO_3.7H_2O$ solid, develops $+ 3·50$

Na_2SO_3 „ $+ 7H_2O$ liquid $= Na_2SO_3.7H_2O$ „ „ $+13·60$

It is also found that—

$$2NaHSO_3 \text{ diss.} + Na_2O \text{ diss., develops } +27·82 \text{ cal.,}$$

and hence it follows that—

$Na_2 + S + O_3 = Na_2SO_3$ solid, develops...... $+261·0$ cal.

SO_2 gas $+ Na_2O$ solid $= Na_2SO_3$ solid, develops $+ 91·5$ „

A solution of the normal sulphite is partially decomposed by hydrochloric acid, the base dividing itself between the two acids with formation of chloride, and acid sulphite, in a manner exactly similar to that observed by Berthelot in the case of potassium sulphite.

When a solution of sodium carbonate is saturated with sulphurous acid and allowed to evaporate slowly in an atmosphere of sulphurous anhydride, sodium metasulphite, $Na_2O,2SO_2$, separates in large anhydrous crystals which do not alter when exposed to the air. The author was unable to obtain any hydrates of this salt. The heat of solution of the metasulphite at 10° is $- 5·24$ cal., and when the solution is immediately treated with an equivalent of sodium hydroxide, there is a development of heat $= + 28·2$ cal. The mean result of several determinations of the heat developed by the action of an equivalent of soda on the metasulphite is $+ 2·83$ cal. In the experiments described above, it was found that the action of an equivalent of soda on a solution of the acid sulphite formed at the same instant is $+ 27·82$ cal. The difference between these numbers is so small, that it cannot be supposed that the metasulphite undergoes any change on solution. It follows that the true sodium hydrogen sulphite does not exist in solution, or rather, is immediately converted into the metasulphite. The various determinations yield the following values:—

$S_2 + O_5 + Na_2 = Na_2O.2SO_2$ solid, develops +348·4 cal.
$2SO_2$ gas + Na_2O anhyd., develops .... +109·8 „
SO_2 gas + Na_2SO_3 anhyd., develops ...... + 18·8 „

A comparison of these results with those of Berthelot and of Sabatier, shows that the heat developed by the combination of oxygen in different proportions with the various sodium sulphites is practically the same as that developed by the combination of the same amount of oxygen with the corresponding potassium sulphides.

C. H. B.

Scales of Temperature and Molecular Weights. By BERTHELOT (*Compt. rend.*, **98**, 952—956).—A summary of recent results respecting the density of the halogens at high temperatures, and the variations in the specific heats of elementary gases at high temperatures.

C. H. B.

Relative Rapidity of Combustion of Explosive Gaseous Mixtures. By BERTHELOT and VIEILLE (*Compt. rend.*, **98**, 646—651).—The maximum pressure observed when a mixture of gases is exploded in a vessel of given capacity is always less than it would be if the system retained the whole of the heat developed by the combustion, the loss of heat being due to contact with the walls of the explosion-vessel and to radiation. The difference is greater the smaller the vessel, or in other words, the smaller the mass of gas with respect to the vessel in which it is contained, and it is also greater the slower the rate of combustion. The rapidity of combustion is very variable, and is intermediate between the rapidity of detonation and that of ordinary combustion. In the experiments described in this paper, three explosion-vessels of different capacities and shapes were employed.

As a rule, the time required for the development of the maximum pressure is longer the greater the capacity of the explosion-vessel and the greater the distance between the point of inflammation and the pressure-piston. With carbonic oxide, the time required is greater than with hydrogen, whilst in the case of cyanogen and of hydrocarbons rich in hydrogen, the time is practically the same as in the case of hydrogen alone, and agrees with the calculated ratios of the velocity of the explosive waves. It is, in fact, the velocity of translation of the molecules which governs the phenomenon. When nitrous oxide is used instead of oxygen, the rapidity of combustion is diminished.

The absolute rapidity of combustion is very difficult to estimate, but assuming that the flame reaches the piston at the moment when the maximum pressure is developed, the velocity of combustion is about 100 metres per second for hydrogen, 8 metres for carbonic oxide, 70 metres for cyanogen. When nitrous oxide is employed, the velocity of combustion of hydrogen is reduced to one-half, and that of cyanogen to one-third.

There is no evidence that the combustion of cyanogen takes place in two stages, but incomplete combustion of the gas is more rapid than complete combustion, probably because in the latter case there is partial dissociation.

The rate of combustion is diminished by the presence of an excess of one of the combustible gases, and also by the presence of an inert gas, but to a much greater extent by the presence of an excess of one of the gases which are produced by the combustion. An inert gas retards combustion partly by lowering the temperature and thus diminishing the velocity of the molecules, and partly by diminishing the number of effective encounters between the molecules which can act on one another.

In the case of so-called isomeric mixtures, the rate of combustion is lowest in the less condensed systems, which are also those which develop the smallest amounts of heat.

When two combustible gases are mixed, the rapidity of combustion of the mixture is never the mean between its constituents, but each gas appears to burn separately with its own proper rapidity, and consequently the maximum pressure observed does not correspond with a uniform state of combination of the system. When carbonic oxide and hydrogen are exploded separately with oxygen, the pressures produced are practically the same, viz., 10·1 and 9·9 atmospheres respectively, whilst with a mixture of equal volumes of the two gases, the maximum pressure developed is 8·7 atmospheres. Similar results are obtained with mixtures of hydrogen and ethylene, and in both cases it would seem that the hydrogen is the first to burn.

The rate of combustion of mixtures of hydrocarbons rich in hydrogen is very similar to that of hydrogen alone, which seems to indicate that the hydrogen burns before the carbon even in cases of complete combustion. These effects play a part in establishing those temporary conditions of equilibrium which result from incomplete combustion, such as the division of oxygen between two mixed combustibles like carbonic oxide and hydrogen, or the hydrogen and carbon in hydrocarbons, or the division of hydrogen between two substances like oxygen and chlorine. During the first moments, this division depends on the relative rapidity of the combinations, and may be very different from the definite equilibrium which would be established in the same system if it were kept at a constant temperature for a sufficient length of time. A system which is suddenly cooled, as is the case with the products of detonation, does not furnish real measures of the relative attractions of its constituents, because it may present an entirely different distribution of its elements.

C. H. B.

Influence of the Density of Explosive Gaseous Mixtures on the Pressures which they Develop. By BERTHELOT and VIEILLE (*Compt. rend.*, **98**, 705—711).—If the pressures exerted by gaseous systems to which a given amount of heat has been communicated vary in the same ratio as their densities, it will follow, independently of all hypotheses on the laws of gases (1), that the specific heat of the system is independent of its density, *i.e.*, of the initial pressure, and depends solely on the absolute temperature, and (2), that the relative variations of the pressures at constant volume produced by the communication of a given quantity of heat is also independent of the pressure, and is solely a function of the temperature. In order to investigate this point, two methods were adopted. The first consisted in exploding similar gaseous mixtures which had previously been heated at different temperatures, whilst the second and more accurate method consisted in exploding isomeric mixtures, *i.e.*, mixtures which originally contain the same elements in different states of combination, but are all brought into exactly the same condition by the explosion. The conclusions drawn from a large number of experiments are: —

(1.) When a given quantity of heat is communicated to a given gaseous system, the variation in the pressure of the system is proportional to its density.

(2.) The specific heat of gases is independent of the density at very high temperatures as well as at 0°.

(3.) For one and the same system, the pressure increases with the quantity of heat communicated, and the specific heat also seems to increase with this quantity.

These purely experimental results confirm the generally accepted laws of gases. C. H. B.

Water of Crystallisation of Salts. By T. SALZER (*Annalen*, **223**, 1—39).—In this paper, several generalisations are collected regarding the number of molecules of water of crystallisation attached to salts, examples being given to illustrate the several points brought out.

(1.) If a monobasic acid forms both neutral and acid salts with a metallic oxide, the number of molecules of water of crystallisation is increased with decrease of proportion of acid.

(2.) If a monobasic acid forms basic as well as neutral salts, the former contain a less number of molecules of water than the latter.

(3.) If a polybasic inorganic acid forms several salts, the number of molecules of water combined increases in proportion as the hydrogen-atoms are replaced. The same rule also holds good in the organic sulphonic and carboxylic acids.

(4.) The crystalline salts of aromatic derivatives, in which two negative groups, as hydroxyl, carboxyl, or the nitro-group stand in the ortho-position, contain less water of crystallisation than the corresponding para-compound. The further introduction of a halogen element does not seem to influence the result.

Further, so far as material is at hand, it would appear that salts, derived from acids containing three electronegative groups in the ortho-position to one another, contain less water of crystallisation than those of corresponding acids in which the groups are in the para-position.

Of the acids of the acetic series, it would appear that the salts of formic acid contain less water than those of acetic acid; the calcium salts of normal butyric, valeric, caproic, œnanthylic, and caprylic acid have only one molecule of water of crystallisation, whilst those of isobutyric, methyl- and methylethyl-acetic have five molecules.

The barium salts do not show such a regularity, which may partly be accounted for from the known variation of the water of crystallisation of barium acetate with alteration of temperature.

V. H. V.

Decomposition of Salts by Water. By H. Le Chatelier (*Compt. rend.*, 98, 675—678).—The author considers that the decomposition of a salt by water with formation of an insoluble product is not really analogous to the dissociation of gases (Ditte, *Compt. rend.*, 1872), but can be explained by the laws of chemical equilibrium in homogeneous liquid systems, taking into account, in accordance with the laws of Berthollet, the insolubility of the product. The insoluble substance which is formed does not play any part in the establishment of equilibrium, but is at once removed from the sphere of action, and equilibrium is established only between those substances which still remain in solution. In the case of the decomposition of normal mercuric sulphate (*loc. cit.*), the mercury which is not precipitated exists in solution as normal sulphate, and not as tribasic sulphate. The true conclusion to be drawn from Ditte's experiments is that "the quantity of acid necessary to prevent the decomposition of a salt increases at first with an increase in the proportion of water, but it does not increase indefinitely, and tends towards a limit." This limit may be due to the partial dissociation of the hydrates of the acid, or, in certain cases, to the comparative insolubility of the particular salt. C. H. B.

Curves of Solubility of Salts. By A. Étard (*Compt. rend.*, 98, 993—996).—The author has determined the solubility of chlorides, bromides, and iodides of calcium, strontium, barium, nickel, cobalt, manganese, cadmium, zinc, magnesium, and iron (ferrous) between the freezing points of their solutions and 180°. Whether the salt employed is usually anhydrous or hydrated, its solubility between a given interval of temperature is always represented by a straight line which makes an angle with the axis of temperature. This line seems to represent the normal solubility for a certain state of equilibrium between the water and the dissolved salt, but as the temperature continues to rise, the condition of equilibrium changes, and during the greater or less interval of temperature in which this change takes place, the curve is inflected. As soon, however, as the new state of equilibrium is established, the solubility again becomes proportional to the temperature, and is represented by a straight line making a particular angle with the axis of temperature. The solubility of all the salts employed is proportional to the temperature, and is represented by a curve consisting usually of two straight lines united by a simple or sinuous curve, but in certain cases they may be two inflexions. It is conceivable that the changes of state in the solution may take place very slowly, and that a curve of perturbation only will be obtained within the limits of observation, but no case of this kind has yet been met with.

The inflections in the curve doubtless correspond with a change in the state of hydration of the salt. The curves given in the books usually extend only between + 20° and 100°, and that these curves are a simple curve or straight line is due to the fact that this interval includes only that part of the phenomenon in which the change in the conditions of equilibrium takes place.
C. H. B.

Freezing Points of Solutions of Salts of Bivalent Metals. By F. M. Raoult (*Compt. rend.*, **98**, 1047—1049).—The author has determined the freezing points of solutions of salts of various bivalent metals and acids of different basicities, and finds that in no case is the molecular reduction of the freezing point greater than 53. It has already been shown that the molecular reduction produced by acids and by alkaline bases and salts never reaches 50. Salts, such as the acetates of lead and copper, which have a low heat of formation, are partially decomposed in solution, and produce abnormal molecular reductions. Omitting cases of this kind, the author's observations lead to the following laws:—

(1.) Normal salts of bivalent metals and monobasic acids produce a molecular reduction of the freezing point varying from 41 to 48, the mean being 45.

(2.) Normal salts of bivalent metals and bibasic acids produce a molecular reduction between 18 and 20, the mean being 20.

(3.) Whenever, in the molecule of a salt of a monobasic or bibasic acid dissolved in 100 grams of water, an atom of a bivalent metal is replaced by an equivalent quantity (2 atoms) of a monovalent metal the molecular reduction is increased by about 20.

It follows from this third law that if the molecular reductions produced by normal salts of bivalent metals and particular acids are known, the molecular reductions which will be produced by the salts of the same acids and monovalent metals can be readily calculated. The molecular reduction produced by equivalent quantities of different salts can also be calculated, and it is found that—

(4.) Double decompositions which take place without the formation of a precipitate in solutions of normal salts of univalent or bivalent metals with monobasic or bibasic acids, produce little or no change in the freezing point of the mixture.

This fourth law has been verified by numerous experiments.
C. H. B.

Constants of Capillarity of Liquids at their Boiling Points. By R. Schiff (*Annalen*, **223**, 47—106). The phenomenon of capillarity considered in relation to the atomic constitution of compounds has hitherto been slightly investigated; the only results are those of Mendelejeff (*Annalen*, **119**), who has determined the ratios of the so-called molecular cohesion Pa^2d, in which P is the molecular weight, a^2 the coefficient of capillarity, and d the sp. gr. The conclusions arrived at were: (I), in an homologous series of compounds, the molecular cohesion increases with increase of molecular weight; (II), isomeric substances have approximately equal molecular cohesion; (III), the molecular cohesion of a compound is not equal to the sum of the atomic cohesions of its components. In this extensive memoir, the constants of capillarity are determined for a large number of carbon compounds, and the relations existing between them discussed.

On account of the alteration of the capillarity-constants with temperature, their determination under strictly comparable conditions presents some difficulty. The boiling point is selected by the author, not as presenting a condition under which liquids are in precisely the same physical state, but as the most practical, and affording, as the elaborate investigations on molecular volumes have shown, a point of sufficiently approximate physical comparability, and analogous aggregation. The process of determination consists in measuring the difference of level of the given liquid in a **U**-tube, whose arms are of different diameter, both however being of sufficiently small calibre that the law of diameters can be assumed to be approximately correct. The **U**-tube is suspended in the vapour of the liquid under examination. In the course of investigation, it was observed that the differences of level of the meniscus at first increased, but finally remained constant after the air had been completely driven out of the **U**-tube by the vapour of the liquid.

If a^2 be the capillary elevation in a tube of 1 mm. radius, H that of the narrower limb, H_1 that of the wider limb, r and R their respective radii, then $H = \frac{a^2}{r}$ and $H_1 = \frac{a^2}{R}$; if then h be the difference of level of the menisci, $a^2 = h\frac{Rr}{R-r}$. This value for a^2 must be corrected for the weight of liquid raised from the plane tangential to the lowest part of the meniscus. If the circular angle of the tube were approximately zero, and the meniscus a semicircle, then for a radius of 1 mm. $a^2 = h + \frac{1}{3}$, but this correction was found to be too large; whilst the correction of Frankenheim $\frac{f}{3}$, where f is the true height of the meniscus, was found to be too small. The author takes the arithmetical mean as affording a sufficiently approximate correction. The equation for a^2 written above will take the form

$$a^2 = \frac{Rr}{R-r}\left(h + \frac{\frac{r}{3} - \frac{R}{3} + \frac{f}{3} - \frac{F}{3}}{2}\right),$$

where f and F are the true heights of the menisci in the true branches of the **U**-tube. Besides the capillarity constant a^2, introduced by Poisson, another $\frac{a^2d}{2}$ is used, which represents the weight of liquid raised through a unit length of the line of contact between the liquid and the solid surface. If m and v be the molecular weight and volume respectively, and since $\frac{m}{d} = v$, then $\frac{\frac{1}{2}a^2d}{m} = \frac{a^2}{2v} = N$, or the relative number of molecules elevated along the line of contact between the liquid and the solid surfaces.

For better comparison these values are multiplied by 1000.

In the table below, the experimental values are given for a^2, $\frac{a^2d}{2}$, and N10^3, determined at the boiling point, and for a'^2 at ordinary temperatures :—

Liquid.	a^2.	$\frac{a^2d}{2}$.	N10^3.	a'^2.
Acetone, C_3H_6O	5·189	1·947	33·6	6·389
Paraldehyde, $C_6H_{12}O_3$	3·530	1·542	11·7	5·632
Diethyl acetal, $C_6H_{14}O_2$	3·656	1·346	11·4	5·611
Dimethyl acetal, $C_4H_{10}O_2$	4·092	1·639	18·4	5·464
Diethyl ether, $C_4H_{10}O$	4·521	1·571	21·3	5·189
Ethyl formate, $C_3H_6O_2$	4·528	1·976	26·8	5·562
Propyl formate, $C_4H_8O_2$	4·486	1·811	20·6	5·850
Isobutyl formate, $C_5H_{10}O_2$	4·149	1·615	15·8	5·871
Isoamyl formate, $C_6H_{12}O_2$	4·064	1·540	13·3	6·041
Methyl acetate, $C_3H_6O_2$	4·556	2·010	27·2	5·759
Ethyl acetate, $C_4H_8O_2$	4·268	1·771	20·2	5·738

Ethyltoluene (1 : 4), C_9H_{12}	4·184	1·546	12·9	7·088
Mesitylene, C_9H_{12}	4·085	1·506	12·6	7·082
Cymene, C_9H_{12}	3·839	1·391	10·4	7·018
Methyl alcohol, MeOH	5·107	1·909	59·8	6·012
Ethyl alcohol, EtOH	4·782	1·765	38·4	5·956
Propyl alcohol, $Pr^{\alpha}OH$	4·718	1·762	29·0	6·223
Isopropyl alcohol, $Pr^{\beta}OH$	4·592	1·702	28·2	5·780

Liquid.	a^2.	$\frac{a^2d}{2}$.	N10³.	a'^2.
Isobutyl alcohol, $C_4H_9.OH$	4·416	1·604	21·7	6·061
Isoamyl alcohol, $C_5H_{11}.OH$	4 289	1·534	17·4	6·223
Dimethyl ethyl carbinol, $C_5H_{11}.OH$	4·283	1·550	17·6	5·919
Allyl carbinol, $C_3H_5.OH$	5·006	1·955	33·8	6·429
Chloroform, $CHCl_3$	3·150	2·210	18·6	3·874
Carbon tetrachloride, CCl_4	2·756	2·040	13·3	3·600
Ethylene chloride, $C_2H_4Cl_2$	4·198	2·429	24·6	5·499
Ethylidene chloride, $C_2H_4Cl_2$	3·684	2·052	20·8	- -
Propyl chloride, C_3H_7Cl	4·359	1·866	23·8	5·330

As regards the amount of confidence to be placed in these results, it is noticed that if the errors of sp. gr., cathetometer reading, &c., be in the same direction, then the greatest possible variation for a^2 will be 0·073 or 1·75 per cent. of the mean value of the constant, and for $N10^3 = \frac{a^2d}{2m}$ it will be 0·45.

From the values of a^2 and a'^2 can be calculated the diminution of this capillarity-constant for each degree temperature; the value so obtained can be denominated the *mean depression coefficient.* This varies with the liquid, and in any series of homologous liquids diminishes with increase of molecular weight.

The table below contains some of the values for the coefficient of various liquids :—

Hydrocarbons.

Paraffin.	Coefficient of depression.	Aromatic.	Coefficient of depression.
Hexane	0·0250	Benzene	0·0235
Octane	0·0225	Toluene	0·0213
Decane	0·0193	Xylenes (3)	0·0192
		Propylbenzene	0·0189
		Cymene	0·0183

Ethereal Salts.

Ethyl formate	0·0211	Methyl acetate	0·0249
Propyl "	0·0188	Ethyl "	0·0213
Butyl "	0·0184	Propyl "	0·0193
Amyl "	0·0175	Butyl "	0·0181
		Amyl "	0·0173

At the critical point, the phenomenon of capillarity disappears, so if the value for a^2 at the boiling point be divided by the coefficient of depression, then a number is obtained, which when added to the boiling point will give that point at which $a^2 = 0$. The critical temperatures calculated by these means are compared with those determined experimentally by Pawlewsky, and the values are fairly concordant.

Discussion of the Results.—I. In isomeric liquids of the paraffinoïd series, those of higher boiling point have higher values for a^2 and N; but in isomeric liquids of the aromatic series these substances are reversed.

II. The constant of capillarity, a^2, depends on the molecular weight, on the chemical nature of the liquid, and on the method of arrangement of the constituent atoms. On comparing the values for 10^3N in the above table, it is seen that the values of hexane, C_6H_{14}, hydrocarbons of formula C_8H_{10}, and of ethereal salts of formula $C_5H_{10}O_2$ are approximately equal. The second differ from the first in containing 2 atoms carbon more and 4 hydrogen atoms less, whilst the third differs from the second in containing 3 carbon atoms less and 2 oxygen atoms more. Hence $2C = 4H$ and $3C = 2O$, and also $C = 2H$ and $O = 3H$. Again, the values for 10^3N of dimethyl acetal and chloroform, or of amyl formate and carbon tetrachloride are approximately equal; if the carbon and oxygen atoms be determined in terms of hydrogen by the results given above, then—

$$
\begin{array}{rll}
\text{Dimethyl acetate, } C_4H_{10}O_2 & = 24H \\
\text{and } CH & = 3H \\
\hline
\text{Therefore } Cl_3 & = 21H \\
Cl & = 7H
\end{array}
\qquad
\begin{array}{rll}
\text{Amyl formate, } C_6H_{12}O_2 & = 30H \\
\text{and } C & = 2H \\
\hline
\text{Therefore } Cl_4 & = 28H \\
Cl & = 7H
\end{array}
$$

The values for N calculated according to this method are found to be practically equal to the experimentally determined values, the only two exceptions being diallyl and ethylene chloride. Or the results may be expressed in the form of a curve, in which y, the values for N, are abscissæ, and x, the ordinates, the values in terms of H; the curve formed is a logarithmic curve, and may be expressed by the formula $\log y = 2{\cdot}8155 - 0{\cdot}00728x - \log x$. The values calculated from this curve are compared, and are found to accord with the experimental value. Further researches in this direction are promised.

Determination of Chemical Affinities. By W. OSTWALD (*J. pr. Chem.* [2], **29**, 49—57).—VI. *Solubility of Hydrogen Potassium Tartarate in Dilute Acids.*—The finely powdered material was shaken with the normal acid for several hours at 20°, and after filtration a portion was titrated with baryta-water. After making a correction for the amount of substance dissolved by water alone, and proportionately increasing the amounts dissolved by each acid so that the quantity dissolved by normal nitric acid became 100, the numbers in the first column were obtained: the second column contains the numbers previously found (*J. pr. Chem.* [2], **28**, 493) when using methyl acetate:—

Nitric acid	100	96
Hydrochloric acid	92	100
Hydrobromic acid	93	99
Hydriodic acid	94	98
Sulphuric acid	69	74
Methyl sulphuric acid	97	100
Ethyl sulphuric acid	94	99
Propyl sulphuric acid	90	99
Ethyl sulphonic acid	87·0	99·0
Isethionic acid	92·0	99·0
Benzenesulphonic acid	91·0	99·0
Formic acid	7·8	11·0
Acetic acid	4·7	5·9
Monochloracetic acid	17·0	21·0
Propionic acid	4·2	5·5
Butyric acid	4·0	5·5

Acids decompose hydrogen potassium tartarate into tartaric acid and the potassium salt of the acid employed, the amount of decomposition depending on the strength and on the coefficient of affinity of the acid. The results are not strictly comparable, however, the presence of the acid increasing or decreasing the solubility of the products of the reaction to a small extent.

VII. *Solubility of the Sulphates of Barium, Strontium, and Calcium in Acids.*—The amount of substance dissolved was in each case determined by evaporation to dryness; a correction was made for the amount dissolved by the water alone. The results are contained in the following table:—

Strength of acid.	Hydrochloric acid.			Nitric acid.		
	$BaSO_4$.	$SrSO_4$.	$CaSO_4$.	$BaSO_4$.	$SrSO_4$.	$CaSO_4$.
5·0 × normal	0·017	0·29	—	0·048	0·73	—
2·0 × normal	0·055	0·96	7·61	0·084	1·46	9·27
normal	0·088	1·72	11·51	0·106	2·01	13·09
0·5 × normal	0·130	2·20	15·75	0·137	2·44	20·37
0·1 × normal	—	3·25	22·96	—	3·22	23·36

Strength of acid.	Monochloracetic acid.		Formic acid.	
	$SrSO_4$.	$CaSO_4$.	$SrSO_4$.	$CaSO_4$.
5·0 × normal	—	—	—	—
2·0 × normal	—	—	—	—
normal	0·104	0·41	0·080	0·31
0·5 × normal	0·133	0·17	—	—
0·1 × normal	—	—	—	—

The numbers give in milligrammes the quantity of salt dissolved by 1 mgrm. equivalent of the acid when diluted to the extent indicated.

These results point in the same direction as the previous ones, viz., that strong nitric acid has a more powerful effect than strong hydrochloric acid; but with dilute acids the effect is the same, for the coefficients of affinity of these two acids are nearly equal. The ratios between the affinities of nitric, monochloracetic, and formic acids are also much the same as those previously deduced. H. B.

Verification of some Atomic Weights. By C. Marignac (*Ann. Chim. Phys.* [6], 1, 289—337).—The investigations on the cerite group of metals have demonstrated the advantages of the method of fractional precipitation for the separation of substances presumably homogeneous into two or more constituents. This method is adopted more particularly by the author in this memoir for the more or less complete elimination of impurities. The stochiometrical analysis of substances thus purified serves as a control for previous determinations of the atomic weights.

Regarding the various scales which have been proposed for the atomic weights, it is remarked that the scale with hydrogen as unity for its basis has the advantage of representing the atomic weights of the greater number, and especially the more important of the elements, by the simplest possible integers.

Bismuth.—The atomic weight of this element is generally taken at 208, as the result of the concordant experiments of Schneider on the oxidation of the metal by nitric acid. From analysis of the chloride, Dumas obtained the number 210 26, but slight decomposition of the chloride by frequent distillation introduces an appreciable source of error in this method. The main points of the processes described at length in this memoir are (I) the fractional precipitation of the nitrate with water; (II) the conversion of the subnitrate into oxide by ignition; (III) the reduction of a known weight of the oxide in a current of hydrogen. The mean of six experiments on different samples of the oxide was 208·6; this process, however, presents this great inconvenience, that the oxygen eliminated forms only one-tenth of the weight of the oxide, so that the smallest error in its determination by loss would involve a tenfold error in the atomic weight of the metal. Secondly, it is observed that during the process the oxide is transformed into a black powder, probably a suboxide, and after this point is reached the reduction requires a far higher temperature by which the bismuth is melted: the molten metal is then liable to retain small quantities of oxygen. A better process consists in converting a known weight of the oxide into the sulphate by solution in dilute nitric acid, and the gradual addition of sulphuric acid to the nitrate formed. The solution of the sulphate is evaporated down and ignited at a temperature below faint red heat. The mean of six determinations with three different samples of the oxide gave the value 208 16 for the atomic weight ($S = 32\ 06$).

Manganese.—The atomic weight of this metal has been determined by Berzelius and Dumas from analysis of the chloride; by v. Hauer, from conversion of the sulphate into the sulphide; Dewar and Scott, from the reduction of silver permanganate. The mean of these analyses points to 55 as the probable atomic weight of the metal, although the experiments of Rawak on the conversion of the red oxide into the peroxide, and of Schneider on the analysis of the oxalate, would lead to the atomic weight 54.

The method here adopted consists in (I) the fractional precipitation of the oxalate from an aqueous solution of the nitrate; (II) in the conversion of the oxalate into the protoxide by ignition in hydrogen; and (III) in the solution of a known weight of the reduced oxide in sulphuric acid to form the sulphate. During this last process, it is impossible to prevent a little oxidation, which is revealed by a brown coloration of the solution; the amount of this oxidation is ascertained by adding a standard solution of oxalic acid to the solution of the sulphate. The solution of the sulphate is evaporated down and ignited at a temperature below red heat. The mean of four determinations was 55·07.

Zinc.—The number 65 is generally adopted as the atomic weight of zinc, from the experiments of Erdmann on the conversion of the metal into the oxide by solution in nitric acid and ignition of the nitrate. Favre and Jacquelain have substituted the value 66, but their experiments are not sufficiently trustworthy.

It is here pointed out that Erdmann's experiments are inexact, owing to the persistent retention of nitrous fumes by the zinc oxide; and if the temperature be raised sufficiently high to completely eliminate them, there is always an appreciable loss in weight of the oxide. The method here adopted consists in the conversion of the oxide into the chloride by solution in hydrochloric acid, and the evaporation of this solution with potassium chloride to obtain the double zinc potassium chloride $2KCl,ZnCl_2$. In this salt the proportion of zinc was determined as oxide and the chlorine by silver nitrate. From the known atomic weights of chlorine, potassium, and silver, that of zinc can be deduced. The mean value of one series consisting of five experiments was 65·29, and of another series of three experiments was 65·33. The mean of this number may be taken as a sufficiently near approximation to the atomic weight of the metal, although there are involved in the process two sources of error, viz., loss of oxide of zinc during ignition, and secondly, the retention by the double chloride of small quantities of mother-liquor, more rich in zinc chloride.

Magnesium.—The atomic weight of magnesium has been determined by various processes, yet the numbers vary from 24 to 24·5, although the preparation of the oxide in a state of purity presents no difficulties. After quoting experiments to show that magnesia may be ignited at a high temperature without appreciable loss of weight, the author describes the details of the conversion of known weights of the oxide into the sulphate by heating with dilute sulphuric acid at a temperature slightly below boiling point. The samples of oxide operated on were obtained by the ignition of the nitrate, sulphate, and carbonate. The mean of ten very concordant experiments gave 24·38 as the atomic weight. Another series of thirteen experiments were also made by a reverse process, viz., by the conversion of known weights of the sulphate into the oxide; the mean of these latter gave 24·37 for the atomic weight. Attempts were also made to determine the proportion of magnesium and chlorine in the double potassium magnesium chloride, but the method proved unsuccessful owing to the retention of magnesium chloride by the crystals of the double salt.

Inorganic Chemistry.

Density and Coefficient of Expansion of Liquid Oxygen. By K. Olszewski (*Monatsh. Chem.*, 5, 124—126).—A long glass bulb of 1·4 c.c. capacity is fused to a thick thermometer tube connected with a Natterer's flask containing oxygen at 50 atmospheres pressure, and also with an air manometer. The bulb is immersed in liquid ethylene, whose temperature can be reduced, by aid of an air-pump, to —139°. On opening the valve of the Natterer's flask the bulb slowly fills with liquid oxygen. At the moment the bulb is completely filled, the supply of oxygen is cut off, the temperature and pressure of the oxygen noted, and the oxygen in the bulb allowed to evaporate and measured in the gaseous state. Corrections are made for the unliquefied oxygen in the tubes. The following table gives the results of the experiments:—

Temperature of the liquid oxygen.	Volume of gaseous oxygen (at 0° and 760 mm.) obtained from the liquid oxygen.	Weight of the liquid oxygen in grams.	Density of the liquid oxygen.
129·57°	737·34 c.c.	1·0577	0·7555
139·29	858 21 „	1·2304	0·8788
137·46	834·29 „	1·1961	0·8544
139·36	856·58 „	1·2280	0·8772
134·43	787·32 „	1·1287	0·8063
139·13	858·05 „	1·2300	0·8787

From these results, the coefficient of expansion for liquid oxygen = 0·01706. The temperatures were determined by a hydrogen thermometer.
A. J. G.

Temperature of Solidification of some Gases and Liquids. By K. Olszewski (*Monatsh. Chem.*, 5, 127—128).—The reduction of temperature required for these results was obtained by means of the evaporation of liquid ethylene at ordinary pressure (—102°); for the lower temperatures, the evaporation was accelerated by the use of an air-pump. The temperatures were taken with a hydrogen thermometer.

Chlorine at —102° forms an orange-yellow liquid, in which yellow crystals separate; on lowering the temperature a few degrees, the whole liquid sodidifies to a yellow crystalline mass.

Hydrochloric acid is a colourless liquid at —102°; it solidifies at —115·7° to a white crystalline mass, and commences to melt again at —112·5.

Arseniuretted hydrogen is a colourless liquid at —102°, forms a white crystalline mass at −118·9°, melts again at −113·5°, and boils at −54·8°.

Silicon fluoride solidifies to a white amorphous mass in a glass tube cooled to −102°; on increasing the temperature, it slowly evaporates without previous fusion.

Ethyl ether solidifies at −129° to a white crystalline mass; it liquefies at −117·4°.

Amyl alcohol is an oily liquid at 102°, has a buttery consistency at −115°, and only becomes quite frozen at −134°, when it forms a hard semitransparent amorphous mass. A. J. G.

Boiling Points of Oxygen, Air, Nitrogen, and Carbonic Oxide under Atmospheric Pressure. By S. Wroblewski (*Compt. rend.*, **98**, 982).—The author measures low temperatures by means of the thermoelectric properties of metals, using very sensitive aperiodic galvanometers of high resistance, the apparatus being previously graduated by comparison with a large hydrogen thermometer. In this way, it is possible to measure 0·0000025 of a volt, which corresponds with a change of temperature of 0·2° at about −200°.

The gases employed were compressed under 100 atmospheres in a metallic receiver, and then conducted into a glass tube surrounded by liquid oxygen. The oxygen was caused to evaporate by releasing the pressure, and the gas in the glass tube was thus liquefied. The glass tube was then gradually put in communication with the air, and the liquefied gas allowed to boil under atmospheric pressure.

Oxygen.—Boils at −184°. The results previously obtained at different pressures were as follow:—

Pressure.	Temperature.
50·00 atmos.	−113·0° (critical point)
27 02 ,,	−129·6
25·85 ,,	−131·6
24·40 ,,	−133·4
23·18 ,,	−134·8
22·20 ,,	−135·8
1·00 ,,	−184·0

Air.—Boils at −192·2°.

Nitrogen, obtained by the action of metallic copper on air, boils at 193·1°. The boiling point of this gas, calculated from that of air, on the assumption that the boiling point of the latter depends on its composition, is −194·3, and it is possible that the nitrogen employed contained a small quantity of oxygen. It is evident in any case that the constituents of the air do not separate on liquefaction.

Carbonic Oxide.—The gas employed contained about 6 per cent. of carbonic anhydride, and the mixture boiled at −186°. Assuming that the boiling point of carbonic anhydride is −80°, that of carbonic oxide is −193°, or the same as that of nitrogen.

By the evaporation of these gases in a vacuum, temperatures are obtained several degrees below −200°. C. H. B.

Presence of Hydrogen Peroxide and Ammonium Nitrite, and Absence of Ozone in the Products of the Combustion of Hydrogen and Hydrocarbons in Air. By A. R. LEEDS (*Chem. News*, **49**, 237—239).—With regard to the question of formation of ozone, hydrogen peroxide, and ammonium nitrate during the combustion of hydrogen, or hydrogenous substances, in air (or oxygen), many communications have been made by various authors, some supporting and some denying the production of the various substances enumerated. After reference to these, the present note contains a description of an apparatus, by means of which the author can burn purified hydrogen or hydrocarbons (coal-gas) in purified air, and collect the products without contact with anything but glass and platinum wire. It consists of a long tube. with a globular enlargement, closed at the top; at the lower end, this fits air-tight into a receiver connected by means of a glass tube and ground stoppers with the first of a series of three bottles similarly connected; these serve for the collection of the products of combustion. Air is admitted by a lateral tube at the top, the hydrogen by a similar tube connected with a platinum jet below the enlargement; combustion is started by means of spark sent through platinum wires fused in the glass; each of the wires terminates in a minute spiral, which is wholly immersed in the flame during the combustion; they are useful, as they indicate by their incandescence the existence of a flame, and also prevent its extinction. With this apparatus, ammonium nitrite and hydrogen peroxide have been detected in the products of the combustion of pure hydrogen and hydrocarbons in purified air; but ozone and ammonium nitrate were not found. In these experiments, the products of combustion were not removed speedily from the influence of the high temperatures of the flame, as was the case in all previous experiments, hence it is possible that the ozone, if formed, was decomposed by the high temperature.

D. A. L.

Nitrogen Iodide. By A. GUYARD (*Ann. Chim. Phys.* [6], **1**, 358—412).—Nitrogen iodide in water is decomposed slowly by the action of sunlight with evolution of nitrogen; the rapidity of the change is increased by the blue and yellow rays, decreased by the violet rays. It proceeds slowly up to a certain point, at which violent explosions occur; but if a moderately concentrated solution of ammonia be substituted for water the change occurs gradually until all the nitrogen iodide is converted into ammonium peroxide and nitrogen. The equation representing the decomposition is as follows:— $3N_2H_4I_2 = N_3 + 3NH_4I_3$, or in the presence of ammonia, $3N_2H_4I_2 + 4NH_4OH = 6NH_4I + 2N_2 + 4H_2O$. It is here proposed to make use of this reaction as a means for determining the chemical intensity of daylight, and several forms of apparatus are described by which the nitrogen evolved may be measured. As regards the formula for nitrogen iodide, the author considers that Meron's and Marchand's formula, NH_2I, or preferably $N_2H_4I_2$, is supported by the greater weight of evidence; it is thus a diiodamine. Its formation has probably been correctly represented by Odling thus: $3NH_3 + I_4 = NHI_2 + 2NH_4I$, although it is noticed that whatever be the quantity of iodine used there is always some unchanged ammonia at the end of the reaction.

The process here adopted for the preparation of nitrogen iodide consists in adding a solution of ammonia to solution of iodine in potassium, sodium, or ammonium iodides (the so-called periodides). If this latter solution be added to an ammoniacal solution of a cupric oxide, there is formed a violet-green double iodide of copper and nitrogen, whose composition is probably expressed by the formula $2CuI_2,N_2H_4I_2$, decomposed by water to form an oxyiodide of copper, CuO_2I.

The analysis of nitrogen iodide may be effected by sodium thiosulphate, which converts the iodine into ammonium iodide, and causes the evolution of ammonia. The proportional quantities of free ammonia, and of combined ammonia, can be determined by distillation, and the iodine by silver nitrate. Several experimental results are here adduced, which point to the reaction between the ammonia and iodine as occurring between a greater number of molecules of these substances than was suspected by Odling.

The mother-liquors from the preparation of nitrogen iodide give precipitates with soluble salts of silver, mercury and bismuth, of which the last is probably a periodide of bismuth, Bi_2I_4. It separates out in graphite-like scales, very stable when dry, but decomposed rapidly in the presence of water to form bismuth oxyiodide.

V. H. V.

Dimorphism of Sodium Thiosulphate. By F. PARMENTIER and L. AMAT (*Compt. rend.*, **98**, 735—738).—It is well known that if a minute crystal of the ordinary form is added to a supersaturated solution of sodium thiosulphate, the latter crystallises in short thick monoclinic prisms, and there is considerable development of heat, but the temperature never rises above 47·9°, the melting point of the salt. If, however, very strong solutions are cooled in a freezing mixture out of contact with any particles of the ordinary salt, the thiosulphate crystallises in long slender needles, and the temperature does not rise so high as in ordinary cases, although there is still considerable development of heat. If crystals of this kind are introduced into a supersaturated solution of the salt, they bring about the formation of precisely similar crystals, but the temperature never rises above 32°. When fragments of the ordinary salt are introduced into a solution containing the needle-shaped crystals, the latter disappear, heat is developed, and the salt crystallises in the ordinary form. When too, an attempt is made to isolate the needles by pouring off the mother-liquor, they are always converted into the ordinary crystals. The needles can, however, be isolated in the following manner. Two flasks, one of which contains thiosulphate, are connected together by a bent tube, the apparatus being entirely closed. The whole apparatus is then heated at 60° in order to destroy every trace of the ordinary crystals, and the flask containing the thiosulphate is cooled in a freezing mixture. When about half the salt has crystallised in needles the mother-liquor is decanted through the tube into the other flask. The needles are then carefully melted, a few of the crystals being left intact, about half the salt is allowed to crystallise, and the mother-liquor decanted through the tube. By several repetitions of this process a small quantity of the salt is finally obtained, crystallised in needles, and entirely free from the ordinary short prisms. As soon, however, as the needles are brought in contact with the air they change into the ordinary crystals.

The needles have exactly the same composition as the ordinary crystals, and they also appear to belong to the monoclinic system, but they melt at 32°, whereas the short prisms melt at 47·9°. Determinations of the heat of solution of the needles show that, taking Berthelot's value — 11·6 cal. for the heat of solution of the short prisms, the heat of transformation of the needles into the ordinary variety is + 2·8 cal.

When partially dehydrated thiosulphate is treated in a similar manner, reduction of temperature does not produce the same crystals, but other salts containing less water, which crystallise at a higher temperature the lower the proportion of water. These salts are always mixed with more or less mother-liquor, and when brought in contact with the ordinary variety they change into it with development of heat. C. H. B.

Chlorides of Lithia and Lime. By G. LUNGE (*Annalen*, **223**, 106—110).—This paper is principally a polemic directed against Kraut's criticism of the author's results of the reaction between lithium hydroxide and chlorine (comp. Abstract, 1883, 953). It is here shown that as at ordinary temperatures, so at 0°, the point at which Kraut investigated the change, chlorine acts very slowly upon lithium hydroxide, with production of a compound containing at most 4 per cent. available chlorine. The presence of a trace of the crystalline hydrate of the hydroxide materially increased the yield.

V. H. V.

Hydrated Aluminium Sulphate. By P. MARGUERITE-DE LA CHARLONNY (*Ann. Chim. Phys.* [6], 1, 425—432).—The aluminium sulphate of commerce crystallises in rather hygroscopic tablets of composition $Al_2(SO_4)_3,18H_2O$. In this paper another hydrate is described of composition $Al_2(SO_4)_3,16H_2O$, crystallising in orthorhombic prisms, which effloresce slowly. This latter salt, which can be more conveniently dealt with than the former, can be obtained by the decomposition of ammonium alum by heat, by recrystallisation of the crude alum of commerce or from alunite; for its preparation care must be taken to prevent its crystallisation, *en masse*, from a concentrated solution, for the salt obtained under those conditions cannot be dried without difficulty. This hydrated sulphate also occurs as an efflorescence on schistose rocks at Rio Saldana in South America.

V. H. V.

Vapour-density of Beryllium Chloride. By L. F. NILSON and O. PETTERSSON (*Compt. rend.*, **98**, 988—990).—The chloride was prepared by the action of dry hydrochloric acid gas on the metal in a platinum tube, and was volatilised in an atmosphere of carbonic anhydride (in which it does not dissociate below 706°) in Schwarz's apparatus, an air thermometer being enclosed along with the latter in an iron tube in the furnace. The following results were obtained:—

Temperature	490°	520°	589°	597°	604°
Density	6·7 (?)	4·174	3·067	3·031	3·090

Temperature	686°	720°	745°	812°
Density	2·853	2·926	2·753	2·793

It follows that between 686° and 812°, the molecule of beryllium chloride is represented by the formula $BeCl_2$, the atomic weight of Be being 9·1. The higher values obtained at lower temperatures are due to the fact that the molecule at these temperatures consists of aggregations which split up as the temperature rises. At 520°, for example, the density 4·174 corresponds with the formula Be_2Cl_4. In this respect, beryllium chloride resembles stannous chloride.

It follows from these results that in accordance with Avogadro's law, the atomic weight of beryllium is 9·1, which agrees with its place in the periodic series, but this is the first case in which the conclusion deduced from this law does not agree with that deduced by means of the law of Dulong and Petit from the determination of the specific heat. C. H. B.

Disintegration of Zircon. By F. Stolba (*Chem. News*, **49**, 174).—One part of finely powdered zircon is mixed with 4 parts of a mixture of 2 of potassium borofluoride and 3 of potassium carbonate, and fused at a red heat in a platinum crucible. The molten mass is poured on a dry metal plate, and as soon as it solidifies is thrown into water to render the mass friable, and thus facilitate subsequent pulverisation. The powder is boiled out with water and filtered. The filtrate contains the greater part of the zirconium as double fluorides, and alkalis precipitate zirconium hydroxide from it. The insoluble portion is dissolved in hydrofluoric acid, the remaining zirconium being by this means converted into zirconium potassium fluoride. Zircon is also attacked by prolonged boiling with caustic alkali. Crucibles of nickel serve well for the fusion of zircon with caustic alkali. D. A. L.

Normal Didymium Molybdate and the Valency of Didymium. By A. Cossa (*Compt. rend.*, **98**, 990—993).—Normal didymium molybdate is obtained as an amorphous precipitate by mixing warm moderately concentrated solutions of didymium nitrate and sodium molybdate. It has the composition DiO 43·39, MoO_3 56·47 = $DiMoO_4$. Attempts to obtain the salt in crystals by fusing didymium sulphate with sodium molybdate and chloride resulted only in the formation of mixtures of acid and basic molybdates; but by simply fusing the amorphous salt at a very high temperature, a crystalline homogeneous mass is obtained. The crystals belong to the quadratic system, and present only the octahedral faces $b\frac{1}{2}$, which are somewhat rounded, although very brilliant. According to Friedel, the angles are, $b\frac{1}{2}b\frac{1}{2}$ 49·6°; terminal face, 79·46°; the corresponding angles on wulfenite being 48·25° and 80·2° respectively. Crystals of a mixed didymium lead molybdate containing 28·56 per cent. of lead molybdate were obtained by fusing the amorphous precipitate formed on mixing sodium molybdate with a solution of lead and didymium nitrates. The angles of these crystals, according to Friedel, are: terminal face, 80° 11′ 3″; $b\frac{1}{2}b\frac{1}{2}$, 49·5°. It is evident that didymium molybdate is strictly isomorphous with lead molybdate, and this fact confirms the conclusions drawn from the author's previous researches on didymium tungstate (Abstr., 1879, 695) that the oxide of didymium is analogous to that of lead or calcium, and has the formula DiO.

C. H. B.

Separation of Gallium. By L. DE BOISBAUDRAN (*Compt. rend.*, **98**, 711—712).—*From Boric Acid.*—1. The solution is strongly acidified with hydrochloric acid, and the gallium precipitated as ferrocyanide. The excess of ferrocyanide is removed by means of cupric chloride, the precipitate washed with dilute hydrochloric acid, and the copper removed from the filtrate by means of hydrogen sulphide. The filtrate from the copper sulphide is evaporated over potash in a vacuum, then mixed with calcium chloride, supersaturated with ammonia, and evaporated to dryness at a gentle heat, the boric acid being estimated by Ditte's method (*Compt. rend.*, 1875, 490). The calcium borate which is thus obtained is sometimes mixed with a little ferric oxide. In this case it is dissolved in hydrochloric acid, neutralised by a mixture of potassium and sodium carbonates or hydroxides in equivalent proportions and ignited. The residue is treated with water, which leaves the ferric oxide undissolved, whilst the boric acid passes into solution, and is again treated by Ditte's method.

2. The slightly acid solution of the chloride is mixed with an excess of sodium and potassium acetates in equivalent proportions, and a suitable quantity of arsenious anhydride, and then treated with hydrogen sulphide. The arsenious sulphide carries down the gallium. A current of air is passed into the filtrate, in order to expel the greater part of the hydrogen sulphide, and the liquid is mixed with a considerable excess of potassium and sodium hydroxides in equivalent proportions, evaporated to dryness in a gold vessel, and strongly heated with exposure to air. The residue is dissolved in very dilute hydrochloric acid, and the boric acid in the solution estimated by Ditte's method. This process is especially useful for the separation of small quantities of gallium from large quantities of boric acid.

An aqueous or hydrochloric acid solution of boric acid loses no sensible trace of this substance when evaporated in a vacuum at ordinary temperatures.

C. H. B.

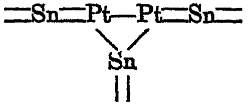
A Metallic Radicle. By P. SCHÜTZENBERGER (*Compt. rend.*, **98**, 985—988).—If spongy platinum is added to four or five times its weight of tin at about 400°, combination takes place with development of heat and light, and the resulting alloy, when granulated by being poured into cold water, is somewhat less white than tin alone. When this alloy is heated, in an atmosphere of hydrogen or carbonic anhydride, with hydrochloric acid diluted with its own volume of water, hydrogen is given off, and part of the tin dissolves as stannous chloride. When the evolution of hydrogen ceases, the residue consists of very thin glistening blackish-grey lamellæ, which closely resemble graphite; these, when washed with acidulated water, and finally with pure water to remove all traces of excess of tin, and then dried, soil the fingers and leave a mark on paper. This residue consists mainly of platinum and tin, with small quantities of hydrogen and oxygen, and a considerable proportion of chlorine. The chloride could not be isolated, because it is gradually decomposed by warm water. By treating the residue with warm dilute ammonia, the whole of the combined chlorine is removed, and a hydrated oxide is obtained resembling the chloride in appearance, but with a slightly brown colour. When dried in a vacuum over sulphuric acid, it has the composition $Pt_2Sn_3O_4H_2$, and on reduction by hydrogen it yields a greyish-white pulverulent almost infusible alloy of the composition Pt_2Sn_3, identical with that obtained by Deville and Debray by melting 1 part of platinum with 6 parts of tin, and treating the cold alloy with hydrochloric acid. In this latter case it is probable that the large crystals in which the alloy Pt_2Sn_3 was obtained, were only superficially attacked by the hydrochloric acid.

If the pulverulent alloy is heated to dull redness in oxygen, combination takes place with incandescence, and the oxide formed has the composition $Pt_2Sn_3O_3$. The reduction and reproduction of this oxide can be repeated any number of times.

If the hydrated oxide is heated in a current of dry oxygen, water is given off, but is replaced by oxygen, and an oxide of the composition $Pt_2Sn_3O_4$ is formed. If, however, this compound is reduced by hydrogen, and the residue reoxidised, the oxide $Pt_2Sn_3O_3$ is alone obtained.

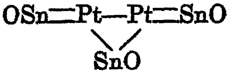
These stanno-platinic compounds have considerable catalytic power. They oxidise alcohol into aldehyde, and when the hydrated oxide is brought in contact with hydrogen, there is a considerable development of heat. When the pulverulent alloy Pt_2Sn_3 is brought in contact with chlorine, a large amount of heat is developed, and stannous chloride volatilises.

The compound Pt_2Sn_3 may be regarded as formed by the combination of a hexavalent group, consisting of two atoms of platinum $\begin{array}{c}\equiv\mathrm{Pt}-\mathrm{Pt}\equiv\\ \diagdown\ \diagup\end{array}$, with three tetravalent atoms of tin, forming a new hexavalent group,



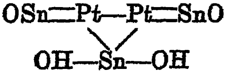
$$\begin{array}{c}\equiv\mathrm{Sn}\equiv\mathrm{Pt}-\mathrm{Pt}\equiv\mathrm{Sn}\equiv\\ \diagdown\ \diagup\\ \mathrm{Sn}\\ \|\end{array}$$

the derivatives of which will have the constitutions



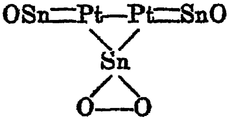
$$\begin{array}{c}\mathrm{OSn}\equiv\mathrm{Pt}-\mathrm{Pt}\equiv\mathrm{SnO}\\ \diagdown\ \diagup\\ \mathrm{SnO}\end{array}$$

1st oxide.



$$\begin{array}{c}\mathrm{OSn}\equiv\mathrm{Pt}-\mathrm{Pt}\equiv\mathrm{SnO}\\ \diagdown\ \diagup\\ \mathrm{OH}-\mathrm{Sn}-\mathrm{OH}\end{array}$$

Hydrated oxide.



$$\begin{array}{c}\mathrm{OSn}\equiv\mathrm{Pt}-\mathrm{Pt}\equiv\mathrm{SnO}\\ \diagdown\ \diagup\\ \mathrm{Sn}\\ \diagup\ \diagdown\\ \mathrm{O}-\mathrm{O}\end{array}$$

2nd oxide.

If the residue left after removing the excess of tin by dilute hydrochloric acid is subjected to prolonged treatment with concentrated hydrochloric acid, a residue is obtained, which contains less than one atom of tin, and continued action of the acid would probably remove the whole of the tin.

The solution of stannous chloride obtained by treating the alloy with dilute acid becomes yellow when exposed to the air, and contains platinum, from which it would seem that stannoplatinic chloride is not completely insoluble. C. H. B.

Yellow and Red Lead Monoxide. By A. Geuther (*Annalen*, **219**, 56—71).—The author has prepared both modifications of lead monoxide in the pure state. The yellow variety is obtained by strongly heating lead carbonate or nitrate, if barely to the melting point as an amorphous powder, if above as a crystalline mass. It is also obtained by adding an excess of strongly diluted sodium or potassium hydroxide solution to a boiling solution of a lead salt, or by heating in a silver basin 1 part lead hydroxide with 7 parts sodium hydroxide and 14 parts water at the boiling point, until nearly all the lead hydroxide is dissolved, and slowly cooling. As the yellow variety is formed at a high temperature, it can also be obtained by strongly heating the red. The red variety is formed when lead hydroxide is heated at 110°; also when 1 part lead hydroxide is dissolved in 5 parts potassium hydroxide, and the mixture is allowed to cool extremely slowly; lastly, the red variety may be obtained by boiling an excess of lead hydroxide in dilute caustic soda, until all the yellow which is first formed has disappeared. The yellow oxide is of a sulphur colour, forming rhombic crystals of 9·25 sp. gr. at 15°, and becomes yellowish-red on pressing and rubbing. The red oxide is of an iron- or garnet-red, according to its state of division, and forms tetragonal crystals of 9·125 sp. gr. at 14°. Both modifications can be obtained from the basic lead nitrate $(PbO)_3,HNO_3$, which is best made by slowly precipitating lead nitrate with double the necessary quantity of ammonia solution, and agitating well. At 170°, this salt loses water and is converted into $Pb_6O_5(NO_3)_2$. If the salt $(PbO)_3,HNO_3$ is treated with pure dilute caustic soda, the yellow variety is formed, and if the second salt $Pb_6O_5(NO_3)_2$ is similarly treated, the red variety is formed. The author therefore considers that the yellow variety must have the formula Pb_3O_3 or $(Pb_3O_3)_m$, and the red variety the formula Pb_6O_6 or $(Pb_6O_6)_m$, and that this polymerism affords an explanation of the dimorphic forms of lead oxide.

A solution of lead monoxide in melted potassium hydroxide rapidly absorbs oxygen, with formation of potassium salts of lead dioxide; these appear to have the formulæ K_2O,PbO_2 and $2K_2O,3PbO_2$; they crystallise in hexagonal plates, and are decomposed by water.

A. B.

Bismuthic Acid. By C. Hoffmann (*Annalen*, **223**, 110—136).—Potassium salts of bismuthic acid are obtained when a current of chlorine is passed into a boiling, not too concentrated, solution of potash, in which bismuth hydroxide is suspended; the resultant substance is then separated off, and the process repeated. The potassium salts have the composition $2KBiO_3 + nBi_2O_5$, and are of a red to dark violet-brown shade; the more concentrated the alkali, the greater is the proportion of potassium present, but this can be removed by boiling with water or preferably by carbonic acid; in no case, however, was pure bismuthic acid obtained. These compounds, when treated with acetic acid, yield the orange bismuthyl bismuthate, Bi_4O_9, and with nitric acid the golden bismuthyl bismuthate, or bismuth dioxide, Bi_4O_8 or BiO_2.

If chlorine is passed into very concentrated potash containing bismuth hydroxide, golden to red basic bismuth salts of bismuthic acid are formed; these intermediate compounds cannot be oxidised by chlorine into bismuthic acid or its derivatives, but are converted by concentrated nitric acid into bismuth dioxide. It has been stated by Bodecher that a bismuthic acid of composition $Bi_2O_5,2H_2O$ is formed, when a solution of the nitrate is precipitated by potassium cyanide. As it appears improbable that a higher oxidation product should result from such a change, the experiments were repeated. It is proved that the substance formed is bismuth bisulphide, Bi_2S_2, the sulphur being derived from impurities contained in the commercial potassium cyanide. V. H. V.

Uranium Compounds. By A. DITTE (*Ann. Chim. Phys.* [6], 1, 338—358).—Hydrofluoric acid converts green uranium oxide into uranyl fluoride, UO_2F_2 ($U = 240$), and uranium hydrogen fluoride, $UF_6,2HF$, of which the latter forms crystals, decomposed by heat into uranium and hydrogen fluorides, whilst the latter is a green insoluble powder, decomposed into uranium dioxide and a volatile oxyfluoride, UOF_2.

On melting the fluorides of the alkali-metals with the oxide U_3O_8, there are produced double fluorides of the general formula $UO_2F_2,2MF$, which are crystalline, and insoluble in water; but the uranium hydrogen fluoride produces with the oxide U_3O_8, salts of the general formula $UOF_2,2MF$, crystallising in well-defined forms, and soluble in water. These latter compounds may also be obtained by treating the green oxide with hydrofluoric acid, and neutralising the liquid, after separation of the black oxide, with metallic carbonates.

The chlorides of the metals of the alkalis and alkaline earths, when calcined with the green oxide, form a crystalline uranate, UO_3,MO, together with a mixture of the crystalline oxides UO_2 and U_2O_5. But in the presence of a chlorate, salts of composition analogous to the dichromate $2UO_3,M_2O$ are obtained; in the particular case of lead, the composition of the uranate is expressed by the formula $2UO_3,PbO$. In the original memoir, the preparation and properties of the various uranates of the alkalis and alkaline earths, together with those of magnesium and lead, are described in full. These compounds are quite insoluble in water, and, with the exception of that of lead, infusible at a white heat. V. H. V.

Mineralogical Chemistry.

Löllingite and other Minerals from Colorado. By W. F. HILLEBRAND (*Amer. J. Sci.* [3], **27**, 349—358).—*Löllingite.*—A cobaltiferous and nickeliferous variety of lollingite is found in several mines at the base of Teocalli Mountain, Colorado. It occurs embedded in a gangue of siderite and barytes in steel-white forms, one-eighth of an inch in diameter, with a radiate structure. When treated with hydrochloric acid, the star-like forms were found to be composed of a number of flattened ellipsoids interpenetrating at a common centre. A microscopic study proved that the fundamental form is that of löllingite, showing only the prism and macrodome. These two forms are often equally developed, producing a resemblance to a low tetragonal pyramid. The angle of the prism was found to be very nearly 122°. An analysis of carefully isolated löllingite gave the following results:—

As.	S.	B.	Cu.	Fe.	Ca.	Ni.	Total.	Sp. gr.
71·18	0·56	0·08	0·39	22·96	4·37	0·21	99·75	7·40

This leads closely to the formula $Fe(CoNi)As(S)_2$.

Some varieties of safflorite, rhombic $CoAs_2$, present similar features, especially as regards the tendency to form twins of interpenetration; and, from the presence of cobalt, it might be supposed that the mineral was safflorite. The high percentage of iron, the high sp. gr., and the occurrence of a macrodome instead of a brachydome render it necessary, however, to classify it with löllingite.

Cosalite.—This mineral occurs in a quartz vein at the Comstock Mine, La Plata Co., Colorado, associated with iron pyrites, blende, sylvanite, and native gold. The analysis gave the following results:—

Bi.	Ag.	Cu.	Pb.	Fe.	Zn.	S.	Total.
42·97	8·43	7·50	22·49	0·70	trace	17·11	99·20

from which the formula $2RS + Bi_2S_3$ may be deduced.

A Mineral Probably New.—A portion of the ore from the Missouri Mine, Park Co., Colorado, is composed of a sulpho-bismuthite of copper and silver. It occurs in a quartz gangue, associated with copper pyrites and wolfram. Small slender crystals (sp. gr. 6·31) resembling bismuthinite occur in numerous cavities. An analysis is given under I. The more compact material gave the results under II, after deducting 59·75 per cent. of gangue. A specimen (sp. gr. 2·643) from another portion of the workings gave the figures under III:—

	Bi.	Ag.	Cu.	Pb.	Fe.	Zn.	S.	Total.
I ..	60·80	0·89	15·96	—	2·13	0·10	19·94	99·82
II ..	63·42	4·09	12·65	—	0·59	0·07	18·83	99·65
III ..	62·51	9·89	6·68	2·74	0·10	0·07	17·90	99·89

After the subtraction of impurities, the atomic ratio becomes in each case nearly 3 : 4 : 15, which leads to the general formula $3RS + 4Bi_2S_3$.

Hübnerite.—This mineral was found in the Royal Albert vein, Ouray Co., Colorado. It occurs in long flattened crystals with a subvitreous lustre and brownish-black to pale yellow colour. The sp. gr. is 7·177, and the composition is as follows:—

SiO_2.	Nb_2O_5.	WO_3.	MnO.	FeO.	CaO.	Total.
0·62	0·05	75·50	23·40	0·24	0·13	100·02

This agrees very closely with the formula $MnWO_4$. B. H. B.

Herderite. By DES CLOIZEAUX (*Compt. rend.*, **98**, 956—959).—The mineral herderite, described by Haidinger, was for a long time found only in very small quantity at Ehrenfriedersdorf, in Saxony, and on the result of blowpipe analyses by Turner and Plattner, it has been regarded as a fluophosphate of calcium and aluminium. According to Haidinger's measurements, the Ehrenfriedersdorf crystals are modified right rhombic prisms of 115° 53′. In 1882, somewhat large crystals were discovered at Stoneham, in Oxford Co., State of Maine, apparently identical with those from Ehrenfriedersdorf, but according to Mackintosh these crystals are calcium-*beryllium*-fluophosphate of the composition—

P_2O_5.	CaO.	BeO.	F.		O.		
44·31	33·21	15·76	11·32	–	4·76	=	99·84

The alumina reported by Plattner and Turner as present in the Ehrenfriedersdorf crystals may really be beryllia, but the specimens are too small and too valuable to be used for analysis. The author has however made a careful optical examination of specimens from both localities, and finds that the crystals from Stoneham are identical in their optical properties with those from Ehrenfriedersdorf, so that in all probability they belong to the same mineral species.

C. H. B.

Identity of Scovillite and Rhabdophane. By G. J. BRUSH and S. L. PENFIELD (*Amer. J. Sci.* [3], **27**, 200).—The authors recently described (*Amer. J. Sci.*, **25**, 459) a hydrous phosphate of the cerium and yttrium earths from Salisbury, Conn., as a new mineral, giving it the name Scovillite. They now find that it is essentially identical with rhabdophane, a Cornish mineral, of which only four specimens are known. The American mineral contains no cerium oxide, and has a larger percentage of the yttrium earths. Assuming the relation of the yttrium to the cerium earths to be 1 : 4, the theoretical composition may be calculated to be P_2O_5, 28·40; $(Y,Er)_2O_3$, 11·12; $(La,Di)_2O_3$, 53·28; H_2O, 7·20. This closely corresponds with the results obtained by W. N. Hartley (Trans., 1882, 210, and 1884, 167) and the authors. The results calculated for comparison up to 100 are as follows:—

	P_2O_5.	$(Y,Er)_2O_3$ +	$(La,Di)_2O_3$.	Fe_2O_3.	H_2O.	Total.
Rhabdophane ..	26·26	65·75		—	7·99	100·00
Scovillite......	29·10	9·93	53·82	0·29	6·86	100·00

B. H. B.

Composition of Idocrase. By P. JANNASCH (*Jahrb. f. Min.*, 1884, 1, Mem., 269—270).—In continuation of his investigations to determine the chemical nature of idocrase (Abstr., 1883, 1067), the author notes that fluorine is a very constant constituent. TiO_2 seems to be still more frequent, and he has now discovered B_2O_3 in the idocrase from the River Wilui, in Siberia. An analysis of this mineral, the so-called wiluite, gave the following results:—

SiO_2.	TiO_2.	B_2O_3.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.
36·17	1·30	2·81	12·23	2·18	1·49	0·15

CaO.	MgO.	H_2O.	F.	Na_2O.	Total.
35·81	6·05	0·72	0·22	0·45	99·58

B. H. B.

White Garnet from Wakefield, Canada. By G. F. KUNZ (*Amer. J. Sci.* [3], 27, 306).—Some remarkable white garnets have been found at Wakefield. They occur in a vein in crystalline magnesian limestone. The crystals vary in size from 1 mm. to 80 mm. in diameter. Associated with the garnet are crystals of pyrrhotine and white pyroxene. An analysis gave the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	MnO.	CaO.	MgO.	Total.	Sp. gr.
38·80	22·66	1·75	0·30	35·00	0·68	99·19	3·60

B. H. B.

Action of Heat on Heulandite. By E. MALLARD (*Jahrb. f. Min.*, 1884, 1, Ref., 312—313).—When examined under the microscope at an increasing temperature, heulandite shows no such alterations as are, for example, displayed by boracite. If a plate of heulandite is heated to 150°, the refractive power alters but slowly; white patches appear at the edges and gradually fill up the plate, showing a change which can evidently be due only to a loss of water. If a plate altered in this way be placed in Canada balsam the changed condition may be retained; but if it remains exposed to the air, it absorbs moisture and returns slowly to its original state. If the plate is laid in water, the change is effected rapidly. When heated to 180°, the plate breaks into pieces, and does not return to its original condition. The author explains these phenomena as follows: Heulandite contains 5 mols. H_2O, two of which belong to its constitution. If the latter, which are set free only at a high temperature, are driven off, the molecular construction is destroyed. This is not the case when the 3 mols. H_2O, set free at a low temperature, are released. They then separate from the substance by a purely physical process, like water from a sponge. After the expulsion they may be taken up again and distributed throughout like the colouring matter in crystals. The successive expulsion of these 3 mols. H_2O is accompanied by a change of the inclination of the optical axis, the position of the axial plane, &c.

The author finds that beaumontite, brewsterite, chabasite, and desmin, minerals with a high percentage of water, behave like heulandite; while heat appears to have no action on mesotype and analcime. B. H. B.

The Olivine of the Melitite-basalt of Hochbohl. By A. STELZNER (*Jahrb. f. Min.*, 1884, 1, Ref., 270—271).—An error having been discovered in the analysis of the olivine from the melitite-basalt of Hochbohl (Abstr., 1883, 719), the author has caused another analysis to be made, which gave the following results:—

SiO_2.	MgO.	FeO.	Ni.	Insol. residue.	Total.
39·12	44·80	13·16	trace	3·00	100·08

B. H. B.

Zeolites in the Dolerites of Chaux-de-Bergonne (Puy-de-Dôme). By F. GONNARD (*Compt. rend.*, **98**, 1067—1068).—In addition to the phacolite, mesolite, and christianite already known to exist in the dolerites of the district of Chaux-de-Bergonne, the author has found gismondite in small white octahedra, apparently macled, and phillipsite in small crystals in cruciform macles. C. H. B.

The Freiberg Gneiss. By A. STELZNER (*Jahrb. f. Min.*, 1884, 1, Mem., 271—275).—The author has for some time been engaged in a petrographic examination of the Freiberg gneiss in order to test the correctness of Sanberger's theory of the formation of ore-deposits by lateral secretion. In the course of his investigations, he has discovered that the gneiss is rich in columnar crystals of zircon, accompanied by tourmaline, garnet, and apatite. In the undecomposed gneiss from the Himmelfahrt Mine, magnetic pyrites, iron pyrites, and probably some arsenical pyrites were found, the qualitative analysis of the non-magnetic pyrites giving Fe, Ni, Co, and As. The principal minerals of the decomposed gneiss are quartz, felspar, and mica. The latter is, partially or entirely, converted into potash-mica and forms, in hexagonal plates and small globular aggregates, the principal mass of the altered gneiss. This secondary mica has been analysed with the remarkable result that it contains, together with 0·41 TiO_2, 0·54 SnO_2 as chemical constituents.

Other products of the decomposition of the gneiss are rutile and anatase. It is evident that these titaniferous minerals are the products of the decomposition of the brown mica of the gneiss, which often contains a large percentage of TiO_2. The analysis of the anatase-holding heavier portion of the country rock of the Carl Stehende vein showed that the portion insoluble in aqua regia and hydrofluoric acid contained 11·44 per cent. SnO_2, and hence the fine needles in the residue are evidently tin-ore.

With regard to the minerals constituting the undecomposed rock, the following may be mentioned: From 715 grams of gneiss from the Himmelfürst Mine were obtained, with the help of Thoulet's solution, 12·20 grams pyrites, rutile, garnet, tourmaline, zircon, and apatite; and from this 4·65 grams magnetic pyrites was extracted with the magnet. The latter gave on analysis 0·61 Ni and 0·12 Co, but no metallic constituent. In 20 grams of the brown mica of the gneiss, traces of Ni and Co were found; whilst in the white mica 4·42 per cent. FeO and 0·03 per cent. Cu, with a little sulphur, were found. The felspar proved to be free from baryta and other abnormal constituents.

The author reserves all conclusions as to the mode of formation of the Frieberg veins for a final report to be published as soon as the analyses are completed. B. H. B.

Organic Chemistry.

Action of Iodine Monochloride on Monobromethylene. By L. Henry (*Compt. rend.*, **98**, 680—682).—Monobromethylene combines slowly with iodine monochloride at the ordinary temperature, but combination is not complete until after several days, the liquid having been frequently agitated. An oily brownish liquid separates from the aqueous solution, and when decolourised with aqueous potash, dried over calcium chloride, and distilled, it yields chlorobromiodethane, C_2H_3ClBrI, a colourless liquid, which rapidly becomes brown. It has a somewhat sharp, agreeable odour, with a sweet, burning taste, and boils under the ordinary pressure at 193—195° with partial decomposition; sp. gr. at 0° = 2·53. When treated with an equivalent quantity of alcoholic potash, chlorobromiodethane is instantly decomposed; potassium chloride and iodide are precipitated together in the proportion of 3KCl to KI, and on adding water to the alcoholic filtrate, a heavy oily liquid is thrown down; this, when decolourised by potash, dried, and distilled, yields a small quantity of unsymmetrical chlorobromethylene, $CH_2 : CClBr$, which boils at 63° and polymerises very rapidly, and a much larger quantity of unsymmetrical bromiodethylene, $CH_2 : CBrI$, which boils at 128—130° with partial decomposition.

It follows from these results that the product of the action of monobromethylene on iodine monochloride is a mixture of the two isomerides, $CH_2I : CHBrCl$ and $CHBrI.CH_2Cl$, in the proportion of 1 mol. of the former to 3 mols. of the latter. The chlorine and the iodine both combine with the two groups CHBr and CH_2, but in unequal proportion, the chlorine combining most readily with the highly hydrogenised CH_2-group; whilst the iodine combines most readily with the CHBr-group, containing the bromine. This reaction is of the same order as that of iodine monochloride on monochlorethylene, but the proportional distribution of the haloïds is essentially different in the two cases.

Chlorobromiodethane is readily decomposed by bromine with the formation of a chlorodibromethane which, when treated with alkalis, yields the two compounds $CH_2 : CBrCl$, boiling at 63°, and $CH_2 : CBr_2$, boiling at 88—90°, the latter being in much larger proportion than the former. C. H. B.

Unsymmetrical Chloriodethylene and Bromiodethylene. By L. Henry (*Compt. rend.*, **98**, 741—744).—*Chloriodethylene*, $CH_2:CClI$, is obtained in small quantity by the action of a slight excess of alcoholic potash on chlorobromiodethane (preceding abstract). It is a colourless liquid which decomposes rapidly when exposed to light, eventually becoming deep purple. It is insoluble in water, and when freshly distilled has a slight ethereal odour, but it slowly absorbs oxygen, and after some time has the odour of acid chlorides. It boils, with partial decomposition, at 100—101° under a pressure of 759 mm.; sp. gr. 0° = 2·1431. Unlike the chlorobromo-derivative it does not readily polymerise.

Bromiodethylene, $CH_2:CBrI$, is the principal product of the action of alcoholic potash on chlorobromiodethane (*loc. cit.*). It is a colourless liquid, which rapidly becomes violet, and is insoluble in water; sp. gr. at 0° = 2·5651. It boils at 128—130° with partial decomposition, under a pressure of 764 mm.; does not readily polymerise, and absorbs oxygen somewhat more slowly than the preceding compound.

The following table gives the formulæ and boiling points of the known symmetrical and unsymmetrical di-haloïd derivatives of ethylene:—

	Symmetrical.			*Unsymmetrical.*		
Diff.		B. p.	Diff.		B. p.	Diff.
55°	$CHCl:CHCl$ ..	55°	20°	$CH_2:CCl_2$....	35°	55°
	$CHBr:CHBr$ ..	110	20	$CH_2:CBr_2$....	90—91	
	$CHI:CHI$	190				
37	$CHCl:CHBr$ ..	81—82	19	$CH_2:CClBr$ ..	63	37—38
31	$CHCl:CHI$....	119	19	$CH_2:CClI$ ..	100—101	29
	$CHBr:CHI$ ..	150	20	$CH_2:CBrI$ ..	128—130	
27	$CHCl:CHCl$ ..	55	20	$CH_2:CCl_2$....	35	28
68	$CHCl:CHBr$ ..	81—82	19	$CH_3:CClBr$ ..	63	67
40	$CHBr:CHI$ ..	150	20	$CH_2:CBrI$ ..	128—130	40
	$CHBr:CHBr$..	110	20	$CH_2:CBr_2$....	90—91	
64	$CHCl:CHCl$ ..	55	20	$CH_2:CCl_2$....	35	65
	$CHCl:CHI$....	119	19	$CH_3:CClI$ ..	100—101	

The unsymmetrical derivatives, whether simple or mixed, are more volatile than the isomeric symmetrical compounds, the difference between the boiling points of the corresponding members of the two series being always 19—20°, and the difference between the boiling points of any two terms in the one series is the same as the difference between the corresponding two terms in the other series. The substitution of one haloïd for another produces the same change of boiling point in both series. If the position of the haloïds with respect to the nucleus $C\equiv C$ in these derivatives exerts great influence on their volatility and determines their boiling point, this position is entirely without influence on their *relative* volatility, which depends exclusively on the nature of the haloïd, that is, on the molecular weight.

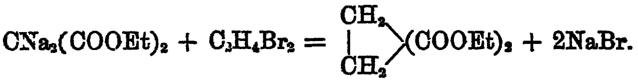
The sp. gr. of the symmetrical derivatives is, as a rule, higher than that of the corresponding unsymmetrical derivatives, as is seen in the following table:—

	Sp. gr. at 0°.
$CHCl:CHI$	2·230
$CH_2:CClI$	2·140
$CHBr:CHI$	2·750
$CH_2:CBrI$	2·560
$CHI:CHI$	3·303
$CH_2:CI_2$	2·942

Precisely similar relations hold good in the case of the di-derivatives of ethane. C. H. B.

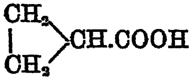
Action of Ethylene Bromide on Ethyl Malonate. By W. H. Perkin, Jun. (*Ber.*, 17, 54—59).

—When sodium (9 grams) is dissolved in absolute alcohol (90—100 grams), and the product treated with a mixture of ethyl malonate (30 grams), and ethylene bromide (36 grams), *ethyl trimethylenedicarboxylate* is produced:



$$CNa_2(COOEt)_2 + C_2H_4Br_2 = \begin{matrix}CH_2\\|\\CH_2\end{matrix}\!\!>\!C(COOEt)_2 + 2NaBr.$$

It is a colourless oil, which boils at 206—208° (720 mm.). The free acid may be obtained by saponifying it with alkali and then adding an acid; it is a crystalline substance, melting at 140—141°, and decomposing slowly at 160° with evolution of carbonic anhydride; it is extremely soluble in water, much more so than in ether. Bromine acts on it very slowly in the cold, but disappears with evolution of hydrobromic acid when heated. The silver salt, $C_5H_4O_4Ag_2$, forms a white precipitate, somewhat soluble in water. When trimethylenedicarboxylic acid is heated in an oil bath at 210°, carbonic anhydride is abundantly evolved, whilst *trimethylenemonocarboxylic acid*,



$$\begin{matrix}CH_2\\|\\CH_2\end{matrix}\!\!>\!CH.COOH$$

distils over. This is a colourless liquid, boiling at 188—190°; it has a slight odour, is somewhat soluble in water, readily in ammonia. The ammonium salt is very readily soluble, and crystallises in scales; the silver salt, $C_4H_5O_2Ag_5$, forms a white amorphous sparingly soluble precipitate, and when heated yields a readily volatile liquid, which is probably the anhydride of the acid. At the ordinary temperature bromine has no action on the monocarboxylic acid, but on warming it reacts with evolution of hydrobromic acid. A. K. M.

Synthesis of Dihydric Alcohols from Mixtures of Aldehydes. (Preliminary Communication.) By W. Fossek (*Monatsh. Chem.*, 5, 119—120).

—The author has previously shown that diisopropylethylene glycol is formed by the action of alcoholic potash on isobutaldehyde; analogous glycols are obtained by the action of alcoholic potash on a mixture of equal molecular weights of isobutaldehyde and another aldehyde, or by the addition of sodium-amalgam to an alcoholic solution of such mixture. These glycols are all crystalline, distil unchanged, are insoluble in water, alcohol, and ether.

Methylisopropylethylene glycol, $CHMe(OH).CHPr^{\beta}.OH$, prepared from acetaldehyde and isobutaldehyde, is a thick colourless liquid, solidifying at about 0° to a compact white crystalline mass. It boils at 204—208°, has a faint agreeable odour, and a burning peppermint-like taste.

Isobutyl-isopropylethylene glycol, $CHBu^{\beta}(OH).CHPr^{\beta}.OH$, obtained from isovaleraldehyde and isobutaldehyde, crystallises in long needles, and melts at 80—81°.

Phenylisopropylethylene glycol, $CPhH(OH).CPr^{\beta}H.OH$, from benzaldehyde and isobutaldehyde, melts at 81—82°, is soluble in benzene, and has an agreeable aromatic odour.

A crystalline product (m. p. 94°) obtained by the action of alcoholic potash on a mixture of acetone and isobutaldehyde, is also under investigation.

A. J. G.

Action of Solutions of Cellulose on Polarised Light. By A. Levallois (*Compt. rend.*, **98**, 732—735).—A 1 per cent. solution of purified cotton in Schweizer's ammonio-cupric reagent, has a lævorotatory power for the light which passes through the ammonio-cupric liquid of about −20°. Comparative experiments on the action of sugar on this light and on sodium light show that the deviations observed in the first case must be multiplied by 1·85, in order to render them comparable with those observed in the second. The degree of rotation is not strictly proportional to the amount of cotton dissolved, but increases somewhat more slowly than the concentration of the solution. If the solution is diluted with water or with ammonia, the rotatory power at first rapidly diminishes, but afterwards a condition of equilibrium is established, beyond which any further dilution has little effect. If the ammonio-cupric solution is prepared by dissolving precipitated cupric hydroxide in ammonia, instead of metallic copper, it dissolves a greater proportion of cellulose, and dilution with water produces different results, the curve being slightly convex towards the axis representing the deviation of the polarised ray. For the same proportion of cellulose, solutions containing increasing proportions of oxide of copper produce increasing amounts of rotation, but the relation between the two quantities has not yet been ascertained.

Flax, hemp, filter-paper, and carefully purified tunicin from *Ascidia intestinalis*, have the same rotatory power as cotton, but hydrocellulose prepared by Girard's method is slightly less active, the rotation produced by a 1 per cent. solution being −19·5°.

C. H. B.

Action of Phosphorous Trichloride on Aldehydes. By W. Fossek (*Monatsh. Chem.*, 5, 121—123).—By the action of phosphorous trichloride on propionic, isobutyric, isovaleric, and benzoic aldehydes, and subsequent treatment with water, similar products are obtained, from which an acid containing phosphorus may be isolated in each case. These acids are crystalline, stable in air, readily soluble in water or alkalis, less soluble in alcohol, still less in ether, and nearly insoluble in benzene. They do not volatilise in a current of steam. The aqueous solutions do not give precipitates with silver nitrate until neutralised with ammonia, when white precipitates are obtained, readily soluble in nitric acid and in ammonia; the latter solution does not yield a precipitate of silver on heating. The potassium and barium salts are readily crystallisable. The acids are not decomposed by several hours' boiling with aqueous potash.

The acid, $C_4H_{11}PO_4$, derived from isobutaldehyde, is granulo-crystalline, and melts at 168—169°. The barium salt has the formula $(C_4H_{10}PO_4)_2Ba$.

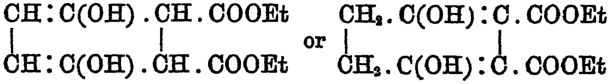
The acid $C_5H_{13}PO_4$, from isovaleraldehyde, crystallises in scales, and melts at 183—184°. It is isomeric with the acid obtained by Guthrie (this Journal, 1856, 139) from amyl alcohol and phosphoric acid.

The acid from propaldehyde crystallises in scales, and melts at 158—160°; that from benzaldehyde is crystalline.

Phosphorous trichloride acts so violently on acetaldehyde that the products are carbonised. A. J. G.

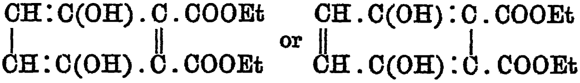
Derivatives of Ethylic Acetoacetate. By W. WEDEL (*Annalen*, **219**, 71—119).—By the action of sodium on *ethylic dibromoacetoacetate*, the author obtained a brown resinous mass, and a substance crystallising in yellow prisms, although in very small quantities; it melts at 133°, is insoluble in water, but soluble in hot alcohol with a strong blue fluorescence. This substance was found to be identical with Hermann's diethyl quinonehydrodicarboxylate, $C_{12}H_{14}O_6$ (Abstr., 1882, 714), obtained by the action of bromine on diethylic succinosuccinate. By the slow action of dilute soda solution and subsequent treatment with hydrochloric acid, the free acid $C_8H_6O_6$ was obtained in colourless crystals, which became yellow on being dried. The acid is sparingly soluble in cold, easily in hot water, and gives a deep blue coloration with ferric chloride. By acting on diethyl quinonehydrodicarboxylate with acetic chloride at 60° in a closed tube, a diacetyl compound, $C_{16}H_{18}O_8$, is formed in bright colourless crystals, insoluble in water, soluble in ether and hot alcohol, melting at 150°, and subliming at a higher temperature. It is decomposed by the action of dilute soda solution, with formation of quinonehydrodicarboxylic acid, $C_6H_2\overline{Ac}_2(COOEt)_2 + 4NaOH = 2EtOH + 2\overline{Ac}Na + C_6H_4O_2(COONa)_2$. In a similar way, by the action of acetic chloride on diethylic succinosuccinate at 115—120°, the author obtained a diacetyl compound, melting at 168°, and subliming at a higher temperature, but in other properties similar to the previously mentioned diacetyl compound. On account of the ease with which the above acetyl compounds are formed or decomposed by dilute caustic alkalis, the author holds that there must be an hydroxyl group in diethylic succinosuccinate, in diethyl quinonehydrodicarboxylate, and consequently also in ethylic acetoacetate, and in this his formulæ differ from those given by

Hermann, and in the case of ethylic acetoacetate from that of Frankland and Duppa. He gives the formula



$$\begin{array}{l} CH:C(OH).CH.COOEt \\ |\qquad\qquad\quad | \\ CH:C(OH).CH.COOEt \end{array} \quad \text{or} \quad \begin{array}{l} CH_2.C(OH):C.COOEt \\ |\qquad\qquad\quad | \\ CH_2.C(OH):C.COOEt \end{array}$$

for diethylic succinosuccinate,



$$\begin{array}{l} CH:C(OH).C.COOEt \\ |\qquad\qquad\quad \| \\ CH:C(OH).C.COOEt \end{array} \quad \text{or} \quad \begin{array}{l} CH.C(OH):C.COOEt \\ \|\qquad\qquad\quad | \\ CH.C(OH):C.COOEt \end{array}$$

for diethyl quinonehydrocarboxylate, and

$$CH_2:C(OH).CH_2.COOEt \text{ or } CH_3.C(OH):CH.COOEt$$

for ethylic acetoacetate. The author also gives various reasons for holding that the hydroxyl in the above compound has more the character of a phenol hydroxyl than an alcoholic, and on this assumption he endeavours to explain the readiness with which quinol is obtained by the distillation of diethyl quinonehydrocarboxylate.

The author failed to obtain any results by the action of sodium on ethylic tribromoacetoacetate. By acting on ethylic mono- or dibromoacetoacetate with sodium alcoholate, he obtained the same products as by the action of sodium. On preparing a bromine derivative of ethylic acetoacetate, which appeared to be a pentabromo-compound, and treating it with cupric acetate, he obtained a salt of ethylic tribromoacetoacetate, $(C_6H_6Br_3O_3)_2Cu$, and he considers that all bromine compounds containing more than 3 atoms of bromine are mixtures of the tribromo-compound and the perbromo-compound. Ethylic perbromacetoacetate, $C_6Br_{10}O_3$, formed by the action of an excess of bromine on brominated ethylic acetoacetate for two days at 60—80°, is obtained as a colourless crystalline mass, melting at 79—80°. The copper derivative of ethylic dibromoacetoacetate, $(C_6H_7Br_2O_3)_2Cu$, crystallises in needles, is insoluble in water, soluble sparingly in cold, but readily in hot alcohol, and is decomposed by bases or acids, or by heating to 100°.

By the action of bromine on ethylic ethylacetoacetate in the cold, brominated compounds were obtained. *Ethylic monobromethylacetoacetate*, $C_8H_{13}BrO_3$, is a brown strongly smelling liquid, of sp. gr. 1·354; gives a violet coloration with ferric chloride; soluble in alcohol and ether, but insoluble in water and in alcoholic solution. *Ethylic dibromethylacetoacetate*, $C_8H_{12}Br_2O_3$, is a yellow fruity smelling liquid, of sp. gr. 1·635; insoluble in water, but soluble in alcohol and ether, and gives a dark wine-red colour with ferric chloride. *Ethylic tribromethylacetoacetate*, $C_8H_{11}Br_3O_3$, is also a yellow liquid, of sp. gr. 1·860. By further action with bromine no definite compounds were obtained, nor did the above yield compounds with cupric acetate. At 100°, the monobromo-compound is decomposed into ethyl bromide, and an acid, $C_6H_8O_3$, or $C_{12}H_{16}O_6$, which the author calls ethylsuccinosuccinic acid.

Ethylsuccinosuccinic acid crystallises in rhombic octahedra; melts at 126·6°, is soluble in water and alcohol, but is nearly insoluble in ether and benzene, and gives a cherry-red coloration with ferric chloride. It is unchanged by boiling with baryta-water, but is completely decomposed when heated with hydrochloric acid at 120—130°.

The barium salt, $C_{12}H_{14}O_6Ba + 2H_2O$, forms very soluble needles; the potassium salt, $C_{12}H_{14}O_6K_2 + H_2O$, is obtained as a very soluble crystalline mass; the ammonium salt, $C_{12}H_{14}O_6(NH_4)_2$, forms needles decomposing at 80°; the sodium salt, $C_{12}H_{14}O_6Na_2 + 2H_2O$, is hygroscopic; the calcium salt. $C_{12}H_{14}O_6Ca + H_2O$, and the magnesium salt, $C_{12}H_{14}O_6Mg + 2\frac{1}{2}H_2O$, are crystalline powders; the zinc salt, $C_{12}H_{14}O_6Zn + 2\frac{1}{2}H_2O$, crystallises in tablets: the manganese salt, $C_{12}H_{14}O_6Mn + 4H_2O$, gives rose-coloured crystals; and the lead salt, $C_{12}H_{14}O_6Pb$. is less soluble. The copper salt is reduced to cuprous oxide by the action of acids. The author failed to obtain any well formed acid salts. The ethyl ether was obtained in very small quantities by the action of hydrochloric acid on an alcoholic solution of the acid. A. B.

Constitution of Ethylic Acetoacetate and of Benzene. By A. GEUTHER (*Annalen*, **219**, 119—128).—The author holds that from the results of Wedel's investigation (preceding Abstract) the constitutional formula for ethylic acetoacetate must be

$$CH_3.C(OH) : CH.COOEt,$$

rather than $CH_2 : C(OH).CH_2.COOEt$. He also endeavours to prove the correctness of Kekulé's constitutional formula for benzene from the ease with which diethyl quinonehydrocarboxylate is formed from ethylic dibromoacetoacetate. A. B.

Formation of Amides from Ammonium Salts. By N. MENSCHUTKIN (*Compt. rend.*, **98**, 1049—1052).—The ammoniacal salts were heated in bulbs at a given temperature for a definite time, and the proportion remaining unaltered was determined by titration with standard soda solution, using phenolphthaleïn as indicator. The amides are formed at temperatures above 100°; the rate of formation increases with the temperature; and, after a sufficient length of time, a maximum limit is attained. The progress of the change is precisely similar to that of etherification, as is shown by the following series of observations on the formation of acetamide from ammonium acetate at 155°:—

Time..............	1	4	8	12	24 hours
Percentage of amide formed	50·9	78·1	80·0	80·0	80·6
Time..............	72	144	192	216	240 hours
Percentage of amide formed	81·0	81·6	81·6	81·5	81·6

The initial velocity of the reaction, *i.e.*, the proportion of amide formed in 1 hour, increases rapidly with the temperature, and depends also on the constitution of the acid. The amides of primary acids are produced much more rapidly than the amides of secondary and tertiary acids, and this rule holds good in both the fatty and aromatic series. In homologous series, the initial velocity diminishes as the molecular weight of the acid increases.

Contrary to the law observed in etherification, the maximum limit to the formation of the amides increases considerably with an increase of temperature. This limit is not affected by the isomerism of the acid; for butyramide at 155° it is 84·13 per cent., and for isobutyramide it is 84·67 per cent. under the same conditions. For phenyl acetamide at 155° the limit is 81·5 per cent., but the formation of benzamide and anisamide take place so slowly that the maximum limit could not be ascertained. At 125°, the maximum limit to the formation of amides of the fatty acids increases with the molecular weight of the acid.

The formation of the amides from the ammoniacal salts follows the same laws as etherification, and this fact that organic compounds, in different reactions, follow the same laws, depending on their chemical constitution, is of very great importance. C. H. B.

Action of Chloraldehydes on Benzene in Presence of Aluminium Chloride. By A. Combes (*Compt. rend.*, **98**, 678—679).—When aluminium chloride is added in successive small portions to a solution of chloral in a large excess of benzene, a somewhat energetic reaction takes place even in the cold. If the liquid is heated at 70° for about an hour and a half, washed with water, and fractionated, it yields a viscous colourless liquid, which has the composition $CPhCl_2.COH,HCl$, and is the hydrochloride of the aldehyde $CPhCl_2.CHO$. This compound is very stable, and can be distilled in a vacuum without decomposition; but when heated under ordinary pressure, it begins to boil at 265° and gradually loses hydrochloric acid, the boiling point rising to 295°. Potash in the cold removes all the hydrochloric acid without attacking the aldehyde, but, when heated, benzaldehyde and products free from chlorine are formed. The aldehyde rapidly reduces Fehling's solution and silver nitrate, and combines, although with difficulty, with sodium hydrogen sulphite. It is readily oxidised and yields the acid $CPhCl_2.COOH$.

The prolonged action of aluminium chloride on a solution of this aldehyde in benzene yields carbon and triphenylethane, $CPh_3.CH_3$, in yellowish-white crystals with a green fluorescence. The crystals melt at 205°. C. H. B.

Colouring Matters formed by the Union of Phenols with Aromatic Aldehydes. By C. Zulkowsky (*Monatsh. Chem.*, **5**, 108—118).—By the action of sulphuric acid mixed with one-third of its weight of glacial acetic acid on a mixture of equal molecular weights of salicylaldehyde and phenol, a mixture of a deep-red and a colourless substance is obtained, the latter being converted into the former by oxidation in an alkaline solution. The red substance could not be obtained in a pure state; it is distinguished from aurin by not yielding a blue colouring matter when boiled with aniline.

If the phenol be employed in excess (4 mols.), the red colouring matter described by Liebermann and Schwarzer (Abstr., 1876, 414) is obtained. Analysis gives numbers agreeing better with the formula $C_{26}O_{20}O_6$ than with Liebermann's formula $C_{26}H_{32}O_6$. At the same time, an ochre-yellow substance was obtained, but could not be purified sufficiently for analysis. The same substances appear to be formed by the action of parahydroxybenzaldehyde on phenol.

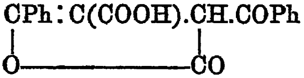
A. J. G.

Hipparaffin. By K. Kraut and Y. Schwartz (*Annalen*, **223**, 40—47).—Schwartz, who isolated the so-called "hipparaffin" as a product of the oxidation of hippuric acid by lead dioxide and sulphuric acid, assigned to it the constitutional formula $C_2H_4(NH\overline{Bz})_2$, or ethylene-dibenzimide. This view was supported by the synthetical production from ethaldehyde and benzamide, of a substance identical in percentage composition with hipparaffin, although differing from it in melting point and solubility in sulphuric and nitric acids. The results of this paper accord with those of Schwartz as regards the physical properties of hipparaffin and its decomposition on distillation, and the non-formation of a bromo-derivative. It is also shown that hipparaffin differs most markedly in melting point and solubility in alcohol both from ethylidene- and ethylene-dibenzamide. Further, ethylidene-dibenzamide decomposes at 130° in presence of water into aldehyde and benzamide, and ethylene-benzamide, on addition of soda, yields ethylenediamine and benzoic acid, but hipparaffin is unaltered. Again, when ethylidene-dibenzamide is boiled with sulphuric acid, it yields ammonia, benzoic acid, and ethaldehyde, whilst hipparaffin under the same conditions yields methaldehyde. This latter reaction would tend to show that hipparaffin is probably methylene dibenzamide; and to prove this conjecture, this compound was prepared synthetically from benzonitrile and methylal. The resultant substance was found to be identical in chemical and physical properties with hipparaffin, whose formation from hippuric acid can be represented by the equation $2CH_2(NH\overline{Bz}).COOH + 4O = CH_2(NH\overline{Bz})_2 + 3CO_2 + 2H_2O$.

V. H. V.

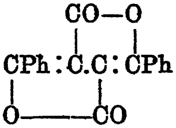
Benzoylacetic Acid. II. By A. Baeyer and W. H. Perkin, Jun (*Ber.*, **17**, 59—66).—By the action of iodine on ethyl sodacetoacetate, Harrow (*Annalen*, **201**, 145) obtained ethyl diacetosuccinate; by boiling with dilute sulphuric acid, this is decomposed into alcohol and ethyl carbopyrotritartarate, the latter becoming saponified by continued boiling. Ethyl benzoylacetate exhibits a perfectly similar behaviour: ethyl dibenzoylsuccinate, $C_{22}H_{22}O_6$, crystallises in small colourless prisms melting at 125—126°; when warmed with concentrated sulphuric acid, it becomes first olive-green and then brownish-red; it dissolves in alcoholic potash with a yellow coloration. The lactonic acid, $C_{18}H_{12}O_5$, obtained on boiling it with 30 per cent. sulphuric acid, is sparingly soluble in water, readily in alcohol, ether, and benzene, and crystallises in small needles melting at 230° with decomposition. From the similarity between this reaction and that described by Harrow (*loc. cit.*), this acid may be assumed to be carbopyrotritartaric acid, in which two phenyl-groups replace methyl. According to Harrow, carbopyrotritartaric acid is a monobasic lactonic acid, and is converted into a dibasic acid by boiling with alkalis. The authors, however, have as yet obtained only dibasic salts of their acid, showing that the aromatic compound takes up the elements of water with greater readiness; the calcium salt, $C_{15}H_{12}O_6Ca$, and the silver salt, $C_{16}H_{12}O_6Ag_2$, form white amorphous precipitates. When the monolactone is boiled with acetic anhydride and the product poured into water, the *dilactone* of dibenzoylsuccinic acid, $C_{18}H_{10}O_4$, separates in colourless scales of silvery lustre. It melts at 254—255° with decomposition, dissolves sparingly in hot alcohol with a splendid violet fluorescence. It is not attacked by alkaline carbonates, but alcoholic potash reconverts it into the original substance.

From the greater instability of the β-lactones, it is probable that the above compounds contain γ-lactone-rings, in which case they stand in a simple relationship to pulvic acid and anhydride:—



$$\begin{array}{l}\text{CPh:C(COOH).CH.COPh}\\ \text{O}\text{———————}\text{CO}\end{array}$$

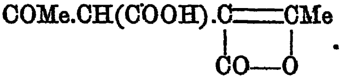
Monolactone of dibenzoylsuccinic acid.



$$\begin{array}{l}\qquad\ \ \text{CO—O}\\ \text{CPh:C.C:CPh}\\ \text{O———CO}\end{array}$$

Dilactone of dibenzoylsuccinic acid.

The monolactone of dibenzoylsuccinic acid, when heated, behaves differently from carbopyrotritartaric acid, this yielding carbonic anhydride and pyrotritartaric acid; whilst the former yields a sublimate (probably the diketone) insoluble in ammonia. This difference may perhaps be accounted for on the supposition that carbopyrotritartaric acid contains a β-lactone-ring:—



$$\begin{array}{l}\text{COMe.CH(COOH).C}{=\!=}\text{CMe}\\ \qquad\qquad\qquad\quad\ \text{CO—O}\end{array}.$$

When ethyl benzoylacetate is boiled, it is decomposed with formation of dehydrobenzoylacetic acid, $C_{18}H_{12}O_4$, the reaction corresponding with the similar production of dehydracetic acid from ethyl acetoacetate:—$2C_6H_5.CO.CH_2.COOEt = C_{18}H_{12}O_4 + 2C_2H_6O$. It crystallises from alcohol in long yellow needles melting at 171—172°, and is also readily soluble in ether and chloroform. With cold concentrated sulphuric acid, it forms an olive-green solution, which becomes violet on warming, and then exhibits the absorption-bands of indigo, the colour disappearing, however, on dilution with water. The alkali salts are readily soluble, whilst the silver salt, $C_{18}H_{11}O_4Ag$, forms a white flocculent precipitate unacted on by light. A solution of the ammonium salt yields a blackish-violet amorphous precipitate with ferrous sulphate, and a deep scarlet-red 'precipitate with ferric chloride. By the action of sodium amalgam, two crystalline acids are produced, $C_{18}H_{14}O_3$ melting at 112°, and $C_{18}H_{14}O$ melting at about 145—150° with decomposition. By the action of cold concentrated alcoholic potash on dehydrobenzoylacetic acid, benzoylacetic acid is reproduced in almost theoretical amount. A. K. M.

Action of Phosphorus Pentachloride on Amido-comenic Acid. By T. BELLMANN (*J. pr. Chem.* [2], 29, 1—22).—How observed that when comenic acid was boiled with ammonia, it yielded a nitrogen-derivative, which he considered to be an amido-acid, and which he consequently called amido-comenic acid. Later researches have shown it to be a monobasic oxy-acid containing nitrogen in the radical nucleus. Ost found that when acted on by phosphorus pentachloride, all the oxygen and nitrogen were replaced by chlorine, hydrochloric acid was liberated, and hexachloropicoline, C_6HCl_6N, was formed. The author has studied the action of phosphorus pentachloride at various temperatures and in various proportions, carefully examining the bye-products formed.

I. *Action of 5 mols. PCl_5 on 1 mol. Amido-comenic Acid at* 220—250° *and at* 275°.—After heating, the mass is thrown into iced water, whereupon a dark-coloured oil separates out. It constitutes the principal product of the reaction, and consists of a mixture of penta- and hexa-chloropicoline. The aqueous portion is evaporated until it crystallises. The crystals, which consist of a chlorinated substance, are separated from the liquor, dissolved in hot water and neutralised with ammonia, in order to separate the body from admixed compounds by the difference in solubility of its ammonium salts. On decomposing it with calcium chloride, the calcium salt is obtained in fine white silky needles. The free acid, which the author calls *monochloro-γ-hydroxypicolinic acid*, $C_6H_4ClNO_3 + H_2O$, forms small colourless pointed needles, which are almost insoluble in cold water, but more soluble in hot. Its aqueous solution, which has an acid reaction, gives a slightly yellow coloration with ferric chloride. It yields a white precipitate with silver nitrate. The free acid melts at 224°. It forms a hydrochloride, crystallising in fine pointed needles.

The *normal calcium salt* forms white efflorescent needles. It is prepared by adding calcium chloride to a solution containing an insufficient quantity of ammonia to neutralise it. The *basic calcium salt* is obtained as a yellowish-white crystalline powder on adding calcium chloride to a neutral solution. Monochloro-γ-hydroxypicolinic acid, when treated with tin and hydrochloric acid, is reduced to γ-hydroxypicolinic acid, $C_5H_3N(OH).COOH + H_2O$, which crystallises in small transparent rhombic pinakoidal plates, containing 1 mol. H_2O, melting at 258°: it differs widely in crystalline form from the α- and β-acids. The *normal barium salt*, $(C_5H_3NOH.COO)_2Ba$, forms slightly yellow microscopic prisms. The *normal calcium salt* crystallises in groups of small white needles, containing 4 mols. H_2O. They become slightly red on standing in the air.

When the aqueous mother-liquor, which remains after separating the monochloro-γ-picolinic acid, is neutralised with concentrated ammonia, it yields a mass of crystals from which the ammonium salt of a new acid can be separated, as it is less soluble than the crystals of ammonium phosphate and chloride. This salt yields a blue coloration with ferric chloride. The author proposes to call it temporarily *monochlorocyamic acid*. It crystallises with 1 mol. H_2O in white silky plates, melting at 186°, and resembling comenic acid. Its *silver salt*, $C_7H_7ClNO_2.COOAg$, forms a voluminous precipitate, which, on stirring, becomes powdery. It is decomposed by boiling with water. The *barium salt* forms small white prisms, which become slightly red on exposure to the air.

II. *Action of 3 mols. of PCl_5 on 1 mol. of Comenic Acid at 200°.*—The principal product is an oil consisting of a mixture of picoline penta- and hexa-chlorides. Mixed with it, in proportions varying directly with the temperature, are small quantities of monochloro- and γ-hydroxy-picolinic acid and chlorocyamic acid.

III. *Action of 3 mols. PCl_5 on 1 mol. at Boiling Point.*—As soon as the reaction has moderated, the contents of the retort are heated until no more hydrochloric acid is evolved. The phosphorus oxychloride is then distilled off as far as possible, and the residue in small portions is thrown into ice-cold water. The amorphous body which separates out is probably a chloride with the composition $C_5H_3Cl_3N.COCl$, combined with phosphoric acid. On reduction, it yields the compound $C_6H_7NO_2$. Ost considers the latter to be the aldehyde of a dihydrohydroxypyridine-carboxylic acid, $C_5H_5N(OH).COH$. However, as it is not altered by sodium amalgam, it cannot be an aldehyde, but is more probably *methylhydroxypyridone*, $C_5H_3NO(OH)CH_3$. It crystallises in large transparent rhombic prisms, with well-formed basic pinakoids. It forms a crystalline acetyl-compound. The *phosphoric acid compound* crystallises in small white warty masses, containing no water of crystallisation; they become reddish on standing in the air. The *hydrochloride* forms long pointed needles, which are very soluble in cold water. A *sodium compound* could not be obtained. The author failed to convert the compound into the corresponding acid. Potassium permanganate converts it into oxalic acid. When treated with bromine, bromomethylhydroxypyridone is obtained, crystallising in small glittering anhydrous plates resembling amido-comenic acid.

Action of Hydriodic Acid on Methylhydroxypyridone.—An excess of hot fuming hydriodic acid was heated with methylhydroxypyridone in a sealed tube at 275°. Ammonium iodide was found in the solution. After separating the precipitated iodine, the mother-liquor was distilled with caustic soda into hydrochloric acid. Platinum chloride was then added, and the ammonium platinochloride removed by filtration. The filtrate yielded crystals of a new platinochloride, which, when decomposed with caustic soda, gave the characteristic smell of a pyridine base.

Action of Phosphorus Pentachloride on Methylhydroxypyridone.—When methylhydroxypyridone is heated with phosphorus pentachloride at 200° in the ratio of 1 to 5—adding phosphorus oxychloride—hexachloropicoline, melting at 60°, and monochloro-γ-hydroxypicolinic acid, melting at 224°, are formed. J. I. W.

Vulpic Acid. By A. SPIEGEL (*Annalen*, **219**, 1—56).—In this paper, a detailed account is given of the direct derivatives, the products of the reduction and of oxidation of pulvinic acid, and of oxytolylic acid, and of the constitutional formulæ of pulvic and vulpic acids (Abstrs., 1881, 97, 173, 1036; 1882, 1076). A. B.

Naphthalene Derivatives. By I. GUARESCHI (*Annalen*, **222**, 262—300).—Besides the dibromonaphthalene melting at 81°, described by Glaser, and that melting at 61° of Jolin, the author has obtained isomerides melting at 67·5—68° and 130—131·5°. *Dibromonaphthalene* melting at 81—82° boils with slight decomposition at 310°; at 56°, 1 part dissolves in 16·5 parts alcohol. On oxidation with nitric acid, it yields dibromophthalic acid, monobromomononitrophthalic acid, and a mixture of dibromonitronaphthalenes; and with chromic acid in acetic acid solution, dibromonaphthaquinone and dibromophthalide. From these reactions, the author considers the constitutional formula of this dibromo-compound to be [Br : Br = 1 : 4].

Dibromonaphthalene, melting at 130—131·5°, boils also with some decomposition at 325·5°; at 56°, 1 part dissolves in 50 parts alcohol. No dibromonaphthaquinone could be obtained from this isomeride. With nitric acid, it yields a monobromonitrophthalic acid and other products. Jolin obtained this dibromo-compound by acting on α-dinitronaphthalene with phosphorus pentabromide, and as this α-derivative contains a nitro-group in each ring, probably this dibromonaphthalene has a similar constitutional formula. *Dibromonaphthalene tetrabromide* can be obtained from the first-mentioned dibromo-compound (m. p. 81—82°), but could not be obtained from that melting at 130—131·5°. *Dibromophthalic acid*, $C_6H_2Br_2(COOH)_2$, obtained as mentioned above, is a white crystalline powder, soluble in hot water and in alcohol, and melting at about 135°. The sodium salt is precipitated by a mixture of alcohol and ether in bright anhydrous laminæ, and is very soluble in water. The anhydride, $C_6H_2Br_2(CO)_2O$, obtained by heating the acid, melts at 207·5—208°, and sublimes in beautiful iridescent needles; when slowly heated with sulphuric acid and benzene, it gives a violet-purple colour.

Dibromonaphthaquinone, $C_{10}H_4Br_2O_2$, is insoluble in water; at 16°, 1 part dissolves in 290—300 parts alcohol. It crystallises in gold-yellow needles melting at 171—173°, and distils in steam. It is isomeric with that (melting at 149·5°) obtained by Diehl and Merz (*Ber.*, **11**, 1064). Dibromophthalide, $C_8H_4Br_2O_2$, crystallises from hot alcohol in white prismatic needles melting at 188—189°.

By the action of bromine on nitronaphthalene melting at 59°, the author obtained monobromonitronaphthalene, dibromonaphthalene, and two tetrabromides of nitronaphthalene, which are always formed even when little bromine is used. *Dibromonitronaphthalene*, $C_{10}H_5Br_2.NO_2$, is formed in small quantities, and crystallises from alcohol in small yellow needles melting at 96·5—98°. *α-Nitronaphthalene tetrabromide*, $C_{10}H_7.NO_2,Br_4$, is sparingly soluble in alcohol (at 15°, 0·26 part dissolves in 100 parts alcohol), and crystallises in groups of colourless needles melting at 131°; when heated to 135—137°, it gives off bromine and hydrobromic acid, and yields bromonitronaphthalene and in part the β-isomeride melting at 142—143·5°. By prolonged boiling with alcohol, it yields a γ-isomeride melting at 172—173°; this is also formed along with the α-derivative in the original reaction. At the melting point, the γ-isomeride decomposes with evolution of bromine and hydrobromic acid, and formation of bromonitronaphthalene, $C_{10}H_7.NO_2.Br_4 = C_{10}H_6Br.NO_2 + HBr + Br_2$. *Bromonitro-*

naphthalene, $C_{10}H_6Br.NO_2$, obtained by the direct action of bromine on nitronaphthalene, and by the decomposition of nitronaphthalene tetrabromide, crystallises from alcohol in yellow needles which melt at 122·5°, and are soluble in ether, benzene, acetic acid, and chloroform. In cold alcohol, 1 part is soluble in 297 parts. By oxidation with potassium permanganate, it is converted into monobromophthalic acid, $C_6H_3Br(COOH)_2$, which crystallises in small white prismatic needles melting at 174—176°; it is soluble in water, alcohol, and ether, but insoluble in chloroform, and yields an anhydride. The barium, lead, and silver salts are nearly insoluble. The anhydride crystallises in colourless needles which melt at 132°; with sulphuric acid and benzene, it yields a purple-violet colouring matter, probably a bromophthalein. This monobromophthalic acid is probably isomeric with that obtained by Faust (m. p. 138—140°), by the direct action of bromine on phthalic acid (*Annalen*, **160**, 62), and identical with Smith's (*Jahresb.*, 1879, 143) melting at 125°, as the author has observed that even traces of impurity will lower the melting point 5° or 6°.

Nitrobromonaphthalene, melting at 122·5°, on reduction, yields *amidobromonaphthalene* melting and subliming at 63—64°. It crystallises in fine plates, sparingly soluble in boiling water, easily in alcohol, ether, benzene, and chloroform; it becomes red on exposure to light, and behaves towards ferric chloride, silver nitrate, &c., as an amidonaphthalene. The hydrochloride crystallises in plates, sparingly soluble in cold water, and still less in hydrochloric acid solution. By oxidation with potassium permanganate, it yields the above-described bromophthalic acid. An isomeric amidobromonaphthalene was also prepared from Jolin's mononitrobromonaphthalene melting at 85° as an oil soluble in alcohol and ether, but not crystallising therefrom.
A. B.

Resin Essences and Oils. By A. Renard (*Ann. Chim. Phys.* [6], 1, 223—255).—The products of the fractional distillation of resin or colophony are separated into two classes, viz., the more volatile portions collectively known by the commercial name of the essences, and the oils whose boiling points are near 300°. By the distillation of large quantities of resin, the author has separated the former class into the following constituents:—

Hydrocarbons.

	B. p.
Pentane, C_5H_{12}	35—38°
Amylene, C_5H_{10}	35—40
Hexane, C_6H_{14}	64—66
Hexylene, C_6H_{12}	67—70
Toluene hexahydride, C_7H_{14}	95—98
Toluene tetrahydride, C_7H_{12}	103—105
Toluene, C_7H_8	111
Xylene hexahydride, C_8H_{16}	120—123°
Xylene tetrahydride, C_8H_{14}	128—130
Xylene, C_8H_{10}	136

Hydrocarbons.

		B. p.
	Cumene hexahydride, C_9H_{18}	147—150
	Cumene tetrahydride, C_9H_{16}	155 ?
	Cumene, C_9H_{12}	151
(1)	Terebenthene, $C_{10}H_{16}$	154—157
(2)	Terebenthene, $C_{10}H_{16}$	171—173
	Cymene hexahydride, $C_{10}H_{20}$	171—173
	Cymene, $C_{10}H_{14}$	175—178
	Metapropyl-ethylbenzene, $C_{11}H_{16}$	193—195
	Dioctene, $C_{16}H_{28}$	260

Aldehydes.

Isobutaldehyde	60—62
Valeraldehyde	96—98

Acids.

Isobutyric acid	153—155
Valeric acid	173—175

Of these compounds the hexa- and tetra-hydrides of toluene, xylene, cumene, and cymene only need be specially noticed. The former or hexahydrides are probably identical with the hydrocarbons obtained by Beilstein and Kurbatow, and by Schützenberger, from the Caucasian petroleums; they are polymeric with the olefine series. *Toluene hexahydride*, C_7H_{14}, boils at 95—98°, sp. gr. = 0·742; it is soluble in alcohol and ether, and is not acted on by hydrochloric acid; with nitric and sulphuric acids, it does not furnish nitro- or sulphonic acid derivatives; by concentrated nitric acid, it is converted into oxalic acid. Cumene hexahydride boiling at 147—150°, and cymene hexahydride boiling at 171—173°, are identical in chemical properties with the above hydrocarbon.

Toluene tetrahydride, C_7H_{12}, boils at 103—105°, sp. gr. = 0·737; it rapidly absorbs oxygen, and is soluble in alcohol and ether. By the action of bromine under various conditions it is converted into two hexabromo-, $C_7H_6Br_6$, and one dibromo-derivative, $C_7H_{10}Br_2$. The first forms crystals which melt at 134°, and at a rather higher temperature decompose with evolution of hydrobromic acid: its isomeride decomposes at about 150°; the dibromide forms white, very unstable crystals. On leaving toluene tetrahydride in contact with water for some time, there are formed long white crystals of a dihydrate, $C_7H_{1},2H_2O$, identical with the colophene hydrate obtained by Tichborne and Anderson. On treatment with sulphuric acid, two isomeric polymerides of the formula $C_{14}H_{24}$ are formed, the one a pale yellow oil, readily oxidised, and the other, a colourless oil, unaltered by the air. *Xylene tetrahydride*, C_8H_{14}, boils at 129—132°, sp. gr. = 0·8158, forms a tribromo- and dibromo-derivative, of which the former, $C_8H_{11}Br_3$, is an orange colour, the latter, a colourless oil; they are both readily decomposed with evolution of hydrobromic acid. By sulphuric acid, the hydrocarbon yields a polymeride, $C_{16}H_{24}$, a yellow oil, readily oxidised in contact with air. Cumene tetrahydride was obtained only in small quantities.

In their chemical properties, the terpenes resembled ordinary terebenthene, they are both lævorotatory. The observations of Kelbe (Abstr., 1882, 711) on the cymene and isobutyric and valeric aldehydes and acids, are confirmed in detail.

The resin oils seem to consist principally of more or less readily oxidised hydrocarbons, probably polymeric with the known hydrocarbons of generic formula, C_nH_{2n-2}. On treatment with sulphuric acid, they are separated into two distinct portions, one insoluble in the acid, not readily oxidised by air; the other soluble in the acid, and rapidly converted into resins by absorption of oxygen.

V. H. V.

A Glucoside from Boldoa Fragrans. By P. CHAPOTEAUT (*Compt. rend.*, **98**, 1052—1053).—The leaves of *Boldoa fragrans* are treated with boiling alcohol, the solution evaporated to dryness, and the residue extracted with very dilute hydrochloric acid in order to remove the alkaloid described by Bourgoin and Verne. The liquid, freed from the greater part of the mucilaginous matter, is then treated with ether or chloroform, and this ethereal or chloroform solution, on evaporation, leaves a transparent amber-coloured syrup with an aromatic taste and smell. This substance, which exists in the leaves to the extent of 0·3 per cent., has the composition $C_{30}H_{52}O_8$, and can be distilled in a current of steam, but cannot be distilled without decomposition in a vacuum or in a current of hydrogen. When heated with very dilute hydrochloric acid, it yields glucose, methyl chloride, and a syrupy substance of the composition $C_{19}H_{28}O_3$, which dissolves in alcohol and benzene, but is insoluble in water. If the benzene solution is treated with sodium, hydrogen is evolved; and if the sodium-derivative thus formed is treated with alcoholic iodides, methyl- or ethyl-derivatives can be obtained. The substance, $C_{30}H_{52}O_8$, is therefore a glucoside or, rather, an ether in which glucose plays the part of an acid. The constitution of the alcoholic constituent has not yet been ascertained.

When the glucoside is injected under the skin of a guinea-pig, or taken into the stomach of a dog, it produces a quiet sleep of longer or shorter duration. If injected into the blood of the dog, it excites and increases the secretory functions, especially the secretion and excretion of bile, saliva, and urine. C. H. B.

Picrotoxin. By E. SCHMIDT (*Annalen*, **222**, 313—352).—The greater part of this paper has already appeared (Abstr., 1881, 740). The author still considers that picrotoxin is a chemical compound of picrotoxinin and picrotin, contrary to the opinion of Barth and Kretschy (Abstr., 1881, 286) that it is a mixture of these two substances. He gives as the formula for picrotoxin, $C_{30}H_{34}O_{13}$; for picrotoxinin, $C_{13}H_{16}O_6 + H_2O$; and for picrotin, $C_{15}H_{18}O_7$. By the action of benzoic chloride on picrotoxinin he obtained picrotoxinin-benzoic anhydride, $(C_{15}H_{16}O_6)_2,\overline{Bz}_2O$, melting at 237—238°, nearly insoluble in water, but soluble in hot alcohol, and crystallising in colourless needles. By acting in a similar way on picrotin, he obtained benzopicrotin, $C_{15}H_{15}O_6,\overline{Bz}O$, melting at 245°, and crystallising from alcohol in colourless needles. A. B.

Picrotoxin. By L. BARTH and M. KRETSCHY (*Monatsh. Chem.*, 5, 65—71).—A criticism of the work of Schmidt on picrotoxin (preceding Abstract). The authors adhere to their view that picrotoxin is a mixture of picrotoxinin and picrotoxin or picrotin, and that the formula of the latter substance is $C_{25}H_{30}O_{12}$. A. J. G.

Morin. By R. BENEDIKT and K. HAZURA (*Monatsh. Chem.*, 5, 63—64).—By treating morin, suspended in glacial acetic acid, with nitric acid, there are obtained oxalic acid, some amorphous products, a small quantity of a nitro-derivative, and resorcylic acid. The amount of the last acid was 18 per cent. of the morin employed. According to Hlasiwetz and Pfaundler (*J. pr. Chem.*, 94, 65), morin is readily reduced by sodium-amalgam, yielding phoroglucinol only: as it is very unlikely that that portion of the morin molecule which yields resorcylic acid on oxidation would yield phloroglucinol on reduction, it seems probable that some other reduction product has been overlooked. A. J. G.

Quercetin and its Derivatives. By J. HERZIG (*Monatsh. Chem.*, 5, 72—93).—The constitution of quercetin is still uncertain. Hlasiwetz and Pfaundler (*J. pr. Chem.*, 94, 65) have shown that on fusing it with potash, phlorglucinol and protocatechuic acid are obtained as end-products, and what is much more important, that by reduction with sodium-amalgam, phoroglucinol and protocatechuic alcohol are formed. Liebermann and Hamburger have shown quercetin to have the formula $C_{24}H_{16}O_{11}$, and have described a diacetyl and a disodium derivative from which they draw the conclusion that only two hydroxyl groups are present (Abstr., 1879, 944). Quercetin crystallises with 3 mols. of water. When heated at 140—150° with concentrated hydrochloric acid, it does not yield methyl or ethyl chloride; heated with hydrochloric acid and alcohol, it does not yield an ethyl salt.

Hexethylquercetin, $C_{24}H_{10}Et_6O_{11}$, is prepared by dissolving 1 molecular proportion of quercetin in 4—5 of alcoholic potash, and then heating with the corresponding amount of ethyl iodide in a sealed tube at 100° for 12 hours. It crystallises in long yellow needles, melts at 120—122° (uncorr.), and is sparingly soluble in cold alcohol. The yield only corresponded to about 50—55 per cent. of the quercetin employed. With potash, it forms a very unstable compound insoluble in alcohol, decomposed on washing with alcohol or water. On heating hexethylquercetin (1 part) with alcoholic potash (5—6 parts) in sealed tubes at 140—150°, a very complete decomposition is effected, the main product of the reaction (53—57 per cent.) being diethylprotocatechuic acid, the identity of which with Kölle's acid (this Journal, 1871, 830) was proved by a comparison of the acid and its salts, and finally by the preparation of *ethylic diethylprotocatechuate* (m. p. 56°)

from both acids. The amount of diethyl protocatechuic acid obtained is nearly equal to that required on the assumption that 1 mol. hexethylquercetin yields 2 mols. of the acid.

Hexamethylquercetin, $C_{24}H_{10}Me_6O_{11}$, prepared in a manner similar to the ethyl salt, crystallises in long golden needles, melts at 156—157° (uncorr.), and when heated with excess of alcoholic potash yields dimethylprotocatechuic acid. On heating hexamethylquercetin with 8—10 parts of acetic anhydride and sodium acetate for 3—4 hours, *diacetylhexamethylquercetin*, $C_{24}H_8Me_6\overline{Ac}_2O_{11}$, is obtained, crystallising in silvery-white needles, melting at 167—169, and sparingly soluble in cold absolute alcohol. On saponification with baryta, it again yields hexamethylquercetin.

The author endeavoured to prepare the diacetylquercetin (m. p. 196—198)° described by Liebermann and Hamburger (*loc. cit.*), but found the product to be *octacetylquercetin*, $C_{24}H_8\overline{Ac}_8O_{11}$; this melts at 189—191°, but otherwise exhibits properties identical with those of the substance they described.

The author considers that these results show quercetin to contain at least six hydroxyl-groups, and also that two protocatechuic acid residues must exist preformed in it. A. J. G.

Contributions to the Histochemistry of Plants. By A. Rossol (*Monatsh. Chem.*, 5, 94—107).—I. *Helichrysin* is a yellow pigment contained in the involucral bracts of *Helichrysum bracteatum*, *H. arenarium*, *H. fœtidum*, *H. hebelepsis*, and *Statice Bonduelli*. In the young bracts, it occurs in the homogeneous protoplasmic cell contents, whilst in the old bracts it is found in the cell membranes only. To obtain it, the flowers are extracted with strong alcohol, the solution evaporated to dryness, the residue treated with water, and the aqueous solution evaporated to dryness at a low temperature. The residue was extracted with absolute alcohol, the solution, after dilution with water, precipitated with lead acetate, the red precipitate well washed, suspended in water and decomposed by hydrogen sulphide; the filtrate on evaporation at 40—50° yields helichrysin as an amorphous, lustrous dark-yellow mass. It is sparingly soluble in cold, readily soluble in boiling water, in alcohol, ether, and acetic, oxalic and tartaric acids, insoluble in benzene, chloroform, and carbon bisulphide. The alcoholic solution has a neutral reaction, and is of a fine golden-yellow colour; addition of either mineral acids or alkalis changes the colour to purple-red, the yellow tint being restored on neutralisation. In alkaline solution, it is readily reduced by sodium amalgam or sulphurous acid.

II. The orange-red colouring matter of the fungi *Peziza aurantia* and *P. convexula* occurs in union with an oily substance dissolved in the plasma of the paraphyses. It dissolves readily in alcohol and ether, sparingly in benzene; the colour is not altered by alkalis or organic acids, is changed to light green by nitric acid, and is destroyed by hydrochloric acid.

III. Using the colour test with sulphuric acid as a means of detecting the position of saponin in the microscopic examination of sections of the roots of *Saponaria officinalis* and *Gypsophila struthium*, the author finds that it occurs dissolved in the contents of all the cells of the parenchyma of the cuticular layer, of the medullary rays and of the wood parenchym and in the parenchyma cells of the cuticular layer of the roots of *Quillaia saponaria.* On drying the plants, it separates in minute amorphous masses.

IV. In the fruits of *Strychnos nux vomica* and *S. potatorum*, strychnine is found to occur in solution in the oil drops suspended in the cells of the endosperm. A. J. G.

Chlorophyll; a Compound of Iron with Glucoside. By A. B. Griffiths (*Chem. News*, **49**, 237).—Arguing from the results published on the probability of chlorophyll being a glucoside (Schunck, *Proc. Roy. Soc.*, **36**, 183), and from the presence of ferrous sulphate in plant cells (Abstr., 1883, 195), and also from the production of a blue colour when Schunck's chlorophyll (*loc. cit.*) is mixed with potassium ferricyanide, it is suggested that the function of ferrous sulphate in the plant is to supply iron to the colourless glucosides (leukoplastids), and so convert them into green glucosides (chlorophyll), whilst the sulphur acts as food to the protoplasm; this would make chlorophyll a compound of iron with a glucoside. It is shown that green chlorophyll is never found in plants grown on soils free from iron: moreover, the author has grown plants to maturity in solutions containing all inorganic salts necessary for plant life, all the sulphur in solution being as ferrous sulphate. D. A. L.

Bark of "Bois Piquant." By E. Heckel and F. Schlagdenhauffen (*Compt. rend.*, **98**, 996—998).—The bark examined was the variety peculiar to Guiana, and agreed exactly with Guibout's description of *Zanthoxylum caribæum.* Its anatomical structure is entirely different from that of angustura bark, which it resembles in external appearance. When macerated with water, it yields a bitter, slightly acid, yellow solution, which turns brown with ferric chloride, and yields an abundant yellow precipitate with mercuric chloride, stannous chloride, tannin, picric acid, double iodides, or phosphomolybdic acid, but gives only a slight turbidity with lead acetate. Nitric acid produces a deep red colour. When extracted with light petroleum, the bark yields a considerable quantity of chlorophyll, fat, and wax, together with a crystalline substance which can also be extracted by alcohol. This substance forms colourless needles of the composition $C_{13}H_{24}O$, which melt at 285°, and give no coloration with nitric, sulphuric, or hydrochloric acid.

If the alcoholic extract, after separation of these crystals, is diluted with water, mixed with lime, evaporated to dryness, and the residue extracted with boiling alcohol, a second crystalline substance is obtained which resembles the vegetable alkaloids in its general properties. It exists in the bark only in very small quantities. With nitric acid, it gives a deep-red coloration, but if the liquid is evaporated on a water-bath and mixed with stannous chloride, no violet colour is produced. Sulphuric and hydrochloric acid have no action on it, but sulphuric acid and potassium dichromate, manganese dioxide, or lead dioxide, produce a violet coloration similar to that produced by strychnine mixed with a little selenium. An alcoholic solution of bromine also produces a deep blue coloration which persists for a long time. 5 mgrms. of this alkaloïd injected in aqueous solution beneath the skin of a frog, produce rapid general paralysis, followed by death in about half an hour, and similar effects are observed with rabbits and guinea-pigs.

A nitrogenous resinous substance, soluble in water, was also obtained from the bark. It has the general properties of the alkaloïds, and in its physiological action very closely resembles the crystalline alkaloïd just described, although it differs from it in physical properties. None of the so-called xanthopicrite could be obtained from the bark. C. H. B.

Decomposition Products of Albumin. By W. KÜHNE and R. H. CHITTENDEN (*Zeits. f. Biol.*, **19**, 159—208).—Kühne from his former researches regards the albumin molecule as composed of two groups (antialbumid and hemialbumin) preformed in it, which are converted into their corresponding peptones by the action of pepsin. Antialbumose and hemialbumose are the intermediate bodies between albumin and peptone, both being produced by the action of pepsin, as well as by weak acid. The two peptones are distinguished by their behaviour under the influence of trypsin. Hemipeptone is converted into leucine and tyrosine, only a small quantity of peptone remaining unchanged, whilst antipeptone on the other hand is unaltered even after long-continued digestion. The authors give an exact description of the behaviour and general properties of these different bodies obtained from egg-albumin, serum-albumin, syntonin, and fibrin. The following table gives the mean of many analyses of the chief bodies:—

	Antialbumid.	Antipeptone.	Hemialbumose.	Hemipeptone.
C	53·79	49·87	50·96	49·38
H	7·08	6·89	6·85	6·81
N	14·55	15·21	15·88	15·07
S	24·58	28·03	1·45	1·10
O			24·86	27·64

Antialbumid is best obtained from coagulated egg-albumin by heating for a long time in 0·5 per cent. H_2SO_4, washing the undissolved residue with water, digesting with pepsin, which however does not dissolve it, but converts it into a substance of jelly-like consistency, finally digesting with trypsin in an alkaline medium. Antipeptone may be obtained from the solution by precipitation with alcohol. No leucine or tyrosine was formed by long digestion of the antipeptone. Antialbumose can only be obtained by a process of fractional peptic digestion, and when digested tryptically, forms antipeptone only.

Hemialbumose and hemipeptone are best obtained by acting on coagulated egg-albumin for a short time with a peptic fluid. The solution thus obtained is neutralised, the precipitate filtered off, the filtrate evaporated down to a small bulk and precipitated with alcohol. The hemialbumose and hemipeptone are separated by extracting the peptone with cold water.

The authors give full details for preparing these bodies from serum-albumin and fibrin. Digesting fibrin tryptically for a short time is another good way of obtaining antialbumid. Hrmialbumose like hemipeptone on digestion furnishes leucin and tyrosin.

J. P. L.

Physiological Chemistry.

Influence of Potassium Bromide on Nutrition. By B. Schulze (*Zeits. f. Biol.*, **19**, 301—312).—More or less accurate experiments have been made with the same view as the author's with morphine, quinine, digitalis, iodine, mercury, arsenic compounds, phosphorus, &c. Of the halogens, chlorine and iodine alone have been experimented with, the former as a sodium salt, the latter as hydriodic acid. Chloride of sodium produces a diuretic action, as well as an increase in the decomposition of albumin and a concomitant increase of nitrogen in the form of urea. Hydriodic acid on the other hand has no decided influence on the decomposition of albumin. The potash and soda salts have not been experimented with; the author presumes the action would be the same as that of the acid.

The favourable results that have been obtained by the use of bromide of potassium in different kinds of nervous disorders, especially epilepsy, lead one to the conclusion that the functions of the nervous system suffer a change under the influence of the drug. The author conducted the experiments on himself, taking a diet of known composition, and observing very regular habits. The drug was taken in 10-gram doses, divided into two portions of 5 grams each, dissolved in 200 c.c. water and taken at intervals of four hours. The daily ration was as follows:—

			Grams.
220	grams	fresh meat, containing..............	7·13 N.
55	„	air-dried wheaten bread, containing	0·92 „
30	„	fat-free cocoa, containing	1·14 „
30	„	butter...........................	—
30	„	sugar............................	—
5	„	salt.............................	—
1500	c.c.	water............................	—
		Total	9·19 N.

The experiment lasted from the 4th to 13th July. On each day, the volume, sp. gr., and absolute weight of the urine were determined, as well as its nitrogen, sulphur, and phosphorus, a record also of the body-weight and temperature was kept (see table, p. 851). In the fæces, the nitrogen only was determined. The numbers obtained from the fæces were so irregular, that it was difficult to say whether the bromide had any influence on the digestion of the food.

Date.	Body-weight.	KBr, gram.	Volume, c.c.	Absolute weight.
July 4th	142·0	—	668·0	685·7
„ 5th	140·5	—	611·0	627·5
„ 6th	139·5	—	678·5	696·2
„ 7th	138·5	—	630·5	646·9
„ 8th	137·5	10	946·5	969·0

„ 11th	1·026	11·10	0·725	0·832
„ 12th	1·023	11·33	0 734	0·699
„ 13th	1·025	10·45	0·704	0·723

Taking the average of the first four days as the normal elimination, there is a large increase in the volume of urine on the day the drug was taken. On repeating the dose on July 9th, the increase was not so marked: this can only be explained, the author says, by the supposition that there was an insufficiency of water in the food and body to cause an increase in volume. The increased quantity of water eliminated is not connected with the excretion of the drug which passes in small quantities only on the first day, but in large quantities on the second day, when the amount of urine excreted is again normal.

When the nitrogen is taken alone, the influence of the bromide is not very clear, for on the 8th July there was a moderate increase; on the 9th, when a further increase might have been expected from the second dose, the nitrogen was normal. The sulphur and phosphorus, however, show a regular and marked change, the former an increase, the latter a decrease. The author supposes the balance of nitrogen elimination is attributable to the fact that the minus-nitrogen of the phosphorised constituents, nuclein, lecithin, and the plus-nitrogen from the increased decomposition of sulphur-yielding bodies, compensate each other. He concludes from this, that under the influence of bromide of potassium, a decided diminution of metabolism occurs in the nervous tissue, and along with it a decided diminution of nervous activity.

J. P. L.

Cocoa-nut Meal for Horses. (*Bied. Centr.*, 1884, 135.)—Some of the horses of the 7th Cuirassiers were fed with a mixture of oats and meal, and then compared with others fed only on oats: the results in the former case were most satisfactory, the reduction in the cost of the horse-keep amounting to 50 frs. per year. E. W. P.

Rearing Calves on Skim Milk. By A. BARTH and H. HENNINGSEN (*Bied. Centr.*, 1884, 120).—The first author says that feeding a calf from birth with skim milk, and calculating the value of the milk from the price obtained for the calf, raised the value of skim milk from 8 pfennigs per litre (market price) to 11·5 in the one case, and to 12·1 in the other. Henningsen on the other hand, with five calves fed on skim milk, after the eighth day reckons skim milk at 4 pfennigs. E. W. P.

Formation of Neutral Fat from Fatty Acid in the Animal System. By I. MUNK (*Bied. Centr.*, 1884, 106).—A dog was fed, after 19 days starving, for 14 days on 3200 grams flesh and 2850 grams of the acids obtained from mutton suet. At the end of that time, when the animal was killed, it was found that a large quantity of fat was deposited, and that it consisted of 96 per cent. of ordinary suet. Consequently, as the fat deposited had the composition of suet, it could not have been produced from the ordinary albuminoïds given in the food, for that would have formed dog-fat. E. W. P.

Properties of Linseed and Sesame Seed. By LANGLEBERT (*Bied. Centr.*, 1884, 138).—By reason of the mucilage, these mucilaginous seeds have a double action. They act mechanically in the stomach by producing an increased flow of gastric juice, thus preventing debility of the stomach; softened in the stomach they pass into the intestines, and there the oil they contain forms an emulsion, and acts in its characteristic manner. E. W. P.

Gases of the Alimentary Canal of Herbivora. By TAPPEINER (*Zeits. f. Biol.*, **19**, 228—279).—Previous observations have shown that a much larger quantity of gas is formed in the intestines of herbivora than of carnivora; at the same time, the aromatic products of the urine derived from putrefactive changes in the intestines are much greater. The author first endeavours to obtain a thorough survey of the gases formed in the different sections of the alimentary canal, and further to examine whether the bacteria can exert the same activity without as within the organism. In order to isolate the different sections, the abdominal cavity is opened immediately after death, and the various parts ligatured without disturbing the organs (*in situ*) more than possible. The collection of the gas in the case of the small animals was carried out under mercury. In the case of the larger animals, saturated salt solution was used in place of mercury, the transference of the gas being performed as quickly as possible.

As the composition of the gas developed in the intestines is modified by diffusion and solution in the blood, the author conducted after-fermentation experiments of the contents of the different sections, in order to determine the true relation. These were performed in glass cylinders, kept at the most favourable temperature in an incubator. Bunsen's method of analysis was first used, afterwards that of Hempel. The author first examines the intestinal gases of the ruminants. The gas of the paunch was found to be of a very constant composition, consisting approximately of 65 per cent. CO_2, 31 per cent. CH_4, 2 to 4 per cent. N_2. The after-fermentation of the contents in the manner described, gave nearly the same results, the most characteristic features of the fermentation being the constant formation of CH_4 and a large quantity of free acid. In the living animal, the contents of the paunch are maintained weakly alkaline or only faintly acid by the constant flow of saliva: directly the flow ceases, the reaction becomes acid. Oxygen in small quantities increases the activity, but in large quantities (as for instance exposing the contents for one hour to the air) retards fermentation. Magnesia also has a very marked influence on the fermentation, if added in a quantity of about 1 per cent.; at first only CO_2 and H_2 are given off, then CO_2 and a little CH_4; later on, the contents become acid, and the usual marsh-gas fermentation appears. If, however, the magnesia be added in a quantity of about 1·5 per cent., the fermentation is arrested for some weeks, and when the fermentation recommences, CO_2 and CH_4 are formed, but the contents throughout remain slightly alkaline, although from the development of the gas, relatively speaking, there must have been more than a sufficiency of acid to combine with the magnesia. The action of antiseptics is the same as in all other fermentative processes, total suspension, or hindrance according to the strength of the antiseptic.

The gases of the reticulum, many-plies, and rennet were not examined.

The production of gas in the small intestine appears to be less than in the paunch. The difference in composition is mainly due to diffusion undergone in transit. The after-fermentation of the contents of the small intestine yields almost exclusively CO_2, SH_2, and H_2. The contents of the cæcum and colon similarly treated yield the same gases as the paunch contents, but less in quantity, and the reaction is feebly alkaline. From this it would appear as though there were two separate kinds of CH_4 fermentations. The author advances two suppositions. 1st. If the acid and CH_4 are developed by one and the same process, then there probably exists another species of bacterium in the colon capable of producing bodies of alkaline reaction which neutralise the acid. 2nd. If the two processes are distinct, the acid-producing bacterium is absent in the colon.

The author next examines the intestinal gases of the horse and rabbit. CH_4 is not found as a constituent of the gas of the stomach, the gas being composed chiefly of CO_2, H_2, and N_2. The small intestine gives the same results as the stomach. It is difficult to understand how the fermentation can proceed in presence of so much free hydrochloric acid in the stomach. The contents of the colon and cæcum subjected to after-fermentation become very acid, CH_4 being produced; this is exactly the opposite result to that obtained in the case of ruminants.

The author then refers to the statement found in most text-books that the fermentative processes which go on in the paunch and colon of herbivora result in the formation of lactic and butyric acids, and the development of CO_2 and H_2, and claims that his experiments show that on an exclusively hay diet such is not the case, and goes on to describe experiments which in his opinion prove that these bodies are not produced even when beans and oats are substituted for half the hay.

In opposition to Hofmann, he finds that there is a development of CH_4 in the large intestine of rabbits when fed on green food.

J. P. L.

Hemialbumose in Urine. By W. KÜHNE (*Zeits. f. Biol.*, 19, 209—227).—The author examined the urine of a patient suffering from osteomalacia, which gave the reactions of Bence Jones's albumin, to which he has given the name of hemialbumose.

The urine contained a sediment of urates, and an amorphous body, which proved to be hemialbumose. It is probable that the urine being very rich in hemialbumose when it leaves the bladder, deposits it on cooling.

The urine throughout 4—5 weeks was precipitated daily, while fresh, with alcohol, the precipitate washed with alcohol and dried at a low temperature; the product resembled the amber-coloured albumin of commerce. Only part of this preserved hemialbumose was slowly soluble in water. The solution showed all the characteristic reactions, as well as those described by Salkowski. Too much sodium chloride or ferrocyanide prevents precipitation by acetic acid and ferrocyanide of potassium. Excess of sodium chloride and acetic acid produce a precipitate which is soluble on removal of the sodium chloride.

A solution of hemialbumose digested with pepsin at 40° yields peptones only.

Hemialbumose was still extracted from the residue insoluble in water by treatment with 5 per cent. sodium chloride solution. In pure hemialbumose, the author found 0·31 to 1·28 per cent. ash, 0·19 P, 1·09 S in the substance free from ash.

C	52·13
H	6·83
N	16·55

If the hemialbumose solution contain the smallest quantity of acid or alkali, it will not coagulate on heating.

The pure hemialbumose obtained by precipitating with alcohol, dissolving the precipitate in water, and coagulating by warming, has the following properties. Digested with pepsin, peptone only is formed. Digested with trypsin in ¼ to 1 per cent. solution of carbonate of soda after six days, peptone and large quantities of leucin and tyrosin. Boiled with sulphuric acid, leucin and tyrosin are produced. Heated with potash, indol is formed. It will thus be seen that the decomposition products of hemialbumose are the same as those of albumen.

J. P. L.

Influence of Oat and Wheat Bran on the Secretion of Milk. By M. SCHRODT and H. HANSEN (*Bied. Centr.*, 1884, 116—120).—The general outcome of these experiments, in which the cows were fed with the above substances, in addition to roots and cotton cake, is that there was a marked increase of milk and fat, more especially during the period when oat-bran was given; this excess is attributed to the avenine, which is said to have a strong stimulating action on the lactic glands. E. W. P.

Chemistry of Vegetable Physiology and Agriculture.

Production of Ether by the Action of "Aspergillus Glaucus" on Lemon-juice. By T. L. Phipson (*Chem. News*, **49**, 198).—The author has observed that, when placed in a damp situation, lemons after a certain time develop *Aspergillus glaucus*, and coincidently emit a strong odour of ether. To explain this phenomenon, it is assumed that ethyl citrate exists in lemon-juice in the same way as ethyl acetate exists in the saps of some plants, or it is suggested as probable that, under the influence of warmth and moisture, fermentation sets up, some of the sugar of the ripe lemon is converted into alcohol, which then combines with the citric acid to form the ethyl citrate; this is ultimately attacked by the *A. glaucus*, and its ethyl groups are evolved as *ether*. D. A. L.

Influence of Light and Heat on Plant Development. By Hellriegel (*Bied. Centr.*, 1884, 123—126).—The temperature during which plant life proceeds is limited within narrow boundaries, there being a boundary for each plant. Near the lowest limit, the growth is very slow, but with rising temperature life becomes more energetic until a certain temperature is reached when the life is most energetic; this temperature is the "optimum," and does not of necessity coincide with the highest temperature at which life ceases. As a rule the optimum temperature lies between 20° and 40°; at 50° life is extinguished. In an analogous manner, light or darkness produces a definite effect, for although germination takes place better in darkness, no plant can grow without light, the plant is bleached, leaves and stems become abnormal, and the weight of dry matter diminishes. In subdued light, assimilation proceeds but slowly, but is more rapid as the intensity of light increases; the maximum of rapidity, however, is not coincident with the maximum intensity of the light. The combination of warmth, light, and moisture form a very important factor in the fertility of the plant, and in many cases it is of more importance than manuring, &c. The lowest limit of temperature at which the majority of seeds can germinate is 4—5°, but a few can germinate at 0°. Experiments were made on various seeds sown in soil kept at different temperatures for 35—60 days. Most of the ordinary seeds germinated below 4°, and winter rye was able to grow at 0°. Wheat germinated and grew at 0°, but hardly so rapidly as rye. Barley and oats required a temperature of 2° to develop, for at 0° they only developed the radical, and no plumule. Maize required a temperature of 8·7°. Linseed developed the radical alone at 2°. Vetches only demanded a temperature of 0°, whilst peas and clover required 2°; beans and lupines, 3°, for the development of the plumule. The lowest temperature for carrots was 3°; for turnips, 5°; and cucumbers showed no signs of germinating at 8·7°. E. W. P.

Influence of Weather on Vegetation. By F. HILDEBRAND (*Bied. Centr.*, 1884, 138).—An account of the abnormal growth of plants during the remarkable winter of 1882. Here we find annuals flowering and growing during the second year. Biennials, as *Digitalis purpurea*, become shrub-like, plants which flower before their leaves, appear flowering afterwards, and *vice versâ*. E. W. P.

Effect of Water holding Sodium Chloride and Zinc Sulphate in Solution on the Soil and on Plants. By F. STORP and others (*Bied. Centr.*, 1884, 76—87).—Solutions of sodium chloride cause the loss of greater amounts of sulphuric acid, lime, and potash from soils, the stronger the solution.

The action of this salt as a manure is to decompose the more stable compounds of the soil, but should the amount applied to the land be great, then an excess of calcium and magnesium chlorides are formed, and if in the presence of humus, free acid. To avoid this danger, the manure should be applied only in small proportions, and at a date long previous to that when vegetation should commence. The influence on the composition of grasses is also considerable, for the percentage of albuminoïds, dry matter, and fat decrease as the sodium chloride increases. Very dilute solutions ($\frac{1}{1000}$ per cent.) aid germination, but stronger arrest the process completely.

Soils can absorb as much as 80 per cent. of zinc sulphate from its solutions, and at the same time lose calcium, potassium, sodium, and magnesium compounds; moreover, the loss of potassium increases with the strength of the zinc solution; in the presence of calcium carbonate, zinc sulphate is converted into the carbonate. The preservative action of zinc is exemplified in the neighbourhood of zinc works, where the dust has settled on the pine-needles, and completely prevented their decomposition, but when humic acid is in solution, then the zinc combines with it, and free sulphuric acid is formed.

To an extent similar to that which is found in the case of sodium chloride, zinc sulphate affects the composition of growing grasses, and the ash may contain as much as 2·3 per cent. of the oxide: some plants, as the oak, are but little affected, either by zinc or sodium. The influence on germination is remarkable, for in the dark no harm is done, but in the light it is arrested and the life destroyed; this destructive action does not seem to affect fungoid growths. Experiments in which water containing the two compounds under consideration was allowed to flow over soil, gave results similar to those already mentioned. J. König repeated these last experiments, adding ferrous sulphate, and found that whereas sodium and zinc sulphate reduced the dry matter in the crop, ferrous sulphate raised it; this result is attributed to the separation of the acid from the base, the acid rendering other material for the plant soluble. E. W. P.

Respiration of Leaves in the Dark. By G. Bonnier and L. Mangin (*Compt. rend.*, 98, 1064—1067).—Comparative experiments respecting the oxygen absorbed and the carbonic anhydride evolved in the dark by the leaves of various species of plants show that the ratio between these two quantities is constant, whatever the temperature, and although the amount of carbonic anhydride evolved increases rapidly with the temperature, the amount of oxygen absorbed increases in exactly the same proportion. The ratio is approximately unity for certain species, *e.g.*, *Euonymus japonicus*, *Æsculus hippocastanum*, whilst for other species, *e.g.*, *Pinus pinaster*, it is considerably less than unity.

The authors have previously shown that the ratio between the carbonic anhydride evolved and the oxygen absorbed is independent of the pressure of the oxygen and of the proportion of carbonic anhydride in the surrounding atmosphere, and it is evident that these two processes of absorption and evolution are most intimately connected.

C. H. B.

Respiratory Combustion. By P. Schützenberger (*Compt. rend.*, 98, 1061—1064).—The experiments described in this paper were made with a view to ascertain the effect of the presence of certain organic substances on the respiratory combustion of yeast cells. Similar flasks were filled with equal quantities of water saturated with oxygen, an equal amount of yeast was added to all of them, and then known weights of the particular substances employed, and after the lapse of a given time, the amount of oxygen which had been absorbed was determined by titration. The organic substances added were different varieties of sugar, mannitol, various alcohols, glycerol, acetic, butyric, tartaric, and other acids, sodium acetate, Rochelle salt, and other salts, amido-compounds, hydrocyanic acid, and chloroform. Some of these substances have no appreciable effect on the respiratory combustion, others, such as hydrocyanic acid and chloroform, check it or retard it considerably. Invert sugar, ethyl alcohol, and sodium acetate accelerate the absorption of oxygen in a very marked manner, whilst glycerol and the higher homologues of ethyl alcohol exert a similar but much less energetic action. Methyl alcohol has little or no influence on the process. The effect of the most active substance is equally well observed with fresh yeast, or with yeast which has been exhausted and washed, but the effect of the less active substances is more clearly observed when the exhausted yeast is employed, because the substances naturally present in the fresh yeast are more combustible than those which are added.

The results show that ethyl alcohol is particularly apt to undergo slow physiological combustion, its power in this respect being equal to that of invert sugar. It is possible, indeed, that the invert sugar is first converted into alcohol, and then consumed, and if this be true, ethyl alcohol and the alkaline acetates must be classed in the first rank amongst those substances which undergo combustion in the living organism. C. H. B.

Constituents of Vegetable Tissues. By URBAIN (*Ann. Agronomiques*, 9, 529—547).—This paper contains a *résumé* of the results of Frémy's researches, commenced in 1859 and continued to the present time. The substances composing vegetable tissue are, according to Frémy, the celluloses (cellulose, paracellulose, metacellulose), pectose, vasculose, and cutose.

Celluloses.—Cellulose proper, as it exists in cotton and in the utricular tissue of certain fruits, such as the apple, is immediately and completely soluble in Schweitzer's reagent. Paracellulose dissolves in the same reagent only after certain preliminary treatment, such as boiling with very dilute hydrochloric acid. It is found in the epidermic cells of leaves and in root tissue. Metacellulose is insoluble in Schweitzer's reagent, even after treatment with acids. It is not so common as the preceding varieties, and is found principally in fungi and lichens. Like cellulose and paracellulose, it dissolves in strong sulphuric acid without coloration, and can be transformed into glucose. It has also the same elementary composition as cellulose, but differs from it under the action of oxidising agents, and in dissolving in the cold in sulphuric acid, diluted with 4—5 equivalents of water.

It has been objected that the insolubility of crude paracellulose in Schweitzer's reagent is due to the protective influence of earthy or waxy impurities. This is not so, for it remains insoluble even after repeated treatment with alcohol, ether, and alkalis, and even with acids, providing they are cold and dilute. Moreover, it can be rendered soluble by being simply moistened with water and heated in a sealed tube at 125° for several hours.

Vasculose is found in almost all the organs of plants, and is particularly abundant in the hard portions. It sometimes constitutes by itself the vessels and tracheæ, and is always the predominant constituent. In the cortical parenchyma and in certain roots, it exists as a continuous membrane. The stony concretions of pears, the stones of fruits, nutshells, &c., contain it in large quantity. It is the "encrusting material" of Payen, but is regarded by Frémy as a definite compound of constant composition and properties, and easy to isolate in a state of purity. One of the easiest modes of isolating it is to remove the cellulose and paracellulose from willow pith by means of sulphuric acid diluted with 3½ equivalents of water, or by Schweitzer's reagent after previous ebullition with dilute hydrochloric acid. It is a yellowish substance resembling in texture the tissue from which it has been obtained. Sp. gr. 1·5 at 16°. Insoluble in neutral solvents. Not affected by ebullition with sulphuric, hydrochloric, phosphoric, or other dilute acids, or with alkalis. Sulphuric acid diluted with 3·5 equivalents of water (the weakest acid capable of dissolving cellulose) converts it in the cold by abstraction of 2 equivalents of water into a dark brown substance, slightly soluble in the acid, from which it may be precipitated by addition of water.

Nitric acid, chromic acid, alkaline permanganates, and hypochlorites and other oxidising agents act readily on vasculose, converting it into a series of uncrystallisable acids containing more oxygen than the vasculose. Some of these acids are soluble in water and alcohol; others, which are more abundantly formed when the oxidising agent is weak or acts for a short time only, dissolve only in alkalis. Atmospheric oxygen gradually effects the same changes, hence the decay of wood exposed to air and water. When vasculose is heated at 130°, under pressure, with moderately concentrated alkaline solutions, it is rapidly dissolved, furnishing a brown liquor, from which acids precipitate black flocks of complex nature. Part of this precipitate is soluble in ether, part in alcohol, and part in alkalis only. It consists of dehydration-products of vasculose. (The digestion of crude fibre with alkalis in the preparation of pulp for paper-making has for its object the dissolution and removal of the vasculose in this way.) By fusion with potash, vasculose yields similar bodies, the one formed in greatest quantity being soluble in alcohol and strong sulphuric acid, and corresponding in its character with ulmic acid. When submitted to destructive distillation, vasculose yields a considerable quantity of acetic acid and methyl alcohol. Cellulose, on the other hand, yields less acetic acid (always accompanied by formic acid, and a little propionic and butyric acids), and no methyl alcohol. Vasculose contains by analysis C = 59·341 per cent., H = 5·494, O = 35·165. The formula $C_{18}H_{20}O_8$ best agrees with its known reactions.

Cutose.—The outer layer of the epidermis of leaves and fruits, heated in succession with boiling dilute hydrochloric acid, Schweitzer's reagent, alcohol and ether, for the purpose of removing mineral matter, cellulose and paracellulose, and waxy substances, yields a residue of pure cutose having the composition C = 68·293 per cent., H = 8·953, O = 22·754.

The cuticle of agave leaves, removed after macerating the leaves in water at 30° for some days, answers well for this preparation. Cutose dissolves slowly in boiling dilute solutions of alkalis and alkaline carbonates. Acids precipitate from these solutions a yellowish flocculent substance, fusible below 100°, soluble in alcohol and ether, having the same composition as cutose. If the alkaline solution be saturated with common salt, a compound of cutose with the alkali separates and rises to the surface of the liquid as soap does under similar circumstances. When subjected to the action of concentrated solutions of potash for some time, cutose undergoes a somewhat different transformation. The precipitate obtained by saturating the solution with an acid still dissolves in boiling alcohol, but a portion separates out on cooling. The latter, when filtered off, consists of a yellow, solid acid melting at about 85°; after fusion, it is brownish, translucent, and very fusible. The alcoholic filtrate, when evaporated to dryness, yields a brown viscous acid (oleocutic acid). Both of these acids dissolve in ether and in weak alkaline solutions; the alkaline salts are separated from their solutions by excess of alkali or by saturation with salts. The acids combine with strong sulphuric acid in the cold, and can be separated by addition of water, in this respect again resembling the fatty acids. The further action of very concentrated potash solution on the yellow acid above mentioned (or on cutose) results in the production of another acid, in the form of a white translucid potash salt, insoluble in water, soluble in boiling alcohol, but almost entirely reprecipitated on cooling. Hydrochloric acid liberates from this salt *stearocutic acid*, a white solid, melting at 76°;

insoluble in ether and cold alcohol, slightly soluble in boiling alcohol, soluble in hot benzene and hot acetic acid. The yellow acid is a compound of oleocutic and stearocutic acids—stearocutic acid, although almost insoluble in alcohol, dissolves readily in an alcoholic solution of oleocutic acid. Similarly, potassium stearocutate is insoluble in water, but soluble in an aqueous solution of potassium oleocutate.

Analysis of the acids gives the following numbers: Stearocutic acid C = 75·000 per cent., H = 10·714, O = 14·286, corresponding with the formula, $C_{28}H_{48}O_4$, deduced from the composition of its salts; oleocutic acid, C = 66·666 per cent., H = 7·946, O = 25·398, formula $C_{14}H_{20}O_4$. These acids, heated at 100° in presence of water or bases, undergo alteration. Stearocutic acid becomes completely insoluble in alcohol, and its melting point rises from 76° to 95°. Oleocutic acid alters more slowly at 100°, but at 135° it becomes insoluble in ether, alcohol, and hot dilute alkalis. Heated with strong potash, it dissolves and regains its former properties. The yellow compound of the two acids behaves in a similar manner. Cutose is thus a combination of stearocutic and oleocutic acids, in their insoluble modifications, in the proportion of one equivalent of stearocutic acid to five equivalents of oleocutic acid. The action of potash on cutose is to transform the insoluble form of those acids into the soluble form.

Weak nitric acid ($\frac{1}{2}$ water) transforms cutose into a yellow, waxy nitro-compound, fusible at 100°, soluble in alcohol and alkalis. By further treatment with nitric acid, it is converted into suberic acid. It is the oleocutic acid which gives rise to suberic acid. Suberin, the substance discovered in cork by Chevreul, which by oxidation also gives rise to suberic acid, appears to be the same as cutose, since it yields the same two acids on treatment with alkalis.

Pectose is transformed by ebullition with weak hydrochloric acid into pectin, soluble in water, and precipitable by alcohol.

The different behaviour of the substances with various solvents, as described above, has been applied by the author to the proximate analysis of the chief vegetable tissues, with the following results:—

Stems, comprising the thin layers of pith parenchyma, wood, and cork.

Wood.—The sample reduced to sawdust or shavings is exhausted by alcohol and ether to remove resins, then by distilled water and water made slightly alkaline with potash to remove soluble substances and pectic compounds, and finally with very weak hydrochloric acid, which dissolves the lime and other mineral salts. Oak sawdust submitted to this treatment yields 10 per cent. of water, 4 per cent. substances soluble in alcohol and ether, and 10 per cent. of substances soluble in water and weak alkali. The wood thus purified is treated with Schweitzer's reagent, washed, and dried; the loss is cellulose. It is then boiled with weak hydrochloric acid for a few minutes, and again repeatedly exhausted with Schweitzer's reagent; the loss this time being paracellulose. The residue is pure vasculose. Purified oak sawdust treated in this way yields in 20 grams 5·41 grams cellulose, 8·58 paracellulose, and 6·01 vasculose; poplar yields in 20 grams

6·82 cellulose, 9·19 paracellulose, and 3·99 vasculose. These results are confirmed by dissolving out the two varieties of cellulose together by sulphuric acid, and weighing the residual vasculose; also by removing the vasculose by treating the sawdust with nitric acid (½ water) in the cold, boiling with ammonia, and weighing the unacted on residue of celluloses. Some varieties of wood, *e.g.*, boxwood, yield no cellulose when analysed, as they are composed entirely of vasculose and paracellulose. The following table shows the percentage composition of six kinds of wood:—

	Vasculose.	Cellulose and paracellulose.	Water and extractives.
Poplar	18	64	18
Oak	28	53	19
Box	34	28	38
Ebony	35	20	45
Guiacum	36	21	43
Ironwood	40	27	33

Pith parenchyma is made up of the same constituents as woody tissue, and is analysed in the same way. Purified elder pith, *e.g.*, contains cellulose 37 per cent., paracellulose 38, vasculose 25.

Cork contains cutose in addition. After purification, the cutose is directly dissolved out by boiling potash, and is estimated by loss of weight. The residue is analysed in the same manner as wood. Common cork has the following percentage composition:—Water 2, soluble in ether and alcohol 9; soluble in water, weak ammonia, and weak hydrochloric acid 5; cutose 43, vasculose 29, cellulose and paracellulose 12.

Roots.—Root tissue is composed of paracellulose, vasculose, and often pectose also. The vasculose forms a continuous membrane over the root surface, and constitutes the chief part of the root vessels. Pectose may be dissolved out of the purified tissue by boiling with weak hydrochloric acid, after which the vasculose and cellulose are separated as indicated above. A root of *Paulowina* gave the following results:—

	Outer layer.	Soft fibre (liber).	Body of root.
Water	8·35	6·64	6·00
Substances soluble in water, alcohol, &c.	10·40	—	26·25
Extractive matters and pectose	—	55·70	—
Ulmic compounds soluble in potash	33·15	—	—
Substances soluble in ammonia and weak HCl	—	—	21·00
Vasculose	44·40	34·25	17·30
Paracellulose	3·70	3·41	29·45
	100·00	00·00	100·00

Leaves.—The parenchyma, chiefly cellulose, may be separated from the epidermis and from the fibres and vessels by maceration in water, or by Schweitzer's reagent.

The *epidermis* is composed of two membranes closely united; the outer one (cuticle) is formed of cutose, the inner one of paracellulose. The paracellulose can be dissolved away from the cutose by treatment with Schweitzer's reagent after boiling with dilute hydrochloric acid, or by treatment with sulphuric acid + 3·5 equivalents of water. Or the cutose may be dissolved away by boiling potash, or by treatment with cold nitric acid, followed by an alkaline solvent. Ivy leaves yielded the following figures:—

Water and substances soluble in water, alcohol, and ether			90·77
Parenchyma (cellulose and pectose)			4·00
Fibres and vessels	vasculose	0·95	1·73
	paracellulose	0·78	
Epidermis	cutose	1·05	3·50
	paracellulose	2·45	
			100·00

Flowers.—Petals have the same constituents as green leaves. They are first boiled with alcohol to remove waxy substance and colouring matter, and then analysed like leaves. Dahlia petals contain—

Water, and substances soluble in water, alcohol, and ether	96·130
Parenchyma (cellulose and pectose)	3·163
Cutose	0·360
Vasculose	0·120
Paracellulose	0·227
	100·000

Fruits.—The *epicarp* of fruits, such as apples, pears, &c., consists of three superposed membranes: the outside one consisting of cutose, the intermediate one of vasculose, and the inside one of paracellulose. They can be separated by the reagents already mentioned.

The composition of the *endocarp* is similar to that of wood, and the analysis is executed in the same manner. Vasculose predominates, and the hardness varies according to the quantity of this substance present—

	Vasculose.	Cellulose and paracellulose.	Water and extractives.
Walnut shells	44	25	31
Hazel nut shells	50	31	19
Cocoanut ,,	58	25	17
Apricot stones	60	26	14
Bankoul nuts	62	14	24

The cells of the *mesocarp* consist of cellulose and pectose, and when the latter of these is removed by ebullition with water, acidulated with hydrochloric acid, and the former by Schweitzer's reagent; nothing is left but the vessels and tracheæ formed of vasculose and paracellulose.

In the seed, the perisperm, after removal of starch, oils, &c., consists entirely of cellulose; whilst the integuments contain vasculose, cutose, cellulose, and paracellulose. J. M. H. M.

Phenol in the Stem, Leaves, and Cones of Pinus Sylvestris. By A. B. Griffiths (*Chem. News*, **49**, 95).—The author has detected and estimated phenol in aqueous decoctions of the stem, leaves, and cones of *Pinus sylvestris*. The various parts are cut into small pieces and digested at 80° for half an hour, with successive quantities of water, until the filtered solution gives no coloration with ferric chloride; it is then evaporated and extracted with ether, &c. The quantity of phenol found in the separate parts varies according to their age; thus: old stem contains 0·1021, whilst young stem contains only 0·0654 per cent. The variation with the leaves is from 0·0936 down to 0·0315 per cent., whilst the amount in the cones varies from 0·0774 to 0·0293.

This result, coupled with the existence of phenol in coal, is adduced in support of the presumed existence of *coniferæ* in the carboniferous age; and, moreover, taking into consideration the many hydrocarbons, &c., common to both coal and petroleum, the author argues that petroleum also is of vegetable origin. D. A. L.

Chemical Investigations on the Kola. By E. Heckel and F. Schlagdenhauffen (*Ann. Chim. Phys.* [6], 1, 129—138).—The extract of the kola-nut, from a plant of the Sterculiaceæ family, is used as a beverage by the inhabitants of Central Africa, as tea or coffee by the Asiatics and Europeans, or maté by the Americans. As few specimens of the plant have come to Europe, investigations on the chemical nature and therapeutic functions of the extract have been incomplete; but the experiments of Daniell and Attfield have proved the presence of an alkaloïd resembling that from tea or coffee. From the opening out of commercial routes into Central Africa considerable quantities of the true kola or *Kola femelle*, and of its principal substitute, Kola bitter, have been shipped into France.

Kola Femelle (*Sterculia acuminata*).—On extracting the kola-nut with chloroform, an alkaloïd is obtained resembling caffeine in all its properties, together with smaller quantities of theobromine.

The results of the analyses are as follows:—

		Per cent.
Extracted by chloroform	Caffeïne	2·348
	Theobromine	0·023
	Tannin	0·027
	Fats	0·585
Extracted by alcohol	Tannin	1·591
	Kola red	1·290
	Glucose	2·875
	Salts	0·070

	Per cent.
Starch	33·754
Gum	3·040
Colouring matters	2·561
Proteïn	6·761
Ash	3·325
Water	11·919
Cellulose	29·830

On comparing these results with the analyses of cacao, tea, and coffee, it is noted that kola contains a considerably larger proportion of carbohydrates and their derivatives, and also of caffeïne and its homologue theobromine. Kola extract should therefore be a valuable therapeutic agent.

False Kola or Kola Bitter (*Kola garcinia*).—In Liberia and Central Africa, a plant of the family of the Guttiferæ grows in abundance, producing a grain known by the name of kola bitter. On extracting this with chloroform, ether, and alcohol, no caffeïne was obtained, but only resins, of which one gave a violet coloration with ferric salts; the other in aqueous solution was dextrorotatory, and precipitated by tartar emetic and basic lead acetate. The physiological action of the extract of this grain is attributable to the presence of these two resins. V. H. V.

Sterilisation of Liquids by Means of Papin's Digester. By L. HEYDENREICH (*Compt. rend.*, 98, 998—1000).—When flasks containing liquids, &c., are introduced into a Papin's digester, the air should be removed as completely as possible, for if this is not done it forms a protecting layer or cushion round the flask or other vessel, and prevents the contents of the latter from attaining the temperature of the water in the digester. From this cause the temperature of the contents of the flask may be but little higher than 60°, even after the temperature of the digester has been at 120° for some time. If, however, care is taken to remove all the air, the contents of the flask quickly acquire a temperature practically as high as that of the water in the digester. C. H. B.

Silage. By G. TOMS (*Bied. Centr.*, 1884, 136).—Composition of heated hay: Fat = 4·26 per cent., trace of aldehyde, acetic acid 5·38, sugar 6·94, starch 3·42, mucilage, &c., 24·77; in the same hay that had not heated was starch = 12·46. Other samples of silage were brown, of bad odour, and contained more acid and less starch.

E. W. P.

Woody Fibre as Fodder. By M. MÄRCKER (*Bied. Centr.*, 1884, 136).—Wood is not digested by animals, for although it does not appear in the dung, it is converted for the most part by fermentation into marsh-gas. E. W. P.

White Mustard as Fodder. By BRÜMMER (*Bied. Centr.*, 1884, 115).—White mustard is strongly recommended as green food, and should be mixed with chaff, &c., because of its highly nitrogenous composition. It produces very highly coloured butter.

E. W. P.

Champion Spice. By C. O. HARZ (*Bied. Centr.*, 1884, 122).—The origin of this spice, which is much used as an addition to cattle food, appears to be the waste from drug stores, factories of ethereal oils, &c., mixed with palm-nut cake, &c. The price is excessive, its feeding value but low, and its purchase not to be recommended. Its chemical composition has been already given in a previous number, but the following is its botanical constitution in parts per 1000: Ginger 40 parts, inula root 24, caroba bean 120, corianders 80, fennel 120, aniseed 80, carraway 40, fenugreek seeds 168, turmeric 120, palm-nut cake 68, maize 40, cereals 40, rice 8, peas, vetches, and hog's bean 4, dirt, &c., 40. E. W. P.

Varieties of Sugar-beet. By M. MÄRCKER (*Bied. Centr.*, 1884, 126).—Of the many varieties of beet grown, the Simon Legrand de Mères Blanches yielded the largest number of centners of sugar per morgen (28·2), but its quotient of purity was 83·4, whilst that of Vilmorin Blanche was 85·8 with a yield per morgen of 23·61. Bestehorn's Imperator was the poorest, 23·52 centners, quotient = 82·4.

E. W. P.

Manuring Potatoes. By M. MÄRCKER (*Bied. Centr.*, 1884, 102—104).—The object of the experiments was to determine the best form in which to apply nitrogen, the extent to which potash salts do harm, the value of superphosphate as compared with fæcal superphosphate, and the best proportions in which to mix nitrogen with phosphoric acid. The soil on which the experiments were first made was sand, containing hardly any plant food, and quite uncultivated, and here it was found that a larger supply than 8 kilos. N and 10 kilos. P_2O_5 per morgen, brought no relatively higher yield. Ammonia with superphosphate was qualitatively and quantitatively better than Chili saltpetre; the addition of large quantities of potash salts in the spring further lowered the quality, the first reduction having been caused by the Chili saltpetre. Superphosphate of organic origin was more valuable than that of mineral origin; ammonia produced as large an increase as Chili saltpetre did a reduction. The second set of experiments with the object of determining the effect of potash on the percentage of starch was made on very light but well cultivated soil; in previous years, potash put in in the spring had a lowering effect on the starch, therefore potash and other artificials were now added in the autumn. The results obtained were very definite, and are as follows: the appearance of the crop is much improved by the addition of the potash salts in the autumn instead of in the spring, moreover the percentage of starch is increased: the qualitative and quantitative yield of tubers is highest when the ratio of nitrogen to soluble phosphate is 7 : 9½; as a rule, as this ratio widens, so is the phosphate less employed: the application of potash alone is distinctly detrimental to the crop, in fact, lowered it below the unmanured plot. The third series was made on light sandy soil, which had been brought into cultivation by peat and farmyard manure; the half of this land was also treated with 2 centners kainite in autumn, one-quarter received kainite in spring, whilst the remaining quarter was left without kainite. In the previous year, we find that the spring manuring reduced both the quantity and the quality, but this year the quality alone was affected; the organic superphosphate was better than the inorganic. The ratio N : P_2O_5 = 7 : 9·5 was again found to be the most favourable. The autumn manuring with kainite produced a larger crop, but of lower quality than in the previous season, and this mineral by itself was again distinctly detrimental; if the application of potash during the autumn regulates the yield of starch, then the best result under the circumstances is obtained when N : P_2O_5 = 5 : 7·5. Although kainite has such an unfavourable action, yet, on the other hand, by its use the plants resist more easily the attacks of disease, and the tubers are more generally normal in form and keep better. E. W. P.

Manuring Potatoes. By C. A. CAMERON (*Bied. Centr.*, 1884, 104—106).—No statement of the character of the soil is given, but remarkable is the yield produced by kainite (736 kilos. per hectare), when the highest absolute yield at the lowest cost was obtained, also we find an advantage gained by the use of this manure in combination; superphosphate with Chili saltpetre brought the largest amount of marketable potatoes, but when mixed with ammonia the result was bad. Nitrogenous manures alone were very unsatisfactory, the yield being below that of the unmanured plot; and even when mixed, these manures were of doubtful advantage as regards quantity, but otherwise as regards quality, as by their use but few diseased tubers were produced. The highest percentage (28·6 per cent.) of dry matter was produced by the aid of nitre and superphosphate, whilst kainite yielded the lowest (24·3 per cent.). E. W. P.

Salt and Herring Offal as Manure. By E. D'ORVAL and A. PAGNOUL (*Bied. Centr.*, 1884, 92—98).—Mixed with earth-nut meal or guano, sodium chloride seemed to produce no further effect than when the two first manures were employed alone. A well-marled field was manured with 3000 kilos. per hectare of herring offal, and then sown with wheat home grown on part, on the other part "golden drop"; on neighbouring fields sown on the same day, but manured with farmyard manure and poudrette, the wheat seeded a fortnight earlier than when the offal had been used, moreover this material had a very depreciating effect on the yield of grain and straw. In the succeeding season, superphosphate was added, and rye and vetches sown; this crop showed that the harmful matter had been removed from the offal, and a good yield was the result. Another trial with oats was also successful on the first season; three experiments show that there is a very considerable variation in the effect exerted by the salt in the offal on the ordinary crops, for native wheat was harmed but little; peas, beans, and English wheat suffered heavily, but oats only during the germinating period; when treated with water so as to remove excess of salt, not much phosphoric acid is lost, but a loss of nitrogen occurs (0·7 per cent.), and from the wash water, ferric chloride, and lime throw down a precipitate containing 2·8 per cent. N. The washed offal is priced at 12 m. per centner, and is a valuable manure, and would be more so if the fat were removed. E. W. P.

Production and Cost of Farmyard Manure. By HOLDEFLEISS and M. HERTER (*Bied. Centr.*, 1884, 87—92).—The composition of four samples of fresh manure produced by 70 head of cattle, fed in boxes, was—dry matter 27·5 per cent., N = 0·666, K_2O = 0·877, P_2O_5 = 0·222; these quantities are in close accordance with those obtained by calculating the amount which after digestion should be produced, in addition to the straw (15 lbs. rye-straw per head), and the reduction in weight of the manure after lying in heaps; the calculated composition is—N = 0·617, K_2O = 0·858, P_2O_5 = 0·299. The values of the constituents of such a manure are 1 lb. (German) = 0·80 m., 1 lb. K_2O = 0·18 m., 1 lb. P_2O_5 = 0·20 m., consequently 20 centners = 22·05 m. The advantages of feeding in boxes are here set forth: no loss of urine, more straw can be worked into manure, and the whole is better made than otherwise.

Herter shows the balance sheet of a dairy farm, which, when account is taken of milk, butter, and cheese produced, the expenses of attendance, &c. (not fodder), shows a nett income of 263 m. per cow. The value of the food given in winter is 203·7 m., in summer 82·5, total 286·2 m. per 1000 lbs. live weight. According to these figures, the costly feeding neutralises the value of the cow and raises the value of the manure to 48 m. per 20 centners. E. W. P.

Manuring with Sea-mud and Peat Compost. By ENCKHAUSEN (*Bied. Centr.*, 1884, 100—102).—On light sandy soils, or on poor land underlaid by a cold subsoil, sea-mud is better than stable manure. A compost was made of mud, farmyard manure, phosphorite, kainite, and sawdust, and contained N = 0·34 per cent., P_2O_5 (soluble in cold acid), 0·21 per cent. When this mixture was applied to oats and potatoes, the result was very satisfactory, and when compared with farmyard manure, was found to be much cheaper; in fact, the use of the latter with oats did not produce grain sufficient to pay the extra cost. E. W. P.

Superphosphate. By F. J. LLOYD (*Chem. News*, **49**, 229—230).—In the annual reports of the experiments of the Sussex Agricultural Association, certain anomalous and detrimental effects are described, and attributed by Jamieson to the superphosphate employed as manure; therefore, superphosphate is denounced as not alone unnecessary, but also injurious. Now, from the analytical data supplied in these reports, it is shown, in the present note, that the superphosphate employed in the experiments in question differed from the ordinary superphosphate of commerce in having a very large excess of free sulphuric acid. This probably accounts for the bad results referred to. D. A. L.

Assimilability of the Phosphoric Acid in Rocks and Soils. By G. LECHARTIER (*Compt. rend.*, **98**, 1058—1061).—The schists and granites employed were crushed, washed to remove organic matter, dried, and finely powdered. A series of pots was filled with the powdered rock mixed with an inorganic manure containing nitric and ammoniacal nitrogen, calcium sulphate, potash, and phosphates, and a second series was filled with a similar mixture, except that no phosphate was added, and buckwheat was sown in all the pots. The influence of the phosphates in the manure was very marked; but in all cases the plants in the pots containing the manure free from phosphates, assimilated a certain quantity of phosphoric acid from the powdered rock. The schists and granites employed contained phosphoric acid in proportions varying from 0·108 to 0·207 per cent.; but in most cases fluorine was also present, so that the phosphoric acid may have existed, in part at least, as apatite.

The phosphates contained in the schists and granites are partly soluble in dilute acetic acid (1 : 5), or a 2 per cent. solution of ammonium oxalate; and since the latter reagent also dissolves a certain proportion of potash, and of the humous substance which can be separated by Grandeau's process, it may be used as a means of determining the degree of solubility of the fertilising constituents of a soil.

Small quantities of phosphoric acid are not precipitated by ammonium molybdate in presence of ammonium oxalate; the latter should therefore be removed by evaporation and ignition. C. H. B.

Kainite and Bone-meal in Sandy Soil. By F. W. STEFFENS (*Bied. Centr.*, 1884, 99).—Rye was sown after one year's clover-ley which had been ploughed in, and 3 centners kainite with 1 centner bone-meal were added at the time of sowing; the gain over unmanured soil was equal to 25 m. per morgen. Bone-meal, without kainite, was unsatisfactory. E. W. P.

Carnallite, a Cheap Substitute for Kainite. By TROSCHSKE (*Bied. Centr.*, 1884, 98).—It is here stated that kainite is nearly twice as costly as carnallite, whilst the properties of the latter surpass those of the former: for example, to absorb 1 kilo. ammonia the expenses are as 44 : 13, so that carnallite may be well employed in stalls to soak up urine. Again, atmospheric ammonia is absorbed to the extent of 9 per cent. by carnallite, 4·5 by kainite. . The reckoning on the other side against carnallite is, that the magnesium chloride it contains is not good for plants; at least not to be recommended for roots and potatoes. E. W. P.

Analytical Chemistry.

Litmus, Rosolic Acid, Methyl-orange, Phenacetolin, and Phenolphthaleïn as Indicators. By R. T. THOMSON (*Chem. News*, 49, 119—121; compare this vol., 691).—The present paper contains further notes to the previous communications already referred to (*loc. cit.*).

Determination of Small Proportions of Hydroxide in presence of Large Quantities of Carbonates and other Compounds of Sodium and Potassium.—The process described is founded on the neutrality of precipitated barium carbonate to phenolphathaleïn; and, employing this indicator, it consists in adding excess of neutral barium chloride to the solution of sodium or potassium carbonate, in which the amount of hydroxide is to be determined, then after the further addition of a little more of the same indicator, titrating the hydroxide in solution with standard acid. The whole process must be conducted in the cold, as heating gives rise to low results. The efficiency of the process is proved by test experiments. The barium chloride cannot be replaced effectually by a calcium salt. Impurities such as chlorides, sulphates, and sulphites, do not interfere with this method, nor do phosphates to any appreciable extent; whilst sulphides may be rendered harmless by treatment with a few drops of hydrogen peroxide. With aluminates, the whole of the alkali is determined, but with silicates, only 90 per cent. of it.

The process may evidently be applied to similar determinations in other salts yielding precipitates with barium neutral to phenolphthaleïn, *e.g.*, normal sulphites and phosphates. By the following scheme, the amount of sodium or potassium sulphite, carbonate, hydrogen carbonate, or hydroxide may be determined in a few minutes. The hydroxide is estimated as already described; then by titrating another portion in the cold, using phenolphthaleïn, the hydroxide and half the carbonate is found; and finally, using methyl-orange, and a further addition of acid, the other half of the carbonate and half the sulphite is obtained. From these data, the various proportions are easily calculated.

Determination of Sodium or Potassium Hydrogen Carbonate in presence of Normal Carbonate.—This is another application of the above process. The solution under examination is mixed with excess of standard caustic soda, in which the hydroxide has been determined by the above method; barium chloride is added, and the excess of hydroxide employed titrated with standard acid; the difference between this quantity and the total soda used gives the amount required to neutralise the hydrogen carbonate. Successful test experiments show the value of this method.

Behaviour of Sodium and Potassium Arsenates.—With *litmus, rosolic acid*, and *phenacetolin*, the change in colour is gradual and the end-reaction indistinct. *Methyl-orange* changes colour suddenly at the finish, although the full pink is not developed until there is a slight excess of acid. With *phenolphthalein*, on the other hand, the neutral points at different stages, as well as the end-reaction, are well defined. The following results have been obtained:—

Na_3AsO_4 used for each test, 2·08 grams (= Na_2O = 0·93 gram).

Indicator.	c.c. normal acid consumed.	Grams Na_2O found.
Litmus	19·90	0·6169
Rosolic acid	19·85	0·6154
Methyl-orange	20·0—20 05	0·6200—0·6215
Phenacetolin	19·90	0·6169
Phenolphthalein, cold	10·0—10·00	0·3100—0·3100
„ „ hot	10·9—11·00	0·3379—0·3410

from which it will be seen that disodium hydrogen arsenate is neutral to phenolphthaleïn, whereas sodium dihydrogen arsenate is neutral to the other four. Therefore, the amount of *arsenic acid in an alkaline arsenate may be determined* as follows:—Dissolve the sample in water, filter, neutralise with methyl-orange as indicator, boil off carbonic anhydride, cool, add phenolphthalein, and determine with normal or $\frac{N}{2}$ sodium hydroxide. Sodium carbonate does not interfere with this change, sodium arsenite does, but this compound is seldom present in commercial arsenate, for which this method is intended.

With *Sodium and Potassium Arsenite*, *litmus*, *rosolic acid*, and *phenacetolin*, change slowly, but give a distinct end-reaction; *methyl-orange* is as good as with carbonate, whilst *phenolphthaleïn* indicates too soon. The results obtained, using 1·30 grams $NaAsO_2$ = 0·31 gram Na_2O for each test, were:—

Indicator.	c.c. normal acid used.	Grams Na_2O found.
Litmus	10	0·310
Rosolic acid	10	0·310
Methyl-orange	10—10	0·310—0·310
Phenacetolin	10	0·310
Phenolphthaleïn, cold	9·05—9·1	0·2805—0·2821
„ „ hot	8·90—9·0	0·2759—0·2790

Arsenious acid is neutral to methyl-orange; but, as will be seen, it requires a large quantity of alkali to make it neutral to phenolphthaleïn: hence its interference in the determination of arsenic acid. Similar experiments on the determination of boric acid in borates have not yielded satisfactory results. D. A. L.

New Volumetric Method for the Estimation of Nitrous Acid. By A. G. Green and S. Rideal (*Chem. News*, 49, 173—174).—The method recommended by the authors is founded on the action of nitrous acid on aniline; the formation of diazo-benzene takes place quite quietly and quantitatively, provided due precautions are observed. The following is the method adopted for applying this reaction to the quantitative determination of nitrous acid:—A decinormal solution of aniline is prepared with slightly more than twice its equivalent of acid, one-half being sulphuric and the other hydrochloric acid. A weighed quantity of nitrite is dissolved in sufficient water to make the solution between deci- and centi-normal. A rough determination of the nitrous acid in the sample is now made with centinormal permanganate, or the aniline solution: and then several experiments are started, employing varying quantities of nitrite approximating to the number found above, along with the same quantity of aniline solution. After remaining overnight (if great accuracy is required in an atmosphere of carbonic anhydride), an equal volume of starch and potassium iodide solution is added to each, which speedily indicates even a very small excess of nitrous acid in any of the experiments, thus showing where too much nitrite was used. Estimations of nitrous acid have been made by this method to less than 0·1 per cent.: moreover, it can be employed where permanganate is inadmissible from the presence of reducing agents.

D. A. L.

Estimation of Nitric Acid. By E. WILDT and A. SCHEIBE (*Zeitschr. Anal. Chem.*, 1884, 151—157).—The authors have constructed a combination of apparatus which admits of the employment of Schloesing's well-known method without the use of mercury, the nitric oxide formed being reoxidised into nitric acid and determined acidimetrically. The test experiments quoted are very satisfactory, and the working of the method, which requires the aid of a diagram for its elucidation, is quite simple. O. H.

Estimation of Phosphoric Acid. By G. H. OGSTON and others (*Chem. News*, **49**, 230—231).—The following directions are given as a step towards getting uniform results when phosphoric acid is determined in the same material by different operators. 1. Two samples should be supplied by the manufacturers, one very finely divided, the other coarsely crushed. 2. The phosphoric acid is to be determined in the ground sample dried at 100°, the moisture in the crushed sample, and, if desired, in both samples. 3. In event of the results obtained by two experimenters differing by more than 1·5 per cent., their opinion is to be asked as to the cause of the difference.

D. A. L.

Estimation of Phosphoric Acid in Arable Soils. By DE GASPARIN (*Compt. rend.*, **98**, 963—964).—The author admits the truth of Lechartier's statement, that in his method (Abstr., 1883, 619) the whole of the phosphoric acid is not extracted from the calcined residue by treatment with dilute nitric acid. The phosphates should be precipitated by ammonia, dissolved in nitric acid *without calcination*, and the phosphoric acid precipitated by ammonium molybdate. In presence of a considerable proportion of alkaline earths, the calcination method gives accurate results. C. H. B.

Estimation of Boric Acid on Borosilicates. By C. BODEWIG (*Zeitschr. Anal. Chem.*, 1884, 143—149).—Such minerals are generally fused with an alkaline carbonate, the mass extracted with water, and in the solution the silicic acid is for the most part precipitated by the addition of ammonium chloride or carbonate. The silica still remaining in solution is precipitated, after the removal of all ammonium carbonate, by a solution of zinc oxide in ammonia. This latter treatment must be repeated, but a little boric acid appears to enter into the precipitate. The author therefore proposes to omit the precipitation with zinc oxide, and to estimate the small amount of silica still remaining in the subsequently obtained borate precipitates. that is, in the magnesium borate (Marignac's method), or in the potassium borofluoride (Stromeyer's method).

E. F. Smith has described (*Amer. J. Sci.*, 1882) a volumetric method of estimating boric acid. He precipitates the borate solution with excess of standard manganous sulphate, filters, and estimates the excess of manganese in the filtrate by potassium permanganate. E. F. Smith fuses insoluble borates with sodium carbonate, adds to the solution of the melted mass an excess of ammonium sulphate, heats until all ammonia is expelled, and then titrates the solution as described. According to Bodewig this method is quite incapable of furnishing even approximate results. O. H.

Estimation of Quartz in Siliceous Rocks and Soils. By J. Hazard (*Zeitschr. Anal. Chem.*, 1884, 158—160).—The exceedingly finely powdered silicate is heated for six hours with 2 parts of concentrated sulphuric acid and 1 part of water at 250°, the insoluble residue washed with water, caustic alkali, and hydrochloric acid.

The author has ascertained that the following silicates are completely decomposed by sulphuric acid:—Muscovite, biotite, garnet, tourmaline, talc, hornblende, hypersthene, diallage, and pyroxene, and of the felspars labradorite and anorthite, whilst albite, orthoclase and oligoclase are not attacked. The residue obtained as described may therefore contain one or more undecomposable silicates. In it therefore the amount of alumina and of lime is estimated, and from the data obtained the proportion of silicates calculated.

For 1 part of lime found in the residue, the author subtracts from the total alumina 1·8321 parts of Al_2O_3, and for each part of this 1·1696 from the SiO_2. Of the Al_2O_3 left, each part corresponds to 3·5068 parts of combined SiO_2; the remainder is quartz. O. H.

Estimation of Cuprous Chloride in Copper Liquors. By S. G. Rawson (*Chem. News*, 49, 161—162).—In the extraction of silver from pyrites by Claudet's method, large quantities of cuprous chloride are prejudicial, because the zinc iodide employed instead of only precipitating the silver, is partially used up for the formation of cuprous iodide. It is therefore important to determine the quantity of cuprous chloride in copper liquors, and for this purpose the only satisfactory method is treatment with ferric chloride (which is reduced to ferrous) and titration with permanganate. Copper liquors generally contain cupric, cuprous, sodium, silver, and ferrous chlorides, free hydrochloric acid, zinc, calcium, lead and sodium sulphates, an insoluble residue, and of course water. It is shown that although the amount of acid added when standardising the permanganate either with ferrous sulphate or iron dissolved in sulphuric acid, does not affect the result, nevertheless the amount of ferric chloride and sulphuric acid added in the titration of cuprous chloride, does alter the result to a considerable extent, in fact, the results increase directly with the quantities of either of these reagents employed. This irregularity is proved to be due to the liberation of hydrochloric acid, and for this reason the author suggests the use of ferric sulphate instead of ferric chloride for these determinations. The ferric salt is best dissolved by making into a paste with sulphuric acid, and then mixing with cold water. Of course the ferrous chloride in the copper liquors is determined from time to time. D. A. L.

Volumetric Estimation of Iron. By R. W. Atkinson (*Chem. News*, 49, 117—119, and 217—218).—In this communication, the direction is pointed out and experimentally illustrated, in which certain quantitative errors in the volumetric estimation of iron may originate. Firstly, during the preparation of the standard solution, and secondly, in standardising this solution. For the preparation of standard dichromate, the salt should not be fused, but the pure salt should be finely powdered, and dried in a steam-oven previous to use. With regard to standardising, it is observed that very different results are obtained, according to the form of iron employed for this purpose. Of materials employed in such case, ferrous sulphate is out of the question; ferrous ammonium sulphate, when pure, will remain constant in composition for several months, but is ultimately liable to alteration; ferric oxide is very good for standardising, but it is very difficult to obtain in a pure state, owing to the facility with which it becomes contaminated during its preparation; on this account, steel of known composition is generally employed, dissolved either in dilute sulphuric, or nitric acid, and in the latter case the nitric acid is eliminated by evaporating the solution to dryness with hydrochloric acid; the residue is then taken up with hydrochloric acid, the solution neutralised, reduced with ammonium hydrogen sulphite, and the sulphurous acid got rid of by treatment with dilute sulphuric acid and boiling. The author has made several series each of many experiments, testing the dichromate solution with ferrous ammonium sulphate, with steel dissolved in dilute sulphuric acid, and with steel dissolved in nitric acid and treated as described above.

The final average results are as follows:—

Potassium dichromate solution.	I. With ferrous ammonium sulphate.	II. Steel dissolved in sulphuric acid.	III. Steel dissolved in nitric acid.
1 c.c. = Fe	0·0053986	0·0053656	0·0053994

From which it is obvious that whereas the results I and III agree very well, result II differs from both by 0·000033 or more, which could amount to a loss of 0·3 per cent. Fe in a determination; therefore steel dissolved in sulphuric acid should not be used for standardising. The low result is probably caused by the presence of the carbonaceous matter of the steel in the sulphuric acid solution, exerting a reducing action on the dichromate, whilst by treatment with nitric acid and evaporating, this matter is destroyed.

In this first part of the paper, the author discusses the preparation and standardising of the potassium dichromate solution for the volumetric determination of iron, and thus fixes a trustworthy standard: the second part treats of the methods used in the titration.

Of course the ore is pulverised as finely as possible, and is thoroughly dried and accurately weighed. It is dissolved by prolonged digestion with hydrochloric acid. In the present instance there was no evidence to show that ferric chloride is volatile at 100°. The next step is to reduce the solution of the ore, which is done either with zinc, or stannous chloride, or sulphurous acid.

Zinc can be used successfully only when it is free from or contains a known quantity of iron. There are, however, other objections to its use, namely, it dissolves but slowly, and secondly, the zinc chloride in solution retards the development of the blue coloration when testing with potassium ferricyanide, both these objections tend unnecessarily to prolong the time of analysis; finally, the end blue reaction is so indistinct that as much as from 0·1 to 0·2 per cent. of the iron in the ore may be overlooked. Consequently, although the zinc method may yield uniformly concordant results, it cannot be regarded as extremely accurate.

The *stannous chloride* method is fully described and most emphatically denounced, inasmuch as it is not only extremely difficult to get accurate results, but the ultimate result is in the hands of the analyst; for owing to the fact that, after adding excess of stannous chloride to effectually reduce the iron in solution, it is necessary to oxidise the unused reagent before proceeding with the titration of the iron, it is obvious that either insufficient oxidation, or too liberal oxidation of this unused stannous chloride must most seriously impair the result.

The most trustworthy method of reduction is with ammonium hydrogen sulphite, which is conducted in the following manner:—The solution of ore is diluted with acidulated water, filtered, neutralised with ammonia, and the slight precipitate of ferric hydroxide redissolved by a few drops of hydrochloric acid. Strong ammonium hydrogen sulphite solution is now added (about 1 c.c. for each 0·1 gram of ore employed), the solution well shaken, and boiling water added. It is now acidified with dilute sulphuric acid (1 to 6), and after boiling for half an hour the solution is titrated with dichromate. Numerous experiments show that by following these directions, constant and accurate results can be obtained. The advantages are that the most stable ferrous compound, ferrous ammonium sulphate, is dealt with, and moreover the ferricyanide reaction is decided and delicate, detecting a difference of 0·00025 gram iron. The decomposition of the ferricyanide solution may be retarded by protecting it from light. A mixture of ferric chloride and potassium ferricyanide is reduced by exposure to light, and therefore blue colour is developed; this is important in testing; it is hence advisable to shade the testing slab during use.

D. A. L.

Estimation of Phosphorus in Iron and in Iron-ores. By A. TAMM (*Chem. News*, **49**, 208—210).—In the present memoir an account is given of systematic investigations on some of the methods employed for the determination of phosphorus in iron and iron-ores, conducted by the author with the assistance of some other chemists. With regard to dissolving the iron previous to the precipitation with ammonium molybdate, the following method is recommended as the best:—The iron is dissolved by boiling with nitric acid, sp. gr. 1·20, using 12 c.c. for each gram of iron taken, the solution is boiled briskly to dryness, and the dry iron salt after heating for one hour at about 200° (or the melting point of tin), is dissolved in hydrochloric acid, sp. gr. 1·19, employing 6 c.c. for each gram of iron. The solution is again boiled quickly to dryness, taken up as before with hydrochloric acid, and the excess of acid evaporated as far as possible without drying any of the iron salt. The solution is then mixed with about twice its volume of water, and the silica filtered off. The first drying and heating (without hydrochloric acid) ensures the complete precipitation of the phosphorus by ammonium molybdate; whilst the second (with hydrochloric acid) facilitates the subsequent separation of the silica.

Other methods which give more or less low results have also been investigated; such are, briefly: dissolving the iron in nitric acid, evaporating to dryness, redissolving in a mixture of hydrochloric and nitric acids diluted with water, &c., which gives the same low results as dissolving in nitric acid and evaporating the solution to only half its volume: dissolve in nitric acid, boil until the solution thickens, add hydrochloric acid, boil to dryness, heat for one hour at 200°, redissolve in hydrochloric acid, &c.; the results in this case are moderately good: dissolving in aqua regia, or adding hydrochloric acid immediately after nitric acid without previous boiling; in another method the solution was prepared in a manner similar to that preceding the last, without, however, evaporating to dryness with hydrochloric acid. In all these methods the low results are of course due to the phosphorus being only partially precipitated: this is attributed to the presence of organic matter, which is, without doubt, entirely destroyed by the treatment in the first method.

The author then proceeds to give a detailed account of his method of precipitation with ammonium molybdate: the following are noteworthy. To prevent the precipitate sticking to the glass, the clean beaker employed for receiving the filtrate from the silica should simply be rinsed with water and dilute ammonia, but not wiped. The solution should be kept as small as possible. When the quantity of phosphorus exceeds several tenths of 1 per cent., 2 c.c. of molybdate solution are added in excess for every 0·001 gram of phosphorus taken. After the addition of the molybdate, the solution is kept at 40° for four hours, when precipitation is found to be complete.' The washing is performed with water containing 1 per cent. of 1·20 nitric acid, and is conducted as quickly as possible. Extra washing does not tend to dissolve the precipitate. The precipitate is dried at 120°, and then contains 1·64 per cent. phosphorus. In the absence of arsenic, the method can be further accelerated, for the molybdate solution may be added warm (50°) to the boiling iron solution, and after an hour filtered. It is proved experimentally that the addition of ammonium nitrate is not necessary when precipitating with molybdate; moreover, neither ammonium nitrate nor molybdate is required for washing the molybdenum precipitate. With regard to other methods of analysis, the "acetate magnesia" and the "molybdate magnesia" methods are referred to. The former is too tedious for general purposes, but is good as a check in doubtful cases by the molybdenum method. The molybdate magnesia method is useful when there are large amounts of phosphorus to be determined, as a large molybdenum precipitate is difficult to dry and weigh. As a general method, the ammonium molybdenum is the most convenient and practical.

It is remarked that the phosphorus in iron is not so uniformly distributed as is generally supposed. For example, in cast-iron made from the same material, the phosphorus varies from 0·020 to 0·027 per cent., or from 0·024 to 0·030 per cent. Moreover, the amount of phosphorus in bar-iron varies not only in the separate bars, but also in the different parts of the same bar. In Bessemer iron and steel ingots, it is usual to find the full amount of phosphorus of the pig-iron employed. Lancashire hearth-iron, when special care is taken, contains $\frac{2}{3}$ or $\frac{3}{4}$ of the phosphorus of the cast-iron, under other circumstances the amount of phosphorus varies from $\frac{2}{3}$ to the whole, or in some few cases to more than that of the cast-iron; the phosphorus in such cases coming from the slag. Walloon hearth-iron on the other hand generally contains at the most $\frac{2}{3}$ down to the smallest trace of the cast-iron phosphorus.

Estimation of Phosphorus in Iron Ores.—The most certain way to determine the total phosphorus present is to fuse with sodium carbonate, using 2 grams of carbonate to 1 gram of ore, dissolve in aqua regia, separate silica in the usual way, and proceed as above described. The ore may be efficiently dissolved in strong hydrochloric acid, taking care to digest sufficiently long before evaporation for silica, then as in the preceding case. D. A. L.

Detection of Adulteration in Portland Cement. By R. and W. FRESENIUS (*Zeitschr. Anal. Chem.*, 1884, 175—185).—Portland cement is stated to be liable to adulteration with hydraulic lime, and with furnace slag. The following tests furnish ready means of distinction between the pure article and substitutes or mixtures.

The sp. gr. of cement lies between 3·12 and 3·15, that of hydraulic lime is 2·44—2·55, and of slag 2·87—3·01. Whilst pure cement, even after lengthy exposure to the air, shows at most 2·6 per cent. of loss on ignition, lime loses from 18 to 19 per cent.: 0·5 gram of the finely powdered substance heated with 50 c.c. of cold distilled water, yields a solution which in the case of slag is practically devoid of alkalinity, whilst the lime solution requires about 20 c.c. standard acid for neutralisation, that from cement requiring from 4 to 6·2 c.c. Treated directly with standard acid, 1 gram of the substance should not consume materially less than 18·8 c.c. of acid, slag neutralising but about one-half that volume. Boiled with dilute sulphuric acid, 1 gram of the substance yields a solution which will decolorise only a few drops normal permanganate solution in the case of cement and lime, but large volumes in that of slag. Lastly, whilst hydraulic lime absorbs carbonic anhydride (1 gram about 10 mgrms.), cement does not combine with that gas.

Experiments made with mixtures containing 10 per cent. of adulterant, readily gave decisive indications with one or other of the above tests. O. H.

Petroleum Testing in Tropical Climates with Abel's Apparatus. By Sir F. A. ABEL and B. REDWOOD* (*Chem. News*, **49**, 196—197).—When the legally recognised testing method is employed, the flashing point of one and the same sample of petroleum is found to be lower in tropical than in temperate climates (compare Abel, *Jour. Soc. Chem. Ind.*, 1882, 471—478). As an illustration of this fact, the flashing point of an oil which was 73° F. in the laboratory atmosphere, was only 66° F. in an apartment heated to a tropical temperature.

This difference is due to the fact that the petroleum, having been exposed to the high temperature previous to testing, cannot so easily hold in solution the more volatile hydrocarbons, and therefore the slightest agitation—such for instance as the pouring of the oil into the testing cup—determines their vaporisation, and the volatile inflammable vapours hover about the surface of the oil in the cup and give rise to the low flashing point. This is especially the case when the oil is poured into the cup in a long thin stream from some distance above the cup. This difficulty can be obviated by prolonged cooling of the oil previous to testing; this method is, however, not recommended as practical; therefore the following are suggested:—Leaving the testing slide withdrawn for some time before applying the test-flame; removal of the vapours by aspirating, or by gently blowing over the surface; to commence applying the test-flame at a temperature much lower than that prescribed by the Acts. Of all these methods, the authors prefer the last mentioned; it causes the removal of the superincumbent vapours in quantities too small to flash by currents of air set up by each application of the test-flame. All the methods occasion the loss of some of the volatile constituents of the petroleum; as, however, there is always an unavoidable loss of these matters whenever the oils are manipulated in any way in hot climates, this loss is unimportant when compared with benefit derived from the attainment of uniform results. D. A. L.

Estimation of Glycerol in Aqueous Solution by means of its Refractive Power. By F. STROHMER (*Monatsh. Chem.*, **5**, 55—62).—The author recommends the estimation of glycerol in aqueous solution by a determination of the refractive index of the liquid. This can be readily and accurately effected by means of Abbé's refractometer. Tables are given showing the specific gravities and refractive indices of aqueous solutions containing from 50—99 per cent. of glycerol. A. J. G.

---

* *Note by Editor.*—The name is misspelt in the original.

Note.—The author appears to be unacquainted with Lenz's paper on this subject (*Zeitschr. Anal. Chem.*, 1880, 297).—A. J. G.

Action of Alkalis on Amides. By E. BOSSHARD (*Zeitschr. Anal. Chem.*, 1884, 160—165).—Contradictory statements have been made in reference to the stability of leucine, tyrosine, aspartic, and glutamic acids when heated with potassium or barium hydroxide. Thus while Mallet and also Schulze assert that ammonia is readily given off at temperatures above 50°, Schützenberger obtained amidic products by heating albumin with excess of barium hydroxide at 200° for several days.

The author prepared the amides above enumerated in a state of purity, and especially perfectly free from ammonia. These on treatment with potassium or barium hydroxide failed to yield any ammonia. Asparagine gives one-half of its nitrogen as ammonia at first, and the remainder gradually when the potash has reached a high degree of concentration. O. H.

Analysis of Mustard. By A. R. LEEDS and E. EVERHART (*Bied. Centr.*, 1884, 140).—The sinapine thiocyanate or potassium myronate is estimated by treatment with aqueous alcohol, after the oil has been removed by dry ether. The solution is evaporated, dried at 105°, weighed and ignited, and the myronate is calculated from the potassium sulphate left. Myrosin and cellulose are not dissolved by dilute alcohol; these are then treated with a half per cent. soda solution; the undissolved cellulose is weighed and ignited, whilst the solution of myrosin is neutralised and precipitated by Ritthausen's solution of copper sulphate. If starch is present as an adulterant, it is converted into glucose. E. W. P.

Technical Chemistry.

Solvent Action of Water on Zinc, and Effects of Drinking Water contaminated with Zinc. By T. STEVENSON (*Chem. News*, 49, 107).—Several authorities are quoted who differ in opinion as to the nocuous or innocuous effects of drinking water containing zinc. It is shown that water after passing over zinc or a zinced surface generally contains zinc in solution, or in suspension, or both. Potassium ferrocyanide is recommended as a very delicate test for zinc, but not confirmatory. D. A. L.

Antiseptic Experiments in a Mortuary Vault. By C. A. CAMERON (*Chem. News*, 49, 215—216).—In the vaults of the ancient church of St. Michan, Dublin, the corpses instead of decomposing became dry, like mummies. The vaults are built of limestone. The author attributed this peculiarity in part to the dryness and freedom from dust which characterises the atmosphere of the vaults. In order to test these antiseptic properties, several tubes of infusion of melon were prepared, sterilised, and sealed up. Many of these were opened at various times in the laboratory and speedily became turbid, &c. Ten of twelve were next carefully opened in one of the vaults which was locked for six weeks, after which period they were removed (on 13th of August, 1879); five of the tubes were filled with mycelium, the other seven were quite clear, &c. (including the sealed tubes), but after a few days' exposure to the air of the laboratory became so thick that they could not be poured out. D. A. L.

Liquid Hydrocarbons from Compressed Petroleum Gas. By G. WILLIAMS (*Chem. News*, **49**, 197).—When the gas obtained from petroleum at a high temperature is stored under pressure, as in Pintsch's system, a liquid condenses which contains benzene, toluene, and certain olefines. In the present case, the olefines are separated from the aromatic hydrocarbons in the following manner:—The hydrocarbon vapours are passed through a powerful rectifying column, and two fractions are collected, one below and the other above 66°. The first is reserved for the preparation of the olefines: the latter is used for the preparation of benzene, &c., for which purpose the olefines are removed by agitation with cold permanganate solution, or preferably by distillation from dilute nitric acid; the latter method is susceptible of yielding accurate quantitative results. Nitro-products obtained in the latter process are under examination.

D. A. L.

Paraffin-shale from Servia. By A. B. GRIFFITHS (*Chem. News*, **49**, 137—138).—This shale, intermingled with beds of whitish clay containing rock-salt and sodium and magnesium sulphides, forms a very extensive deposit near the River Golabara in Western Servia. It is nearly white and odourless, and contains no bituminous matter. When heated to about 426° it takes fire and burns with a clear, bright, smokeless flame, leaving a grey ash. On distillation, it yields 2 per cent. of a semi-solid hydrocarbon, of which 1·75 per cent. is wax soluble in petroleum. In addition to this, it contains 3·02 per cent. of water and 1·18 per cent. of ammonia, the remainder being mineral matter, which would probably be useful for the preparation of a hydraulic cement. D. A. L.

Presence of Manganese in Wines and other Vegetable and Animal Products. By E. J. MAUMENÉ (*Compt. rend.*, **98**, 1056——1058).—Thirty-one wines of different vintages from various localities in Europe and Africa were found to contain amounts of manganese varying from 0·0001 to 0·0020 gram per litre. All these wines contained an extremely minute proportion of potassium hydrogen tartrate, but in other respects were of normal composition. Wheat grown in the district of Beaujolais contains a considerable proportion of manganese, and this metal is also present in many other vegetable and animal organisms, details concerning which will be given in subsequent papers. C. H. B.

Preserving Ground Coffee. By F. SCHNITZER (*Dingl. polyt. J.*, **250**, 554).—Ground coffee is mixed with a certain proportion of calcium sucrate, with or without the addition of pure powdered sugar, and the mixture pressed into cakes. The calcium sucrate is said to prevent decomposition, *i.e.*, it fixes the organic acids formed at the commencement of the decomposition. D. B.

Manufacture of Etching Ink. (*Dingl. polyt. J.*, **250**, 555.)—According to Müller, a liquid for etching on glass has recently been introduced into commerce, and can be used with an ordinary pen. It consists of hydrofluoric acid, ammonium fluoride, and oxalic acid, and is thickened with barium sulphate. A better ink is obtained as follows:—Equal parts of the double fluoride of hydrogen and ammonium and dried precipitated barium sulphate are ground together in a porcelain mortar. The mixture is then treated in a platinum, lead, or gutta-percha dish with fuming hydrofluoric acid, until the latter ceases to react. D. B.

Process for Preserving and Colouring Stone Work. By A. KEIM and J. THENN (*Dingl. polyt. J.*, **250**, 556).—The authors preserve white stones without changing their original colour by drenching them with lime, baryta-water, magnesium sulphate, or potash alum, then with potash water-glass, and finally with hydrofluosilicic acid. If it is intended to colour the stone work, metallic sulphates are used, the bases becoming fixed by the potash water-glass, and the sulphuric acid combining with the baryta, whilst the potash unites with the hydrofluosilicic acid. The stones are then painted with a solution of paraffin in benzene or petroleum. D. B.

The Liebig Memorial Statue at Munich. By M. v. PETTENKOFER, A. BAEYER, and C. ZIMMERMANN (*Ber.*, **17**, 230—234).—On November 6th, 1883, it was found that the marble statue of Liebig was covered with a number of black spots and stripes. Further examination showed these stains to consist of a mixture of silver and a little hydrated manganese dioxide. From this it is very probable that the liquid employed to deface the statue was a solution of silver nitrate and potassium permanganate. The method employed for the removal of the stains was founded on the conversion of the metals into sulphides and subsequent solution of the sulphides by means of potassium cyanide. Each stain was covered with a paste made of yellow ammonium sulphide and porcelain clay. This was renewed after 24 hours, and after the lapse of another day carefully washed off, and each stain then treated twice in succession with a paste of porcelain clay and concentrated solution of potassium cyanide. In most cases this was sufficient to remove all stain, but some few of the very deep stripes had to be treated in this way several times to effect complete removal. The success of the operation was so complete, that no sign of the stains can be seen now. A. J. G.

General and Physical Chemistry.

Skrivanoff's Cell (Pocket Form). By D. MONNIER (*Compt. rend.*, 98, 224).—This cell is formed of plates of zinc and of chloride of silver wrapped in parchment-paper and immersed in a concentrated solution of potassium hydroxide, contained in a gutta-percha vessel, which may be hermetically sealed. The external conductors are of silver, and the cell complete weighs about 100 grams. Its electromotive force is 1·5 volt, and it will maintain a current of 1 ampère for an hour, when it becomes necessary to renew the alkaline solution. R. R.

Variation of Electromotive Force in Accumulators. By E. REYNIER (*Compt. rend.*, 98, 224—225).—The secondary electromotive force is decidedly greater during the charge of accumulators than during the discharge. Of the three kinds of accumulator examined, the difference was found to be greatest in that formed with copper, lead peroxide, and acidulated solution of copper sulphate; much less in Planté's accumulator; and least in that made with amalgamated zinc, lead peroxide, and acidulated zinc sulphate solution. R. R.

A Mercurial Galvanometer. By G. LIPPMANN (*Compt. rend.*, 98, 1256—1257).—A mercurial manometer with a narrow tube is placed between the arms of a fixed magnet in such a way that the horizontal branch of the manometer passes between the poles of the magnet. The current to be measured passes vertically through the horizontal limb of the manometer, and produces a difference in level in the two branches of the manometer, which is proportional to the intensity of the current. That portion of the column of mercury through which the current passes, constitutes a moveable conductor which tends to repel the magnet in its neighbourhood. Since, however, the magnet is fixed, the conductor itself is displaced, and produces hydrostatic pressure resulting in an alteration of the levels of the mercury. The sensibility of the galvanometer increases with the intensity of the magnetic field, and with a decrease in the diameter of the column of mercury through which the current passes.

This apparatus is reversible; if the mercury is moved mechanically, an electric current is produced in the circuit forming the poles of the apparatus. C. H. B.

Joule's Law. By P. GARBE (*Compt. rend.*, 98, 360—363).—The paper describes the electrometric measurement of energy radiated from incandescent lamps, and the results are found to be in complete accordance with Joule's law. R. R.

Electric Conductivity of very Dilute Saline Solutions. By E. BOUTY (*Compt. rend.*, 98, 140—142).—The experiments recorded in this paper tend to prove that the more dilute the saline solutions operated on, the more closely do their relative electric resistances approximate to the ratios between the "equivalents" of the respective salts compared.

The author believes that dilution tends to eliminate the differences due to interfering causes, such as non-identity of the physical properties of the solution, and formation of more or less stable hydrates, &c., and that in the limit the conductivity of solutions containing in the same volume quantities of neutral salts proportional to their "equivalents," is the same, that is, the molecular conductivity of all the neutral salts is the same. R. R.

Note by Abstractor.—By "equivalents" is here meant the sum of the "equivalent" weights in the formula of the salt, $O = 8$.—R. R.

Faraday's Law, and the Law discovered by Bouty. By Wurtz (*Compt. rend.*, **89**, 176).—Bouty thinks that the expression (see preceding Abstract) of these laws in terms of the *atomic* weights, is obscure and complicated. Now for 1 atom of chlorine liberated at the positive pole, the quantities of metal deposited at the negative pole in the electrolysis of the chlorides $NaCl$, Cu_2Cl_2, $CuCl_2$, $BiCl_3$, $SnCl_4$, Fe_2Cl_6 are $Na, \frac{2Cu}{2}, \frac{Cu}{2}, \frac{Bi}{3}, \frac{Sn}{4}, \frac{2Fe}{6}$, and these quantities are strictly equivalent, although they by no means correspond to the "equivalents" in the case of cuprous, bismuthic, stannic and ferric chlorides. Similarly, in the electrolysis of HCl, H_2O, H_3N, for one volume of hydrogen liberated at the negative pole, there is set free at the positive pole 1 vol. chlorine, $\frac{1}{2}$ vol. oxygen, $\frac{1}{3}$ vol. nitrogen. These last are strictly equivalent, but it cannot be said that $\frac{1}{3}$ vol. nitrogen represents 1 equivalent of nitrogen. But here it is a question neither of atomic weights, nor of "equivalents" in the sense usually attached to that word, but in fact of the valency or atomicity of the elements, a notion that has superseded the old idea of equivalents.

Bouty has shown that the electric resistance of saline solutions is the same when they contain equivalent quantities of metal. But as the above-mentioned chlorides do not contain equivalent quantities of metal, there is reason to believe that the *molecules*, which differ so much by their form and relative sizes, will oppose different *molecular* resistances to the current. R. R.

Electric Conductivity of very Dilute Saline Solutions. By E. Bouty (*Compt. rend.*, **89**, 362—365).—The electric conductivity of a neutral salt in a very dilute solution increases with the temperature, thus:—$Ct = C_0(1 + kt)$. The value of k is the same for all neutral salts, and is equal to 0·033543. R. R.

Electric Conductivity of Saline Solutions. By Wurtz (*Compt. rend.*, **98**, 176).—Referring to the paper of Bouty (preceding Abstract), the author remarks that Bouty has shown that the electric resistance of saline solutions is the same when the solutions contain equivalent quantities of metal. Otherwise he thinks the molecules must offer different resistances to the electric current on account of the difference of their forms and sizes, and therefore he would not expect to find the same conductivity in such salts as $NaNO_3$, $NaSO_4$, Na_3PO_4, $Na_4P_2O_7$. R. R.

Temperature Regulator. By L. Meyer (*Ber.*, **17**, 478—484).—In order to maintain an air-bath at a constant temperature, the author recommends the use of a modification of Babo's gas regulator. The apparatus cannot be intelligibly described without the accompanying woodcut. The "rheometers" of Giroud of Paris are also very useful when one and the same temperature is always required. Each rheometer allows a definite number of litres of gas (*e.g.*, 50, 60, 80, 100 up to 200 litres) to pass through it per hour. W. C. W.

Law of Thermic Substitution Constants. By D. Tommasi (*Compt. rend.*, **98**, 368).—The author contends that his law of thermic constants is applicable to all soluble salts without exception, and that dissociation explains those cases in which the law appears to fail. R. R.

Bromine Substitution. By Berthelot and Werner (*Compt. rend.*, **98**, 1213—1218).—It is usually very difficult to determine the thermal disturbance accompanying substitution, because in most cases the reactions proceed very slowly at ordinary temperatures, and secondary products are frequently formed. The action of bromine on the phenols, however, takes place rapidly, and yields a definite product. The heat of formation of tribromophenol was determined by the action of bromine, both pure and in aqueous solution, on an aqueous solution of phenol; by the action of bromine on phenol in presence of potassium bromide; and by the action of bromine on sodium phenolate. The heat of formation of dibromophenol was determined by the action of bromine on sodium dibromophenolate, and that of the monobromo-derivative by the action of the proper proportion of bromine on sodium phenolate, and by the action of bromine on monobromophenol. The mean results obtained were—

C_6H_6O diss. + Br_2 diss. = C_6H_5BrO solid + HBr diss.	develops	+ 26·1 cal.
C_6H_6O diss. + $2Br_2$ diss. = $C_6H_4Br_2O$ solid + 2HBr diss.	„	+ 46·0 „
C_6H_6O diss. + $3Br_2$ diss. = $C_6H_3Br_3O$ solid + 3HBr diss.	„	+ 68·3 „

or—

C_6H_6O solid + Br_2 gas = C_6H_3BrO solid + HBr gas	„	+ 12·1 „
C_6H_6O solid + $2Br_2$ gas = $C_6H_4Br_2O$ solid + 2HBr gas	„	+ 20·4 „
C_6H_6O solid + $3Br_2$ gas = $C_6H_3Br_3O$ solid + 3HBr gas	„	+ 31·0 „

The amount of heat developed is approximately proportional to the amount of bromine introduced, and is about + 10·5 cal. for each atom of bromine. The introduction of a fourth atom of bromine, however, develops a much smaller quantity of heat, a result which agrees with the known stability of the tribromo-derivative. The number + 10·5 cal. is approximately one-third the heat of formation of hydrobromic acid from its elements (27 cal.); hence it follows that the simple substitution of bromine for hydrogen would absorb 3 × 3 cal, which indicates that substitution in the phenols only takes place by reason of the heat developed by the simultaneous formation of hydrobromic acid.
C. H. B.

Thermochemistry of the Oxychlorides of Mercury. By G. André (*Compt. rend.*, 98, 298—300).—From experiments described in the paper, the quantities of heat disengaged in the following combinations are deduced:—

$HgO + HgCl_2$ .... + 3·30 cal.
$2HgO + HgCl_2$ .... + 6·30 „
$3HgO + HgCl_2$ .... + 7·90 „
$4HgO + HgCl_2$ .... + 9·86 „

R. R.

Thermochemistry of Antimony Fluoride. By Guntz (*Compt. rend.*, 98, 300—303).—Hydrofluoric acid, even when very dilute, rapidly dissolves crystallised or amorphous antimony oxide, and the solution, unlike that of other antimony salts, is not decomposed by water: on evaporation over the water-bath, it leaves crystallised antimony fluoride. As antimony fluoride dissolves in hydrofluoric acid with liberation of heat, which increases with the quantity of acid until eight molecular weights of the latter are present for one of the fluoride, there is reason to believe that an acid fluoride is formed. The author has not succeeded in isolating this compound in a pure state, although he has obtained a crystallised fluoride containing an excess of acid. The thermic determinations of the formation of antimony fluoride and oxide perfectly explain the stability of the former in presence of water, and furnish another experimental confirmation of the theory advanced by Berthelot in his *Mécanique chimique*.
R. R.

Thermochemistry of Alkaline Fluosilicates. By C. Truchot (*Compt. rend.*, 98, 1330—1333).—The heats of formation of potassium, sodium, and lithium silicofluorides were determined by three different methods.

(1.) *Action of Silicon Fluoride on the Alkaline Fluorides*—

SiF_4 gas + 2KF diss. = K_2SiF_6 solid ...... develops + 45·6 cal.
SiF_4 „ + 2NaF „ = Na_2SiF_6 „ ...... „ + 36·6 „
SiF_4 „ + 2LiF solid = Li_2SiF_6 diss. ...... „ + 27·0 „

Potassium and sodium silicofluorides are insoluble in solutions of the corresponding fluorides, which were always in excess. The heat of solution of lithium silicofluoride = + 1·84 cal., hence—

SiF_4 gas + 2KF solid = Ki_2SiF_6 solid...... develops + 52·8 cal.
SiF_4 „ + 2NaF „ = Na_2SiF_6 „ ...... „ + 35·4 „
SiF_4 „ + 2LiF „ = Li_2SiF_6 „ ...... „ + 25·16 „

(2.) *Action of Silicon Fluorides on Dilute Solutions of the Hydroxides.*—This reaction yields a fluosilicate in the case of potassium only; in the other two cases a simple fluoride is formed—

$3SiF_4$ gas + 4KHO diss. = $2K_2SiF_6$ solid + H_4SiO_4 solid .... develops + 165·88 cal.

hence—

$3SiF_4$ gas + 4KHO solid = $2K_2SiF_6$ solid .. „ + 215·88 „

In the other two cases—

SiF_4 gas + 4NaHO diss. = 4NaF diss. + H_4SiO_4 solid .... „ + 65·4 „
SiF_4 gas + 4LiHO diss. = 4LiF diss. + $4H_4SiO_4$ solid .... „ + 69·2 „

The silicic acid liberated in these reactions is not acted on by potash, and the action of lithia is negligeable; but the action of soda varies with the proportion in which it is present in excess. A correction being made for this secondary action, it is found that—

SiF_4 gas + 4NaHO solid = 4NaF solid + H_4SiO_4 solid .... develops + 107·0 cal.
SiF_4 gas + 4LiHO solid = 4LiF solid + H_4SiO_4 solid .... „ + 92·48 „

Thomsen has found that—

Na_2O diss. + 2HF diss. = 2NaF diss....... „ + 32·6 „

hence it follows that if H is substituted for Na in one of the above reactions, we find that $SiF_4 + 4H_2O + nH_2O = 4HF$ dil. + H_4SiO_4, develops practically 0 cal., a result which explains why the action of silicon fluoride on water does not take place in this manner.

(3.) *Action of Fluosilicic Acid on Dilute Alkalis*—

H_2SiF_6 diss. + 2KHO diss. = K_2SiF_6 solid + $2H_2O$ .... develops + 44·0 cal.
H_2SiF_6 diss. + 2NaHO diss. = Na_2SiF_6 solid + $2H_2O$ .... „ + 31·6 „
H_2SiF_6 diss. + 2LiHO diss. = Li_2SiF_6 diss. + $2H_2O$.+.............................. „ + 28·6 „

whence—

$H_2SiF_6,4H_2O$ solid + 2KHO solid = K_2SiF_6 solid + $2H_2O$ solid .... „ + 79·8 „
$H_2SiF_6,4H_2O$ solid + 2NaHO solid = Na_2SiF_6 solid + $2H_2O$ solid .... „ + 62·0 „
$H_2SiF_6,4H_2O$ solid + 2LiHO solid = Li_2SiF_6 solid + $2H_2O$ solid .... „ + 49·2 „

If 6 mols. of sodium or lithium hydroxide are allowed to act on 1 mol. of fluosilicic acid, the reaction is entirely different—

H_2SiF_6 diss. + 6NaHO diss. = 6NaF diss. + H_4SiO_4 solid	develops	+ 66·6 cal.
H_2SiF_6 diss + 6LiHO diss. = 6LiF diss. + H_4SiO_4 solid	„	+ 69·5 „

whence—

$H_2SiF_6,4H_2O$ solid + 6NaHO solid = 6NaF solid + H_4SiO_4	„	+ 137·0 „
$H_2SiF_6,4H_2O$ solid + 6LiHO liquid = 6LiF solid + H_4SiO_4 solid	„	+ 112·3 „

C. H. B.

Determination of Vapour-densities by Gaseous Displacement under Low and Variable Pressures. By J. MEUNIER (*Compt. rend.*, **98**, 1268—1271).—The apparatus employed is a modification of that of Crafts and Meyer (*Bull. Soc. Chim.*, **33**, 550). The upper part of each limb of the graduated U-tube is provided with a stopcock so that they communicate with each other and with a vacuous globe. Above the stopcock, on the left branch of the tube, is sealed a capillary tube which communicates with the heated reservoir. By this arrangement, communication between the reservoir and left limb of the tube, and the vacuous globe, can be cut off or opened as required. The two branches of the tube are graduated in millimetres and filled with strong sulphuric acid, the tube being surrounded by cold water. The reservoir is heated by means of some liquid boiling at the required temperature, and communication is opened between the apparatus and the vacuous vessel. The communication between this vessel and the left limb of the tube is then cut off. If the levels of the sulphuric acid in the U-tube remain stationary, indicating that the temperature is constant, the pressure in the vacuous vessel h, the temperature of the water surrounding the U-tube t, and the levels of the sulphuric acid in each limb of the tube are read off, and the substance is dropped into the reservoir. When the evolution of gas ceases, the levels of the sulphuric acid are again read off, and the density is calculated by means of the formula

$$D = \frac{P + 76 \times (1 + at)}{1{\cdot}293 \times vh},$$

where P is the weight of the substance taken. In this formula, v represents the volume of air expelled at the pressure h, but the volume v' actually read off is smaller, because the pressure has changed to h' in consequence of the alteration in the levels of the sulphuric acid. The true value of vh is obtained with sufficient accuracy by means of the expression $vh = V(h' - h) + v'h'$.

If the levels of the sulphuric acid are made equal, so that $h = h'$, the formula becomes identical with Victor Meyer's. The volumes corresponding with the divisions on the left branch of the U-tube are determined by calibration with mercury, and the volume V of the reservoir, connecting tube, and left limb of the U-tube down to the initial graduation, are determined by Regnault's manometric method.

This method gives accurate results even at low pressures. An amount of the substance should be taken sufficient to cause a difference of 0·15 metre between the levels of the sulphuric acid. When too large a quantity of the substance is taken, the expulsion of gas ceases, and the sulphuric acid acquires a constant level when the vapour attains the maximum tension corresponding with the temperature of the reservoir, this tension being measured by *h*. By operating in this way at various temperatures, it will be possible, with very small quantities of matter, to ascertain the curves representing the vapour-tension, and thus determine the boiling point of substances which boil with decomposition at high temperatures.

Determinations of the vapour-density of the new isomeride of benzene hexachloride (this vol., p. 733) by the above method gave 9·186, which shows that its formula is $C_6H_6Cl_6$. C. H. B.

Differential Dilatometer and its Application in an Investigation on the Formation of Alums. By W. SPRING (*Ber.*, **17**, 404—408).—E. Wiedemann (*Ann. Phys. Chem.*, **17**, 561) has recently pointed out that the alums and other salts containing water of crystallisation, lose a portion of their water and are converted into salts of different composition by an increase in temperature. This fact explains why the author obtained constant results in his experiments on the dilatation of alums (*Ber.*, **15**, 1254), when the salts had been previously heated at 70°, and varying results when this had not been done.

By means of a dilatometer (the construction of which cannot be described without the accompanying woodcut), the author has measured the relative contraction which takes place, owing to dissociation, when the different alums are heated from 0° to 70°. Thallium, potassium, and chromium alums all contract more than ammonium alum. W. C. W.

Solubility of Salts. By ÉTARD (*Compt. rend.*, **98**, 1276—1279). —The author has previously shown (this vol., 807) that the solubility of all salts is proportional to the temperature, and is therefore represented by a straight line. Any deviations from this law are merely temporary, and correspond with the dissociation of the combination between the dissolved substance and the solvent. The curves representing the solubilities of various salts as determined by other observers are generally straight lines, and in cases where the curve is inflected, the determinations have been made between too narrow limits of temperature. When the determinations are extended to higher and lower temperatures, it is found that the solubility follows the law already stated. In order to describe concisely the solubility of a salt, it is sufficient to express the straight portions of the curve of complete solubility by the formula $s = a + bt$, and to give some points on the curve of deviation. The curves representing the solubility of the haloïd salts of a family of metals such as Ca, Ba, Sr, or Mg, Zn, Cd, are almost identical.

For determinations of solubility at low temperatures, methyl chloride may be used with advantage, and will give a temperature of −20°. To determine solubilities at high temperatures, an excess of the crystallised salt is introduced, together with a certain quantity of the cold saturated solution, into a strong glass tube. The tube is drawn out in the middle to about half its original diameter, bent at the contraction at an angle of 45°, and the open end sealed. It is then heated at the required temperature, with occasional agitation, and after a sufficient length of time the tube is inverted so as to decant the saturated solution from the first limb into the second. Matters are so arranged that the two limbs of the tube are of equal capacity, and both contain the same quantity of liquid (about 15 grams). In this way, errors due to unequal condensation of the vapour are avoided. When the tube has cooled to about 90° it is cut at the bend, the second half and its contents weighed, the contents analysed, and the empty tube weighed afterwards. Concordant and accurate results are obtained, and the curve representing these results is a continuation of that representing the results under ordinary pressure. It is evident therefore that the influence exerted by pressure on the solubility, within the limits of temperature employed, is very slight. Moreover, the solubility above 100° undergoes perturbations strictly analogous to those observed at lower temperatures, sometimes increasing, sometimes rapidly diminishing.

The solubility of sodium chloride between 0° and 100° is represented by the formula $S = 26{\cdot}4 + 0{\cdot}0248t$, if 26·4 is the amount dissolved at 0°; and the author finds that this formula holds good up to 160°. When, however, the solubility is determined at low temperatures, it is found that below 0° the curve of solubility alters, and at −21° the solution contains only 23·5 per cent. of salt, instead of 26·0 as required by the formula. This deviation in the curve takes place at the temperatures at which the hydrate $NaCl,2H_2O$ is respectively formed and dissociated, and thus agrees with the author's theory. C. H. B.

Inorganic Chemistry.

Liquefaction of Hydrogen. By S. Wroblewski (*Compt. rend.*, **98**, 304—306).—The author compressed hydrogen gas under 100 atmospheres in a vertical tube of 0·2 mm. diameter. The apparatus was so constructed that the pressure could be removed instantaneously when the tube had been cooled by the vaporisation of liquid oxygen. The moment the pressure was removed, ebullition took place in the tube, similar to that observed by Cailletet with oxygen, in his experiments of 1882; it occurred at a certain distance from the bottom of the tube, continued but a short time, and was less marked and more difficult to observe than in the case of oxygen. The reason of this difficulty is that the density of liquid hydrogen, as deduced by

Cailletet and Hautefeuille, being only 0·033, and the density of gaseous hydrogen at low temperatures and under moderate pressure being nearly the same, the liquid and the gaseous parts are not optically distinguishable. The analogy between these phenomena and those presented by oxygen leads to the conclusion that the temperature required for the complete liquefaction of hydrogen is not far removed from that which may be obtained by the ebullition of liquid oxygen. R. R.

Liquefaction of Hydrogen. By R. Olszewski (*Compt. rend.*, **98**, 365).—Referring to Wroblewski's paper (preceding Abstract) the author states that he was unable to liquefy hydrogen by submitting it to a pressure of 100 atmospheres, cooling with liquid oxygen, and sudden removal of pressure. Nor did he succeed when liquefied air, boiling in a vacuum, was substituted for the oxygen. More recently he has liquefied hydrogen under a pressure of 190 atmospheres, cooling with oxygen boiling in a vacuum. When the pressure is suddenly removed, a momentary ebullition takes place, and small colourless drops are projected into the upper part of the tube. R. R.

Expansion of Elementary Gases. By J. M. Crafts (*Compt. rend.*, **98**, 1259—1261).—A criticism of Berthelot's paper on this subject. Chlorine gas has an abnormally high specific heat even below 200°, but it obeys the ordinary laws of expansion of gases up to 1400°, and similar phenomena are observed in the case of bromine and iodine. There is therefore no correlation between the coefficient of expansion of a gas and its specific heat. The heat which is absorbed without increasing the energy of translation of the molecules increases their internal energy, and thus facilitates their dissociation at a higher temperature. C. H. B.

Crystallisation of Sulphur. By D. Gernez (*Compt. rend.*, **98**, 144—146).—When sulphur has been heated to 160°, allowed to cool to 100°, and maintained at that temperature for some time, the liquid is capable of yielding several crystalline modifications. By rubbing the interior surface of the vessel, and by other means, a deposition of pearly crystals is caused, and the liquid from which these have separated may be converted at will into the ordinary prismatic, or the octahedral crystals of sulphur by the touch of a corresponding crystal. The experiments described in the paper show that the conversion of the fused sulphur into the ordinary crystals takes place with sevenfold rapidity in the liquids from which the nacreous crystals have been deposited, as compared with the same liquid before such deposit has taken place. The author considers that at the temperature of 160° the allotropic modification that crystallises with pearly lustre is produced, and by its solution in the rest of the liquid the latter is in the condition of a supersaturated solution. R. R.

Physical Properties of Sea-water and Ice. By O. Pettersson (*Bied. Centr.*, 1884, 61—63).—The investigations were carried on during the expedition of the "Vega," in the Siberian Sea, where salt water in all grades of saturation was found from 3·4 per cent. of solid residue in the lower strata to almost soft water at the surface from the many rivers which flow into the sea. The experiments related to the changes in temperature and volume at freezing point of pure water, brackish water with slight proportion of salt, and of sea water. Previous experiments had shown the author that the presence of foreign bodies capable of passing into solution with another substance greatly altered the melting process. The general results of the experiments justify previous opinions, and show that the process of thawing begins at a point below the freezing point; skating is unpleasant on fresh-water ice, from yielding; in Arctic seas, the ice takes deep impressions at much lower temperatures; ice from open seas is considered useless in commerce because it softens and melts at temperatures when fresh-water ice is clear and hard.

He explains the phenomenon of the dreaded heaping up of pack ice in Arctic seas thus: a sudden fall in the temperature causes the superficies of the ice fields to extend enormously, the lower strata remaining somewhere about freezing point; a further fall of temperature causes a violent contraction and splitting up of the ice with loud noises. He answers the question as to whether sea-water ice contains salt in the affirmative, and says it is present both mechanically in the pores and chemically in the substance; but that whilst chlorides predominate in water, sulphates are chiefly found in the ice. J. F.

Crystallised Ammonio-Silver Chloride and Ammonio-Silver Iodide. By TERREIL (*Compt. rend.*, **98**, 1279—1280).—When silver chloride saturated with ammonia is heated with a saturated solution of ammonia in a sealed tube at 100°, the chloride dissolves in large quantity, and the solution, on cooling, deposits long white lamellar prisms, formed by the aggregation of needles. They rapidly give off ammonia when exposed to the air, are blackened by light, and are decomposed by water. When dried over quick-lime, they have the composition $AgCl.2NH_3$.

Silver iodide, when treated in the same way, is only slightly soluble, and yields thin white micaceous plates, which rapidly acquire a violet tint. The undissolved amorphous portion remains permanently white. If the violet plates are heated with the ammonia, they dissolve, and separate again in a colourless condition on cooling. When exposed to the air, these crystals give off ammonia, lose their violet tint, and become yellow. They have the composition $AgI,2NH_3$, and are shown by microscopical examination to be octagonal tables.

Ammoniacal silver bromide was treated in the same way; but as soon as the water in the water-bath boiled, the silver bromide melted, and in a few minutes there was a very violent explosion. It would seem, therefore, that ammoniacal silver bromide is very slightly soluble in ammonia, melts at about 90°, and detonates at about 100°. Ammoniacal silver phosphate, under the same conditions, dissolves rapidly, but the liquid quickly turns brown and deposits an amorphous brownish-black substance resembling silver fulminate.

C. H. B.

Barium Hydrogen Phosphates. By A. Joly (*Compt. rend*, **98**, 1274—1276).—When monobarium hydrogen phosphate is brought in contact with a constant quantity of water in proportions varying from 1 to 72 per cent., the ratio of the total phosphoric acid to that remaining in combination increases from 1 to 1·99, or, in other words, the most concentrated solution which can be obtained by bringing an excess of monobarium hydrogen phosphate in contact with water, contains 2 equivalents of the acid to 1 equivalent of the base. One-, third of the phosphoric acid is dissolved in its original state of combination, whilst the remaining two-thirds are decomposed into dibasic phosphate, which is precipitated, and free phosphoric acid, which remains in solution.

The decomposition of monobarium hydrogen phosphate by water takes place in two phases. At first, as the total weight of the salt brought in contact with the same quantity of water increases in arithmetical progression, the weight which is dissolved without decomposition decreases in geometrical progression; but as soon as about half the original salt has been decomposed, the character of the reaction changes, and a di-acid salt, $BaO,2P_2O_5 + xH_2O$, is formed in the liquid. The proportion of this salt increases as the acidity of the liquid increases, and eventually it exists alone in solution.

The phenomena observed when the most acid solutions are diluted with water in presence of the precipitated dibarium phosphate, are analogous to those observed in the case of the calcium phosphates (this vol., p. 556). C. H. B.

New Method for Preparing Barium Permanganate. By G. Rousseau and B. Bruneau (*Compt. rend.*, **98**, 229—231).—All attempts to obtain barium permanganate directly from manganic peroxide and barium salts failed; but a satisfactory method was found in the decomposition of potassium permanganate by hydrofluosilicic acid, using the latter in slight excess. The mixture is kept cool, and after the separation of the potassium fluosilicate, the clear supernatant liquor is decanted and the deposit drained on an asbestos filter and washed. The solution containing permanganic and hydrofluosilicic acids is saturated in the cold with barium hydroxide. The solution of barium permanganate, after separation of the insoluble barium fluosilicate, is evaporated until the salt crystallises out on cooling. The crystals may be obtained in very large orthorhombic octahedra, almost black, with a violet reflection. R. R.

Solubility of Calcium Hydroxide in Water at Different Temperatures. By T. Maben (*Pharm. J. Trans.* [3], **14**, 505—506).—After referring to the numerous conflicting statements made by various eminent authorities with regard to the solubility of calcium hydroxide in water, the author proceeds to describe his method of investigating this subject and its results. Pure calcium oxide is slaked with distilled water. The slaked lime and water are left in contact in a flask in a bath, which is kept at a definite temperature. When the lime and water is of the required temperature, the mixture is filtered through a funnel kept at the same temperature. Thermometers were used in the funnel as well as the flask. The results are as follows:—

Temperature.	Parts of water to dissolve 1 part CaO.	Temperature.	Parts of water to dissolve 1 part CaO.	Temperature.	Parts of water to dissolve 1 part CaO.
0°	759	35°	909	70°	1235
5	764	40	932	75	1313
10	770	45	985	80	1362
15	779	50	1019	85	1388
20	791	55	1104	90	1579
25	831	60	1136	95	1650
30	862	65	1208	99	1650

In addition to this effect of temperature, the presence of calcium carbonate also interferes with the solubility of calcium hydroxide: hence it is important when lime-water of definite strength is required, as in pharmaceutical purposes, that the lime should be kept out of contact with the air if it is to be employed for the preparation of lime-water; the latter should also be kept in a well-stoppered bottle. One part of calcium carbonate is soluble in 40,000 of water, giving it a distinctly alkaline reaction. D. A. L.

Molecular Calcium Compounds. By C. W. Folkard (*Chem. News*, **49**, 258).—By exposing calcium hydroxide to hydrogen sulphide until it ceases to gain weight, a grey powder is obtained containing hydrogen sulphide very feebly combined with calcium hydroxide in the proportions represented by the formula $4Ca(HO)_2,3H_2S$. Hydrogen sulphide is evolved from this substance by the action of coal-gas, and at 100° water is eliminated, leaving a compound $2CaH_2O_2,2CaOH_2S$. This grey-green compound loses 1 mol. H_2O at a gentle heat, in a current of coal-gas, yielding a yellowish-white salt, $2CaH_2O_2,CaOH_2S,CaS$; and this at a red heat out of contact with the air yields up 2 mols. H_2O, producing the substance $2CaO,CaOH_2S,CaS$, which, when ignited in the air, burns like tinder, producing calcium sulphate. (Comp. Divers, Trans., 1884, p. 270.) D. A. L.

Preparation of Dicalcium and Tricalcium Phosphate. By C. L. de Bouquet (*Dingl. polyt. J.*, **252**, 88).—The author employs calcium hydrogen sulphide for the precipitation of acid solutions of phosphates. D. B.

Expansion of Alums. By W. Spring (*Ber.*, **17**, 408—412).—The following numbers show the expansion of alums which have been previously heated at 60—70° in a vacuum, and of alums which have not been heated.

Alums not previously Heated.

t°.	Ammonium aluminium.	Potassium aluminium.	Rubidium aluminium.	Cæsium aluminium.	Thallium aluminium.	Potassium chromium.

W. C. W.

Action of Potassium Sulphide on Mercuric Sulphide. By A. Ditté (*Compt. rend.*, **98**, 1271—1273).—When mercuric sulphide is brought in contact with a dilute solution of potassium sulphide, a certain quantity of the former is simply dissolved, but no other change takes place even if the substances are left in contact for several months. If, however, the alkaline solution is moderately concentrated, the excess of mercuric sulphide is converted into brilliant black needles of the composition $5HgS,K_2S$, the change being more rapid the higher the temperature. The crystals are larger and more brilliant the more slowly they are formed. They are decomposed by water, which gradually removes the alkaline sulphide and leaves a residue of mercuric sulphide, the decomposition taking place much more rapidly on heating.

If the solution of potassium sulphide is very highly concentrated, a large quantity of mercuric sulphide is dissolved, and the excess is gradually converted in the cold into brilliant transparent white needles of the composition $HgS,K_2S,7H_2O$. If the liquid is heated, the excess of the sulphide is converted, not into white needles, but into brilliant golden-yellow plates, of the composition HgS,K_2S,H_2O. The formation of this double sulphide develops a considerable amount of heat. When powdered mercuric sulphide is allowed to fall into a cold concentrated solution of potassium sulphide, it instantly forms a hard compact mass, the liquid becomes very hot, and after some time the mercuric sulphide is completely converted into white crystals.

The sulphide HgS,K_2S dissolves without decomposition in a cold concentrated solution of potassium sulphide, but is decomposed by a dilute solution or by pure water. If the concentrated solution is gradually heated, the liquid becomes turbid at a certain temperature and the sulphide $5HgS,K_2S,5H_2O$ is deposited in black needles, which increase in quantity as the temperature rises, but redissolve as the liquid cools.

The formation and stability of these sulphides depend on the strength of the solution of potassium sulphide, the relative proportion of mercuric sulphide, and the temperature. At a given temperature, the formation of one or the other double sulphide depends on the strength of the solution, and with a certain degree of concentration of the solution and a certain proportion of mercuric sulphide, one or the other double sulphide can be formed by raising or lowering the temperature. If a cold solution containing crystals of the compound $HgS,K_2S,7H_2O$ is mixed with mercuric sulphide, the white crystals gradually disappear and are soon completely converted into black needles. C. H. B.

Transformation of Prismatic Antimony Oxide into the Octahedral Oxide. By M. GUNTZ (*Compt. rend.*, **98**, 303).—The two modifications of antimony oxide dissolve in hydrofluoric acid with development of unequal amounts of heat, namely, 9·5 cal. for octahedric oxide, and 10·1 cal. for the prismatic; whence it may be concluded that the transformation of the one form into the other develops heat = 0·6 cal. R. R.

Determination of the Atomic Weight of Chromium. By H. BAUBIGNY (*Compt rend.*, **98**, 146—148).—The author has determined the atomic weight of chromium by igniting the pure sulphate (this vol, 558). One series of experiments gave a mean of 52·03; whilst another series with the sulphate prepared from chlorochromic acid, gave 52·16; the author considers the latter to be the more trustworthy. R. R.

Mineralogical Chemistry.

Samarskite from Berthier County, Quebec. By J. T. DONALD (*Chem. News*, **49**, 259—260).—Samarskite has not hitherto been found in Canada. The following is the description of the specimen examined:—It consisted of irregular brownish-black (almost black) opaque amorphous fragments (sp. gr. 4·9478), with a sub-metallic shining lustre; in parts iridescent. It is brittle, fracture uneven; streak greyish-brown; hardness about 6, and fuses between 4—4·5°, decrepitating and giving off a small quantity of acid water in a closed tube. When heated with concentrated sulphuric acid, it i decomposed readily and completely. Analysis gave:—

Nb_2O_5,Ta_2O_5	SnO_2.	YO.	Ce_2O_3.	U_2O_3.	MnO.	FeO.	CaO.
55·41*	0·10	14·34	4·78	10·75	0 51	4·83	5·38

MgO.	K_2O.	Na_2O.	Fl.	H_2O.
0 11	0·39	0·23	trace	2·21 = 99·04

Another specimen has been found very similar to the above. Its sp. gr. (5·305) is, however, higher. This mineral is not rare in the locality mentioned. D. A. L.

Artificial Pseudomorphism of Silica. By A. GORGEU (*Compt. rend.*, **98**, 1281—1282).—When crystals of artificial fayalite are calcined at a cherry-red heat for seven or eight hours with exposure to air, the ferrous oxide is completely oxidised, and the transparent grey crystals of the original silicate become black and opaque, but retain their original form. On treatment with concentrated boiling hydrochloric acid, the whole of the silica is left undissolved. This insoluble silica is transparent, has a pale yellow colour due to the presence of a small quantity of ferric oxide, and contains from 4 to 5 per cent. of water, which it gives off when heated. It dissolves in a boiling solution of sodium carbonate. This silica retains the exact form of the original crystals of fayalite. When examined in the dry state with polarised light, it behaves like a doubly refracting substance, but if placed in water, it loses this property, and behaves like a singly refracting substance; it is, in fact, not truly crystalline.

The same pseudomorphism can be obtained by treating artificial knebelite in the same manner, but the silica obtained in this way from natural knebelite, which only occurs in lamellar masses, does not possess the same property. Tephroite, rhodonite, hypersthene, diallage, hornblende, &c., do not sensibly oxidise when roasted in the air, and do not give rise to a pseudomorphism of silica under the above conditions. C. H. B.

Mineral Water at Brucourt. By C. CLOËZ (*Compt. rend.*, **98**, 1282—1285).—The mineral water at Brucourt (Calvados) about 4 kilom. south of Dives, was described by Musner in 1637, and by Lepecq de la Clôture in 1776, and the water has been frequently analysed, the last analysis being that of O. Henry in 1862. Since that time, however, alterations have been made in the spring, whereby infiltration has been prevented, and the flow of water considerably increased. The sample examined was collected on April 1st, 1884. The water has a neutral reaction, is very transparent, and keeps well in bottles. The following results were obtained, in grams per litre:—

Total residue at 180°.	Na_2O.	K_2O.	MgO.	CaO.	FeO.	Al_2O_3 and SiO_2.
2·3305	0·1122	0·0151	0·3006	0·4933	0 0213	0·0710

SO_3.	Cl.	CO_2.
0·8156	0·1802	0·5076

---

* Almost entirely Ta_2O_5.

or arranging these constituents conventionally—

	Per litre.	
Free carbonic anhydride ..	185	c.c.
Sodium chloride	0·2113	gram
Potassium „	0·0238	„
Magnesium „	0·0477	„
„ sulphate	0·5280	„
Calcium „	0·7881	„
„ bicarbonate	0·4880	„
Magnesium „	0·3815	„
Ferrous „	0·0526	„
Alumina and silica	0·0710	„
	2·5920	„

The water is therefore both a magnesian and a chalybeate water, and is the only spring in France which combines both these qualities. Moreover, three litres of the water yield very distinct traces of iodine, and the presence of this element doubtless has considerable influence on the therapeutic action of the water. C. H. B.

Organic Chemistry.

Formation of Methyl Iodide and Methylene Iodide from Iodoform. By P. CAZENEUVE (*Compt. rend.*, **98**, 369—370).—When water (2 parts) is added to a mixture of powdered iodoform with an equal weight of iron reduced by hydrogen (5 parts of each), and the whole slightly heated, iodine is displaced by the nascent hydrogen and a mixture of methyl iodide and methylene iodide is obtained, which are easily separated by distillation in a vacuum; in this way the decomposition of the methylene iodide by heat is avoided.

The hydrogenating action is progressive; acetylene, methylene iodide, methyl iodide, and hydrogen, being produced in succession.

R. R.

Action of Arsenious Anhydride on Glycerol. By H. JACKSON (*Chem. News*, **49**, 258).—When about equal parts of arsenious anhydride and glycerol (1 mol. of former to 2 mols. of latter) are heated in a sealed tube at 250° for two hours, the arsenic displaces the hydroxylic hydrogen-atoms, and water is eliminated according to the equation: $2C_3H_5(OH)_3 + As_2O_3 = 2C_3H_5AsO_3 + 3H_2O$. The arsenious glyceride formed in this manner is a colourless, transparent, very deliquescent, vitreous solid, soluble in absolute alcohol and glycerol, but decomposed by water into glycerol and arsenious anhydride. It softens at 100°, is liquid at 200°, and when dry is not decomposed until the temperature exceeds 290°. D. A. L.

Reduction of Erythrol by Formic Acid. By A. HENNINGER (*Compt. rend.*, **98**, 149—151).—The action of formic acid on the polyhydric alcohols is to successively displace the OH-groups in pairs by formyl, giving rise to unsaturated compounds, and the author found that this reduction is necessarily preceded by the formation of a formin. When erythrol is boiled for six hours with two and a half times its weight of formic acid, and the excess of acid is distilled off at 200°, the crystalline residue contains 49 to 50 per cent. of combined formic acid corresponding nearly in composition with a diformin, $(H.COO)_2C_4H_6(OH)_2$, but in reality is a mixture of formins, which may be separated by fractional crystallisation from alcohol and ether. Amongst these is the tetraformin $(H.COO)_4C_4H_6$, which is obtained in long silky needles, almost insoluble in cold alcohol, still less in water and in ether, and fusible at 150°. Hot water saponifies it with regeneration of erythrol. When the mixture of formins is distilled at 250°, carbonic anhydride, carbonic oxide, and a gas identical with Caventou's crotonylene, C_4H_6, are evolved, and a complex liquid passes over into the receiver, consisting of water, formic acid, crotonaldehyde, and two new substances, namely, *crotonylene glycol*, $C_4H_6(OH)_2$, and a liquid (C_4H_6O) boiling at 67°, for which the author proposes the name of *dihydrofurfurane*. The reaction also gives rise to *erythrane*, $C_4H_8O_3$, the hitherto unknown first anhydride of erthyrol. R. R.

Hydroxycellulose and Phenylhydrazine. By C. F. CROSS and E. J. BEVAN (*Chem. News*, **49**, 257—258).—The authors remark that in addition to reactions of the salts of phenylhydrazine already described, the hydrochloride of the base gives other characteristic reactions. When warmed with hydroxycelluloses, for example, it gives a deep yellow, and with lignose a dull yellow coloration. D. A. L.

Action of Hydrobromic Acid on the Ethereal Salts of Hydroxyacids. By A. FÖLSING (*Ber.*, **17**, 484—486).—A series of experiments on the action of hydrobromic acid on the methyl and ethyl salts of methyl- and ethyl-glycollic and methyl- and ethyl-salicylic acids, shows that the reaction takes place in two stages, the alcoholic radical in the carboxyl group being expelled first. Methyl ethylglycollate yields first methyl bromide and ethylglycollic acid, and finally ethyl bromide and glycollic acid. Methyl ethylsalicylate behaves in a similar manner. W. C. W.

Boiling Points of the Ethereal Salts of Glycollic and Salicylic Acids. By A. FÖLSING (*Ber.*, **17**, 486—488).—The author has redetermined the boiling points of the ethers of glycollic and salicylic acids, and finds that Schreiner's numbers (*Annalen*, **197**, 1) are invariably too high. The correct results are shown below:—

	CH_3.	C_2H_5.
Methylglycollic acid	127°	131°
Ethylglycollic „	148	152
Methylsalicylic „	228	235
Ethylsalicylic „	245	251

The displacement of methyl by ethyl in the carboxyl-group raises the boiling point from 4° to 6°, but in the alcoholic or phenolic hydroxyl it raises it about 20°.

The difference in boiling points diminishes with a reduced pressure. W. C. W.

Transformation of Glyoxal into Glycollic Acid. By DE FORCRAND (*Compt. rend.*, **98**, 295—297).—In preparing glyoxal, the author substitutes aldehyde for the alcohol first used by Debus. The crude product of the action of nitric acid on aldehyde is evaporated, dissolved in water, neutralised by calcium carbonate, and filtered. Glycollic and glyoxylic acids are then precipitated from the filtrate by basic lead acetate, and from this second filtrate the calcium is exactly precipitated by oxalic acid; a liquid is thus obtained containing nothing but acetic acid and glyoxal. This, when evaporated over the water-bath, yields an amorphous residue which, after being dried in a vacuum at a temperature not exceeding 120°, consists of nearly pure glyoxal.

Glyoxal dissolves readily in cold water with a very partial transformation into glycollic acid, but at 150° the quantity so transformed may amount to one-third of the glyoxal; hence the difficulties attending the preparation of glyoxal. The paper gives determinations of the thermic phenomena accompanying this transformation. R. R.

Derivatives of Orthoxylene. By A. BAEYER and C. PAPE (*Ber.*, **17**, 447—448).—Orthoxylyl cyanide, $C_{10}H_8N_2$, is prepared by the action of orthoxylyl bromide on potassium cyanide dissolved in a mixture of alcohol and water. The cyanide is extracted from the mixture by ether. It is a crystalline salt melting at 60°, and soluble in alcohol and ether. On saponification with alkalis or acids, it yields *phenyleneorthodiacetic acid*, $C_6H_4(CH_2.COOH)_2$, crystallising in needles, which melt at 150°. It is soluble in alcohol, ether, and in hot water. The silver salt, $C_{10}H_8O_4Ag_2$, is insoluble in water.

W. C. W.

English and Scotch Coal-tar Xylenes. By I. LEVINSTEIN (*Ber.*, **17**, 444—446).—Orthoxylene is invariably present in English and Scotch coal-tar xylenes. Metaxylene and the non-aromatic hydrocarbons in commercial xylene are estimated by the following process: 100 c.c. of the xylene is boiled with 40 c.c. of nitric acid (sp. gr. 1·44) diluted with 60 c.c. of water, until the para- and orthoxylene is completely oxidised. The acid is run off by means of a separating funnel. The hydrocarbons are washed with caustic soda and distilled in a current of steam. The distillate consisting of metaxylene and non-aromatic hydrocarbons is first measured and afterwards well shaken with strong sulphuric acid (1½ vols.) for half an hour; this dissolves the metaxylene and leaves the other hydrocarbons.

In order to estimate the paraxylene, 100 c.c. of crude xylene are shaken with 120 c.c. of strong sulphuric acid to dissolve ortho- and metaxylene.

The volume of the residual paraxylene and other hydrocarbons having been noted, the liquid is then treated with an equal bulk of fuming sulphuric acid containing 20 per cent. of SO_3 to dissolve the paraxylene. The difference between the volume of residual hydrocarbons and the former volume gives the amount of paraxylene. The percentage of orthoxylene is obtained by deducting the volume of para- and metaxylene and that of the non-aromatic hydrocarbons from 100, the volume of crude xylene originally taken. This method would not yield correct results with a very impure product, as toluene and cymene, &c., are attacked by nitric and sulphuric acids: in such cases it is advisable to convert the ortho- and metaxylenesulphonic acids into their sodium salts, which can be separated by recrystallisation.

The following table shows the composition of different specimens of crude xylene.

	Sp. gr. at 19°.	B. p.	Meta-	Para- xylenes.	Ortho-	Non-aromatic hydrocarbons.

W. C. W.

Triphenylmethylamine. By O. NAUEN (*Ber.*, 17, 442—443).—Triphenylmethylamine is prepared by passing ammonia gas into a mixture of triphenylmethane chloride and naphthalene at 130°. The product is extracted with light petroleum and the triphenylmethylamine is precipitated from this solution by hydrochloric acid gas. The precipitate is dissolved in dilute hydrochloric acid, and the liquid shaken up with ether. The amine is reprecipitated on adding soda to the acid solution. Triphenylmethylamine crystallises in prisms which dissolve freely in alcohol, ether, benzene, and carbon bisulphide. It melts at 102°, and decomposes on distillation. The hydrochloride forms needle-shaped crystals sparingly soluble in water.

On boiling triphenylmethylamine with acetic anhydride, it is decomposed, forming acetamide and triphenylcarbinol. W. C. W.

Isomeric Isobutylorthamidotoluenes. By J. EFFRONT (*Ber.*, 17, 419—420).—When orthotoluidine hydrochloride and isobutyl alcohol are heated at 300°, an isobutylorthamidotoluene is formed in large quantities; this is isomeric with the amine Erhardt obtained by heating isobutyl alcohol and orthotoluidine with zinc chloride. The amine was converted into a nitrile from which isobutylorthotoluic acid, $C_6H_3Me(C_4H_9).COOH$, was obtained in needle-shaped crystals melting at 140°.

The amine was also converted into a diazo-chloride, which on reduction with stannous chloride yields isobutyltoluene (b. p. 185°), probably identical with Kelbe's meta-isobutyltoluene (*Ber.*, **16**, 2560).

W. C. W.

Bromophenols. By E. Werner (*Compt. rend.*, **98**, 1333—1336).—*Monobromophenol*, C_6H_5BrO, obtained by the action of bromine vapour on an equivalent quantity of crystallised phenol, boils at 137° under a pressure of 28 mm., and melts at 64°, but remains liquid at 13°. Its heat of neutralisation when liquid at 13° = + 7·43 cal.; when solid at 11° = + 4·42 cal.; when dissolved = + 8·09. From these numbers it follows that its molecular heat of fusion at 12° = − 3·01 cal.; its heat of solution when liquid = + 0·63 cal.; when solid = + 3·67 cal. Specific heat of the liquid between 18° and 77° = 0·3157: molecular heat = + 54·6 cal.

Dibromophenol obtained by the same method as the preceding compound, using twice as much bromine, boils at 154° under a pressure of 47 mm., and melts at 40°, but remains superfused at 12°. Its heat of neutralisation when liquid = + 8·46 cal.; when solid + 4·93 cal., whence the molecular heat of fusion at 12° = − 3·52 cal. Specific heat of the liquid between 18·5° and 73° = 0·2436; molecular heat = 61·4.

Tribromophenol prepared in the ordinary way, melts at 92°. Its heat of neutralisation when solid at 13°, = + 5·41 cal.

The solubility of the three compounds at 15° is as follows:—

	Per litre.
C_6H_5BrO	14·22 grams
$C_6H_4Br_2O$	1·94 „
$C_6H_3Br_3O$	0·07 „

It will be seen that the solubility decreases as the amount of bromine increases, but that the heat of fusion and heat of solution increase with the amount of bromine. In the solid state, phenol and its bromo-substitution derivatives have practically the same heat of neutralisation, but in solution they would probably show differences similar to those observed in the case of other phenol derivatives.

C. H. B.

Azo- and Disazo-compounds of Cresols. By E. Nölting and O. Kohn (*Ber.*, **17**, 351—369).—Paracresol unites with diazo-compounds to form substances in which the diazo-residue occupies the ortho-position as regards the hydroxyl-group. Neither disazo- nor nitroso-derivatives have been obtained.

Ortho- and meta-cresol form oxyazo-compounds with diazo-derivatives. The azo-group occupies the para-position. They also yield disazo-compounds in which the azo-groups occupy the para- and ortho-positions as regards the hydroxyl-group.

Phenylazoparacresol, $Ph.N_2.C_6H_3Me.OH$ [1 : 4], described by Mazzara (*Gazzetta*, **9**, 424; *Ber.*, **12**, 2367), is best prepared by pouring diazobenzene chloride into a strongly alkaline solution of paracresol. The mixture must be cooled down to 0° during the reaction. Phenylazoparacresol forms orange-coloured plates (m. p. 108°) soluble in benzene. The *acetic* derivative, $Ph.N_2.C_6H_3Me.OAc$, crystallises in yellow needles which melt at 67·5°, and are freely soluble in alcohol, ether, chloroform, and acetone. It is slowly saponified by alkaline carbonates. The *benzoic* derivative melts at 113°. It is soluble in ether, chloroform, hydrocarbons, and hot alcohol. It is slowly attacked by free alkalis, but not by carbonates.

Azobenzene-azoparacresol, $Ph.N_2.C_6H_4.N_2.C_6H_3Me.OH$, is prepared by adding sodium nitrite to an ice-cold solution of amidoazobenzene hydrochloride containing free hydrochloric acid. The mixture is poured into an alkaline solution of paracresol. After recrystallising the precipitate from glacial acetic acid, azobenzeneparacresol is obtained in brown needle-shaped crystals, which melt at 160°, and are insoluble in alkalis at the ordinary temperature.

Paratolylazoparacresol, $C_6H_4Me.N_2.C_6H_3Me.OH$ [$CH_3 : N_2 = 4 : 1$, and $OH : CH_3 = 1 : 4$], crystallises in plates which melt at 112°. It is soluble in ether, chloroform, hydrocarbons, and in hot alcohol. The acetic and benzoic derivatives crystallise in yellow needles which melt at 91° and 95° respectively.

Parasulphophenylazoparacresol, $C_6H_4(SO_3H).N_2.C_6H_3Me.OH$, crystallises in scales of yellowish-brown colour, which are decomposed by heat. The compound is soluble in water, but dissolves very sparingly in cold alcohol. The acid potassium, sodium, magnesium, and barium salts of this body crystallise in plates of a yellow or yellowish-brown colour. The magnesium and barium salts are almost insoluble in cold water. The acid and its salts dye wool and silk yellow. This acid is also formed by the action of fuming sulphuric acid (containing 60 to 65 per cent. SO_3) on phenylazoparacresol.

Phenylazoparacresolsulphonic acid, $Ph.N_2.C_6H_2(OH)Me(SO_3H)$ [6 : 1 : 4 : 2], formed by the action of paracresolsulphonic acid on an alkaline solution of diazobenzene chloride, crystallises in small plates, soluble in water. The acid sodium salt forms anhydrous plates of a reddish-brown colour. The acid solution dyes wool and silk orange.

As the paracresoldisulphonic acid prepared by Engelhardt and Latschinoff (*Zeitschr. f. Chem.*, 1869, 619) is converted into dinitroparacresol by dilute nitric acid, the two sulphonic groups must occupy the position [2 : 6]. This acid does not combine with diazo-compounds.

Metasulphoparatolylazoparacresol yields crystalline salts. The anhydrous acid sodium salt is freely soluble. The barium salt containing 4 mols. H_2O is sparingly soluble.

On reduction with stannous chloride, the azoparacresol-derivatives yield amidoparacresol, $C_6H_3(OH)Me.NH_2$ [1 : 4 : 2]; this melts at 135°, and sublimes without decomposition. It is soluble in alcohol, ether, and chloroform. Methenylamidoparacresol has been previously described by Hofmann and Miller (*Ber.*, **14**, 573). The ethenyl-derivative,  $C_6H_3Me\left\langle\begin{matrix}O\\N\end{matrix}\right\rangle CMe$, is a liquid boiling at 218°, and miscible with alcohol and ether. It also dissolves in acids forming salts which easily decompose, yielding acetylamidoparacresol (m. p. 160°).

Azo-compounds of Orthocresol.—*Phenylazorthocresol* forms glistening yellow plates melting at 130° and soluble in alcohol, ether, chloroform, and hydrocarbons, and also in caustic alkalis. It is formed, together with the *disazo*-compound $(PhN_2)_2C_6H_2Me.OH$, by the action of diazobenzene chloride on an alkaline solution of orthocresol. The two bodies are separated by treatment with alcohol. *Phenyldisazo-orthocresol* crystallises in reddish-brown plates, which melt at 115°, and are very sparingly soluble in cold alcohol. The acetic derivative melts at 121°. *Phenylazorthacetylcresol* forms yellow plates, melting at 82°, and freely soluble in alcohol, ether, and chloroform. The benzoic derivative melts at 110°.

Parasulphophenylazorthocresol crystallises in needles which are sparingly soluble in alcohol and cold water. The acid sodium salt crystallises in scales containing 2 mols. H_2O, and the acid barium salt in plates containing 3 mols. H_2O. On reduction with stannous chloride, amidorthocresol, $C_6H_3(OH)Me(NH_2)$ [1 : 2 : 4] is produced. This body melts at 175°, and is obtained by sublimation in needles soluble in alcohol and ether.

The hydrochloride is very soluble in alcohol and water. When diazobenzene chloride acts on an alkaline solution of metacresol, *phenylazometacresol* remains in solution, and the disazo-compound is precipitated. The azo-compound is deposited on acidifying the alkaline filtrate. Phenylazometacresol crystallises in yellow needles melting at 109° and soluble in alcohol. On reduction, it yields amidometacresol melting at 151°.

Sulphorthotolylazometacresol, $C_6H_3Me(SO_3H).N_2.C_6H_3Me.OH$, forms small reddish-brown crystals soluble in water. The acid sodium and barium salts are anhydrous. The former is freely, and the latter sparingly soluble in cold water. The azo-compounds of ortho- and metacresol dye silk and wool orange.

Phenyldisazometacresol $(PhN_2)_2C_6H_2Me.OH$, can also be prepared by pouring diazobenzene into an alkaline solution of metacresol. It is deposited from a hot alcoholic solution in plates which melt at 149°, and dissolve freely in ether, chloroform, and benzene. The acetic derivative melts at 157°.

Phenyldisazomethoxybenzene $(PhN_2)_2C_6H_3.OMe$ (m. p. 110°), and the corresponding acetoxy-derivative (m. p. 116°) and benzoyl-derivative (m. p. 139°), yield on reduction with zinc-dust and acetic acid, diamido-derivatives in which the amido-groups occupy the meta-position. This shows that in phenyldisazophenol $OH : N_2Ph \cdot N_2Ph_2 : = 1 : 2 : 4$.
W. C. W.

Molecular Changes of Hydrazo-compounds. By G. SCHULTZ (*Ber.*, 17, 463—478).—An alcoholic solution of acetylamidoazobenzene is converted into a hydrazo-compound by the action of ammonium sulphide. This substance forms crystalline plates (m. p. 146°) soluble in alcohol and ether. It is turned blue by strong hydrochloric acid, and is decomposed by stannous chloride into aniline and paraphenylenediamine.

When paradichlorazobenzene is treated with stannous chloride, it takes up 2 atoms of hydrogen, forming a diphenyl base, which crystallises in violet-coloured plates (m. p. 60°). The base gives a violet coloration with strong sulphuric acid, red with ferric chloride, and yellow with bleaching powder.

Metadichlorazobenzene is converted into dichlorodiamidodiphenyl (m. p. 163°) by stannous chloride.

Metadichloroxyazobenzene (m. p. 114°) is formed, together with a small quantity of metadichlorazobenzene, when metadichlorazoxybenzene is dissolved in strong sulphuric acid. It is deposited from alcohol in brown scales, which melt at 114°. Stannous chloride converts paradibromazobenzene into parabromaniline and dibromodiamidodiphenyl. The latter body crystallises in red scales (m. p. 108°), which dissolve in dilute acids and in absolute alcohol. By the action of nitrous acid on the alcoholic solution, the azoimido-compound, $C_{12}H_7N_3Br_2$ (m. p. 206°), is produced.

Benzene-azoparatoluene, $C_6H_4Me.N_2.Ph$, is prepared by adding an alcoholic solution of nitrous acid to an alcoholic solution of amidobenzeneazoparatoluene. The mixture is left at rest for 12 hours, and is then distilled with soda-lye. Benzeneazotoluene forms orange-red plates, which melt at 63° and dissolve freely in alcohol. It is decomposed by treatment with stannous chloride, yielding aniline, paratoluidine, a crystalline compound melting at 116°, volatile in steam, and a small quantity of a base which does not distil in a current of steam.

Orthazotoluene crystallises in monoclinic plates of a reddish-brown colour melting at 55°; it is soluble in alcohol and ether. Hydrazotoluene melts at 146°. The *tolidine* derived from it has been described by Petrieff. When the alcoholic solution of orthotolidine is treated with nitrous acid, a nitrogenous compound is deposited in needle-shaped crystals melting at 287°; the mother-liquor contains ditolyl- and diethyl ditolyl ether melting at 156°. Ditolyl yields isophthalic acid on oxidation, but by the cautious addition of chromic acid to an acetic acid solution of ditolyl, diphenyldicarboxylic acid melting at 193° may be obtained.

Orthotolueneazometatoluene, $C_6H_4\overset{2}{Me}.\overset{1}{N}:\overset{1}{N}.C_6H_4\overset{3}{Me}$, is prepared by the action of an alcoholic solution of nitrous acid on amidoazotoluene (from orthotoluidine) at 0°. When stannous chloride acts on it in alcoholic solution, *orthometatolidine* is formed. It yields crystalline salts. It is converted into ditolyl by an alcoholic solution of nitrous acid: the hydrocarbon boils at 270°, and is oxidised by chromic acid to isophthalic acid. An alcoholic solution of parazotoluene is slowly converted into tolidine at the ordinary temperature by the action of an acid solution of stannous chloride. The ditolyl obtained by treating an alcoholic solution of the tolidine with nitrous acid, crystallises in needles or plates, which melt at 91°. The crystals dissolve freely in ether and alcohol. On oxidation, the hydrocarbon yields an acid which melts at 273°, and is insoluble in water.

Orthazoethylbenzene is prepared by the action of zinc-dust on a solution of orthonitroethylbenzene in alcoholic potash. After the addition of the zinc-dust, the mixture is boiled for six hours in a flask provided with a reversed condenser, and is then filtered hot. The alcohol is removed from the filtrate by distillation, and the residue is poured into water. The aqueous mixture is extracted with ether, and the extract is shaken with dilute hydrochloric acid and then evaporated, when the azo-compound is obtained in dark-red quadratic needles or prisms, $a : c = 1 : 0·3455$. The crystals melt at 46·5°, and dissolve freely in hot alcohol.

The base which is produced by the reduction of azoethylbenzene with stannous chloride does not crystallise, but its acetic derivative, $NH\overline{Ac}.C_6H_3Et.C_6H_3Et.NH\overline{Ac}$, crystallises in needles which melt at 307°. It dissolves in acetic acid, but is very sparingly soluble in alcohol. When the alcoholic solution of the base is treated with nitrous acid, a small quantity of a liquid hydrocarbon is produced, together with diethylphenyldiethyl oxide, melting at 120°.

$$Et_2C_{12}H_6(OEt)_2,$$

Parazoethylbenzene is deposited from alcohol in orange-red plates or prisms, which melt at 63° and boil above 340°. On reduction with stannous chloride in presence of sulphuric acid, it yields paramidoethylbenzene and an unstable diphenyl base, $C_{16}H_{20}N_2$.

Azometaxylene could not be converted into a diphenyl base.

Azomesitylene prepared by oxidising an alkaline solution of mesidine hydrochloride with potassium ferricyanide, crystallises in thin needles melting at 75°, soluble in hot alcohol. Attempts to obtain a diphenyl base from this body failed.

No azo-compound could be obtained from amidoazonaphthalene or from nitroquinoline. W. C. W.

An Aromatic Diketone. By E. LOUISE (*Compt. rend.*, **98**, 151—153).—In a recent paper the author has already described the preparation of the ketone benzoylmesitylene by the action of benzoic chloride on mesitylene in presence of aluminium chloride. By dissolving benzoylmesitylene in benzoic chloride, and maintaining the liquid at 150°, while aluminium chloride is gradually added until the evolution of hydrochloric acid ceases (about 24 hours are required), a black mass is obtained; this, after treatment first with hot water and a little potassium hydroxide to remove unaltered benzoic chloride, is treated with a mixture of alcohol and ether, which leaves the carbonaceous matters undissolved. The filtered solution is set aside to crystallise, and the crystals are purified by distillation in a vacuum at 300°. The analysis corresponds with the formula $C_{23}H_{20}O_2$, or dibenzoylmesitylene, $C_6HMe_3(COPh)_2$. This body forms well defined, transparent, colourless crystals, soluble in alcohol, ether, light petroleum, &c., and melts at 117°. R. R.

Pure Benzoic Acid from Urine. By T. S. DYMOND (*Pharm. J. Trans.* [3], **14**, 463—464).—Benzoic acid, prepared from urine (hippuric acid), crystallises in plates, and has an unpleasant urine-like odour. By careful sublimation it can be deprived of this odour, and is obtained pure, crystallising in the same way as benzoic acid obtained from gum-benzoin. D. A. L.

A Nitrogenised Colloïd derived from Amidobenzoic Acid. By E. GRIMAUX (*Compt. rend.*, **98**, 231—234).—The white powder produced by the action of phosphorus pentachloride on amidobenzoic acid is dissolved in ammonia, filtered, and evaporated in a vacuum at ordinary temperatures. The amidobenzoic colloïd at first forms a thick jelly, which, by drying, is converted into transparent, yellowish, tasteless, indorous plates resembling the albumin of serum. It swells up in cold water and slowly dissolves, but is readily soluble in hot water. It may be heated to 100° without losing its solubility in water; but if the solution be evaporated to dryness on the water-bath, the residue, although retaining the same appearance, becomes altogether insoluble, and in this respect resembles albumin. It dissolves however in ammonia, in sodium phosphate, and in alkaline solutions. A 2 per cent. solution of the amidobenzoic colloïd behaves like the nitrogenised colloïds derived from living organisms; it is precipitated by acids, and is redissolved with difficulty by acetic acid; hot nitric acid dissolves it with a yellow coloration, changed to orange by alkalis. An excess of lime-water precipitates the solution, but if only one-twentieth of lime-water is added, the liquid remains clear, or becomes merely opalescent; it then becomes coagulable by heat, forming a stiff jelly. Dilute ammonium chloride solution, saturated solution of sodium chloride, a 1 per cent. solution of magnesium sulphate, and certain other saline solutions, have the same effect as lime-water; that is, when added to the cold solution in quantity insufficient to render it turbid, they confer upon it the property of coagulating by heat. At about 50° the liquid becomes opalescent, then milky, and the coagulum forms between 70° and 80°, the temperature varying with the proportion of salt that has been added. The effect of the latter, however, is much modified by various circumstances, as dilution, the presence of other salts, &c. If the quantity of the coagulating salt be insufficient to produce the effect even at the boiling point, yet by passing carbonic anhydride through the liquid either before or after the addition of the salt, the solution becomes coagulable by heat. This fact appears to have a relation with Mathieu and Urbain's experiments on the part played by carbonic anhydride in the coagulation of albumin (*Bull. Soc. Chim.*, **21**, 181; **22**, 484). The coagulum formed by the action of acid or of alkaline salts is soluble in ammonia; while that produced by salts of calcium, barium, or magnesium, is not. The phenomena of coagulation in the amidobenzoic colloïd being the same as those observed in the coagulation of albuminoïds, the latter, when separated from the organism, must be subject to physico-chemical laws only.

Bismuth Salicylate. By L. WOLFF (*Pharm. J. Trans.* [3], **14**, 508).—This substance may be obtained pure by either of the following methods:—By decomposing a glycerol solution of crystalline bismuthous nitrate with a concentrated solution of sodium salicylate, bismuthyl salicylate, sodium nitrate, nitric acid, salicylic acid, and water being produced; the latter products are removed by successive washing with water, hot water, and alcohol. Or by boiling bismuthyl nitrate, $BiONO_3,H_2O$, with a concentrated solution of sodium salicylate; the precipitate is well washed with hot water.

Bismuthyl salicylate, $BiOC_7H_5O_3$, forms slightly pinkish amorphous granules, insoluble in water, glycerol, alcohol, and ether; soluble, probably with decomposition, in acids. It burns rapidly on platinum foil. D. A. L.

Phenylisocrotonic Acid and Nitric Acid. Phenylnitroethylene. By H. ERDMANN (*Ber.*, **17**, 412—415).—*Phenylnitroethylene*, $CHPh:CH.NO_2$, is formed when phenylisocrotonic acid is slowly added to fuming nitric acid which has been cooled down below zero. An unstable acid is formed which is dissolved in dilute sodium hydroxide, and reprecipitated by hydrochloric acid. The acid is rapidly decomposed with evolution of carbonic anhydride. On distillation in a current of steam, yellow needle-shaped crystals of phenylnitroethylene melting at 58° are obtained. This compound is identical with that which Priebs (*Ber.*, **16**, 2591) prepared by the action of nitromethane on benzaldehyde. W. C. W.

Constitution of Phenylparaconic Acid. By H. ERDMANN (*Ber.*, **17**, 415—418).—On boiling ethylic phenylparaconate with dilute ammonia, it is converted into ethylic phenylitamalate. At 150°, phenylparaconic acid is decomposed into α-naphthol and phenylisocrotonic acid, but the ethylic salt boils above 360° without decomposition. The author regards these facts, first, as evidence in favour of the hypothesis that the carbonic anhydride which escapes when phenylparaconic acid is decomposed is derived from the carboxyl-group, and not from the lactone ring; and, secondly, as evidence in favour of the formulæ proposed by Fittig and Jayne for phenylparaconic acid :—

$CHPh(OH).CH(COOH).CH_2.COOH.$

Phenylitamalic acid.

$$COOH.CH<\begin{matrix}—CH_2—\\ CHPh.O\end{matrix}>CO.$$

Phenylparaconic acid.

W. C. W.

Oxalamido-acids. By H. SCHIFF (*Ber.*, **17**, 401—404).—When metamidobenzoic acid is dissolved in a warm mixture of absolute alcohol and ethyl oxalate, colourless crystals of *ethyl metabenzamoxalate*, $COOH.C_6H_4.NH.CO.COOEt$, are deposited. The crystals melt at 225° with decomposition, forming ethyl oxalate and *metoxalyldibenzamic acid*, $C_2O_2(NH.C_6H_4.COOH)_2$. An alcoholic solution of ethyl oxalate converts metamidobenzamide into *ethyl metamidobenzamoxalate*, $CONH_2.C_6H_4.NH.CO.COOEt$, a crystalline compound melting at 191·5°, soluble in alcohol. An excess of amidobenzamide converts the compound into the *diamide* of *metoxalyldibenzamic acid*, $C_2O(NH.C_6H_4.CONH_2)_2$, a white infusible and sparingly soluble powder.

Malonyldibenzamic acid, $C_3H_3O_2(NH.C_6H_4.COOH)_2$, and *ethyl metabenzammalonate*, $COOH.C_6H_4.NH.CO.CH_2.COOEt$, are formed when metamidobenzoic acid is boiled with ethyl malonate diluted with alcohol. The former is deposited from the boiling mixture in the form of a white powder, and the latter is deposited in silvery needles on evaporating the mother-liquor. These crystals melt at 172°, and decompose at the same temperature, forming malonyldibenzamic acid and ethyl malonate.

Ethyl oxalate slowly dissolves alanine with evolution of carbonic anhydride. The solution, in course of time, deposits crystals of ethylimidodiethyldioxamide, $NEt(CO.CO.NHEt)_2$. This compound melts between 135° and 138° with decomposition. The mother-liquor appears to contain several acids which have not yet been isolated.

W. C. W.

Action of Thiocarbimides on Amido-acids. By O. Aschan (*Ber.*, **17**, 420—431).—The author has obtained compounds isomeric with the phenylthiohydantoïn and hydantoic acid of P. Meyer (*Ber.*, **10**, 1965; and **14**, 1660), in which the sulphur-atom only is attached to a carbon-atom, and he proposes to distinguish these compounds as "*phenylsulphhydantoïn*," "*phenylsulphhydantoic acid*," &c.,

$$CS<^{-NPh-}_{NH.CH_2}>CO \quad NHPh.CS.NH.CH_2.COOH.$$

From the results of his experiments, the author concludes that aromatic thiocarbimides act on those amido-acids of the fatty series which contain the amine-group in the α-position, forming an homologous series of substituted sulphhydantoïns.

These bodies are decomposed by boiling with alcoholic potash. They take up a molecule of water, yielding sulphhydantoic acids, which are very unstable, losing a molecule of water at the ordinary temperature forming sulphhydantoïns.

Aromatic and non-aromatic thiocarbimides act on metamidobenzoic acid, forming sulphuramidobenzoic acids, which are stable compounds, *e.g.*:—

Metaphenylthiamidobenzoic acid, $NHPh.CS.NH.C_6H_4.COOH$,

Metaethylthiamidobenzoic acid, $NHEt.CS.NH.C_6H_4.COOH$, melting at 195°; and

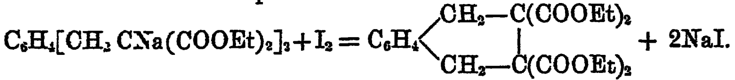
Metallylthiamidobenzoic acid, $C_3H_5.NH.CS.NH.C_6H_4.COOH$, melting at 189°.

W. C. W.

Synthesis of Naphthalene Derivatives. By A. Baeyer and W. H. Perkin, junr. (*Ber.*, **17**, 448—453).—The synthesis of tetrahydronaphthalenedicarboxylic acid (ββ) is accomplished by the action of orthoxylyl bromide on ethyl disodium acetylenetetracarboxylate.

For this purpose, the bromide (1 mol.) is dissolved in ether, 5 parts of alcohol are added, and the ether distilled off. Ethyl acetylenetetracarboxylate (1 mol.) dissolved in 5 parts of alcohol, and sodium (2 atoms) dissolved in 15 parts of alcohol, are added to the solution of the bromide, and the mixture is heated in sealed tubes at 130°. The product of the reaction is boiled with alcoholic potash, and after removing the alcohol by evaporation, the residue is dissolved in water, acidified, filtered, and the filtrate extracted with ether. The residue which is left on evaporating the ethereal extract is gradually heated to 185°, water and carbonic acid are given off, and the anhydride of tetrahydronaphthalenedicarboxylic acid remains as a crystalline mass, soluble in alcohol, ether, and chloroform. It melts at 184°, and sublimes at a higher temperature. The anhydride is changed into the acid by solution in hot water and in alkalis. Tetrahydronaphthalenedicarboxylic acid,  $C_6H_4\left\langle\begin{matrix}CH_2—CH.COOH\\ \quad\;\; |\\ CH_2—CH.COOH\end{matrix}\right.$, is freely soluble in warm ether, chloroform, alcohol, and acetone, and less readily in hot water. It melts at 199° passing into the anhydride. The silver salt, $C_{12}H_{10}Ag_2O_4$, is thrown down as an amorphous precipitate, which gradually becomes crystalline. It is decomposed by heat into naphthalene and tetrahydronaphthalenedicarboxylic anhydride. The anhydride also yields naphthalene when its vapour is passed through a red hot tube.

Ethylorthoxylyldichlorodimalonic acid, $C_6H_4[CH_2.CCl(COOEt)_2]_2$, is formed by the action of orthoxylyl bromide on an alcoholic solution of ethyl sodic chloromalonate at 100°. On reduction with zinc-dust and acetic acid, the chlorine is displaced by hydrogen, and *ethyl orthoxylydimalonate* is obtained. Ethylic tetrahydronaphthalenetetracarboxylate is produced by the action of an ethereal solution of iodine on the sodium-compound of this ethereal salt.



$$C_6H_4[CH_2.CNa(COOEt)_2]_2 + I_2 = C_6H_4\left\langle\begin{matrix}CH_2—C(COOEt)_2\\ \quad\;\; |\\ CH_2—C(COOEt)_2\end{matrix}\right. + 2NaI.$$

—On saponification, 2 mols. of carbonic anhydride are eliminated, and tetrahydronaphthalene-dicarboxylic acid melting at 199° is formed.
W. C. W.

Acridine Picrate. By R. Anschütz (*Ber.*, **17**, 438—439).—*Acridine picrate* is a canary-coloured crystalline salt which begins to melt at 208°. It is insoluble in cold water, and is partially decomposed by boiling water. It is very sparingly soluble in benzene and alcohol. Chrysaniline picrate is a brick-red powder, sparingly soluble in benzene.
W. C. W.

Preparation of Quassin. By Adrian and Moreaux (*Pharm. J. Trans.* [3], **14**, 507—508).—The method recommended for the extraction, &c., of quassin yields a purer and more abundant product than the methods introduced by Wurtz, Wigger, &c.

Thin shavings of the wood are extracted with boiling water, potassium carbonate being added, 5 grams for every kilo. of quassia; the liquor is then concentrated to a magma, and exhausted with hot 90 per cent. alcohol. After 24 hours, the solution is decanted and treated with sulphuric acid diluted with 10 times its weight of 90° alcohol. until a precipitate forms, which is filtered off. The filtrate is treated with lime, 4 to 5 grams for every kilo. of wood, and after some hours the solution is removed from the solid matter by filtration, pressure, and washing with alcohol. The alkaline liquors are neutralised with carbonic anhydride, filtered, the alcohol distilled off, and the residue dried. In this way, a kilo. of quassia yields 8 grams of a friable substance, which is amorphous quassin. Crystalline quassin may be obtained by stopping the distillation of the alcohol before all the alcohol has volatilised, filtering, and allowing the remaining spirit to evaporate slowly. The crystals may be purified by frequent recrystallisations and washing with 90° alcohol. The mother-liquors retain considerable quantities of both crystalline and amorphous quassin, which to a great extent can be regained by repeated agitation with chloroform. Crystalline quassin is white, light, soluble in chloroform, also in about 90 parts of cold absolute, or in 35 to 40 parts of 88° alcohol, scarcely soluble in ether; whilst 300 parts of hot water are required for its solution, from which it recrystallises on cooling. Amorphous quassin is nearly as bitter as the crystalline; it is readily soluble in absolute alcohol, and it is more soluble in ether and less so in water than the latter variety. D. A. L.

Vesicating Principle of Croton-oil. By H. SENIER (*Pharm. J. Trans.* [3], **14**, 446).—In this paper, the conditions which affect the solution of English pressed croton-oil in alcohol and the composition and properties of the soluble portion are discussed.

It is observed that when croton-oil is mixed with equal volumes, or less, of alcohol (sp. gr. 0·794 to 0·800), a perfect solution is formed, which is permanent at ordinary temperatures. When, however, alcohol is added in larger quantities—for example, 7 of alcohol to 6 of croton-oil, or in still larger proportions, then part of the oil separates, the amount which separates varying in different samples. The dissolved oil is now soluble, whilst the separated oil is insoluble, in all proportions of alcohol. The insoluble oil is described in the Abstract (p. 947). The soluble oil (sp. gr. 0·987) at 60° F. is brown and holds in suspension acicular crystals, which dissolve on warming. It has an acid reaction, the characteristic croton-oil odour, a persistent burning taste, and produces pustules when applied to the skin. It is soluble in water, alcohol of various strengths, benzene, chloroform, ether, petroleum, &c.

Experiments were now made to determine the components or component of the vesicating principle. Various distillation experiments proved it to be neither a free volatile substance nor a combined volatile alkaloïd or alcohol. By saponification with sodium carbonate, it was shown not to be a free fatty acid; whilst a subsequent saponification of the neutral oils with sodium hydroxide showed it to be present amongst the combined non-volatile fatty acids. Several methods of separating the various acids were tried without success, and finally the following were adopted for separating these acids into groups:—Firstly, refrigerating the glycerides; those of the vesicating oils have the lowest solidifying point. Secondly, by the solution of the lead salts in ether and alcohol; the vesicating oil salt being soluble in ether, but insoluble, or nearly so, in alcohol. Thirdly, by fractional saponification; the vesicating oils being the least readily saponified. Fourthly, by fractional decomposition of the sodium salts; the vesicating principle being amongst the first acids liberated. In other experiments, after the successive removal of (1) acids having ammonia salts insoluble in alcohol (palmitic acid), (2) those precipitated by magnesium acetate from alcoholic solutions, (3) those having barium salts insoluble in alcohol; the vesicating substance was detected in those having (4) barium salts soluble in alcohol.

These latter acids, when separated, are dark brown and remain liquid at 50° F. From the various properties indicated, viz., low melting point of acid and glyceride, difficult saponification, solubility of lead salt, &c., it is assumed as probable that the new acid is allied to oleic acid, and its analogues ricinoleic and linoleic acids. The fatty acids of the neutral soluble croton-oil contain about 15 per cent. of (1), 20 per cent. of (2), 40 per cent. of (3), and 25 per cent. of (4). The free fatty acid, palmitic acid, constitutes about 22·5 per cent. of the soluble croton-oil. D. A. L.

A Crystallisable Colouring-matter in Chlorophyll. By J. Borodin (*Bied. Centr.*, 1884, 40—42).—In view of the unsatisfactory results obtained by the macrochemical or optical mode of investigation, the author has employed microchemical methods of investigation; the process is very simple. The green plants, which are the subjects of experiment, are digested with a little alcohol in the dark for about 24 hours, a drop of the fluid is then brought under the microscope, when a mixture of crystalline forms of different colours is seen; the observation is more satisfactory when a polariscope is used. The deep-green crystals formerly described by the author are formed and are easily distinguished by their colour and absence of double refraction; the behaviour of the various crystals with reagents is distinctive. Dilute sulphuric acid causes a green coloration, which is destroyed by ammonia or by merely washing with water; the dilution of the acid can be so managed that some of the crystals are coloured and others remain unaltered, pointing to a mixture of different colouring-matters. The behaviour towards solvents is confirmatory of this; certain red crystals dissolve easily in benzene, and sparingly in alcohol. There are violet crystals, but these are probably identical with the red viewed through a thinner medium. The crystals which dissolve readily in alcohol and sparingly in benzene are very different; they are of a yellow or brown colour, and are quickly attacked and dissolved by glacial acetic acid yielding a clear yellow fluid. Amongst the mass in the original fluid are scale-like forms of a straw-colour.

The plants which were the subject of experiment were *Spirogyra* and *Betula verrucosa*. J. F.

Orantin and Carottin. By E. Schmitt (*Bied. Centr.*, 1884, 215).—These two compounds are the principal constituents of annatto. The first is obtained by digesting 50 grams annatto with 100 grams sodium carbonate and 1 litre water, and evaporating to one-half. Carottin is prepared by digesting 125 grams annatto in $\frac{1}{2}$ litre of oil. E. W. P.

Coal-tar Lutidine. By O. de Coninck (*Compt. rend.*, 98, 235).—Coal-tar contains a lutidine identical with that one of the lutidines in Dippel's oil, which Ladenburg has lately synthesised, which he regards as a γ-ethylpyridine, C_5H_4NEt. R. R.

Some Reactions of Albumin. By E. Grimaux (*Compt. rend.*, 98, 1336—1338).—When dilute solutions of albumin are mixed with small quantities of sodium chloride, calcium sulphate, magnesium sulphate, ammonium chloride, &c., they become coagulable by the action of heat. In the case of albumin, as in that of the amidobenzoic colloid (p. 905), dilution with water neutralises the coagulating influence of salts. A similar effect is produced by passing carbonic anhydride into the solution. Albumin, as is well known, is not modified by dilution in the cold, but if the liquid is boiled, modification takes place. The author finds that if a 1 per cent. solution of albumin is heated at 90° for some minutes, the albumin undergoes complete modification. The limpid solution is not coagulated by boiling, but simply becomes opalescent. When treated with carbonic anhydride in the cold, it yields a gelatinous precipitate, which redissolves when a current of air is passed into the liquid. The precipitate also redissolves if the liquid is placed in a vacuum over potash, or if the precipitate is collected, washed, and placed in aërated water. Dilute acetic acid produces a gelatinous precipitate, easily soluble in excess, reprecipitated on neutralising with an alkali, but soluble in an excess of the latter. The addition of sodium phosphate prevents precipitation by carbonic anhydride, but not by acetic acid, and the solution gives all the reactions for casein. The modified albumin becomes coagulable by heat when the solution is mixed with small quantities of sodium chloride, calcium sulphate, &c. Carbonic anhydride does not completely precipitate solutions of modified albumin. The filtrate contains a peptone, and if the solution of albumin has been boiled for some hours instead of being heated at 80°, the substance precipitated by carbonic anhydride diminishes, and the amount of soluble peptone increases. It would seem that dilution dissociates albumin into free soda and an albuminoid which becomes hydrated and converted into an albuminate. With carbonic anhydride, this albuminate forms an unstable insoluble compound, which loses carbonic anhydride when exposed to air or in a vacuum, and redissolves. This last reaction is common to many colloids.

All the above reactions are obtained with the amidobenzoic colloïd.

C. H. B.

Metahæmoglobin. By J. G. Otto (*Bied. Centr.*, 1884, 212).—Metahæmoglobin contains as much oxygen as oxyhæmoglobin, only it is more firmly combined. The conversion of oxy- into meta-hæmoglobin is a change from a loose molecular into a chemical combination.

E. W. P.

Physiological Chemistry.

Respiration in a Superoxygenated Atmosphere. By L. de St. Martin (*Compt. rend.*, 98, 241—243).—The paper describes experiments on the products of the respiration of animals in a superoxygenated atmosphere; the result being that the chemical phenomena are found to undergo no sensible change. R. R.

Experiments on Digestion. By M. Ogata and others (*Bied. Centr.*, 1884, 18—20).—The author reports experiments on digestion when the inner coating of the stomach had been removed, and he finds that the glands of the large intestine are capable of carrying on the process of digestion of flesh, raw and cooked eggs, and other albuminous foods, which, when divided into small portions, are easily decomposed by the secretions. Edinger concludes from his investigations that acid reaction does not take place in the intestine, but on the surface of the stomach. Falk has investigated the action of the digestive fluids on ferments. Yeast is not injured in its action by trypsin or decomposing infusion of pancreas, but it is by bile, which precipitates the invertin, at least after standing some hours. The influence of saliva and gastric juice could not be determined, as both secretions invert cane-sugar. Alcoholic fermentation is not hindered by saliva, pancreatic fluid, or bile; gastric juice and hydrochloric acid of equal concentration prevent it; bacteria destroy yeast in a short time. Zawarykin contributes to the knowledge of absorption of fat in the intestines of animals. He has observed that the lymph cells take up the fatty particles by a sort of amœboïd movement, raising and lowering themselves in alternate regular motions; the fat is then directly absorbed into the venous blood. Voigt has made extensive experiments on the functions of the bile in taking up nourishment from the intestinal canal. He says that in the digestion and absorption of albumin in the form of flesh, the bile does not play an important part. Glucose or bread, when eaten with meat, does not affect the absorption. On the contrary, bile plays a most important part in the absorption of fat. The antiseptic properties of bile have not been proved, and the food taken does not appear to influence the composition of the bile; but the dry matter contained in it depends greatly on the amount of nourishment taken.

J. F.

Formation of Fibrin. By J. Hlava (*Bied. Centr.*, 1884, 212).—Fibrin is formed by the death of the white blood-corpuscles, and is at first granular, afterwards more consolidated; the fibrin ferment does not exist in the protoplasm of the corpuscles. E. W. P.

Formation of Fat from Carbohydrates in Animals. By N. Tschirwinsky and others (*Bied. Centr.*, 1884, 9—16).—The subjects of experiment were two young pigs from the same litter, similar liveweight, and brought up under the same conditions. At the commencement of the experiment, one of the animals was slaughtered, and the quantity of substances found taken to represent the composition of the living animal: two series of experiments were made under these conditions. The one pig was killed and analysed on 10th December, the other was fed on barley until 10th April following; the food contained altogether 9526·59 grams nitrogenous matter, and 1114·43 grams of fat: three estimations were made during that time of the amount actually digested, and it was reckoned that the quantity was 7493·87 grams nitrogenous matter, and 655·56 grams fat. The animal was then killed, and immediately examined.

The body was found to contain—

	Nitrogenous compounds.	Fat.
	2516·92 grams	9264·18
From which deduct, found in animal killed at commencement of experiment......	957·47 „	687·58
Leaving............	1559·45 „	8576·60

as deposited from 10th December to 10th April: assuming that the fat contained in the food and digested was directly assimilated, there remains to be accounted for 7921 grams of newly formed fat. The albuminous matter present was not sufficient to form this quantity; if from the total amount digested the amount formed, 1559·45 grams, be subtracted, the remainder, 5935 grams, would only produce at the rate of 51·4 per cent. a maximum of 3051 grams of fat, leaving a considerable balance to be accounted for.

A second experiment carried out in a similar manner gave similar results. The nitrogenous matter and fat digested were far from sufficient to account for the amount of fat found in the carcase. Both experiments show that the carbohydrates take part in the formation of fat.

The experiments of Meissl and Strohmer were also made on swine, but a different course was taken, the total amount of nitrogenous matter and fat in the food given being estimated, also the amounts excreted in the excrement, urine, and respiration products. The animal was kept in a peculiarly constructed moveable stall arranged so that the excrement and urine were separately collected: in close proximity was a respiration apparatus on Pettenkofer's system. The experiment lasted for seven days; barley meal and rice were employed as fodder; the result *per day* in grams is given—

Carbon.			Nitrogen.		
Consumed. grams.	Excreted. grams.	Assimilated. grams.	Consumed. grams.	Excreted. grams.	Assimilated. grams.
756·37	476·15	289·22	18·67	12·59	6·08

The calculations of the authors show the fat to be derived from three sources: from the food, 7·9 grams; from nitrogenous matter in the body, 33·6 grams; from carbohydrates, 310·3 grams per day, and their opinion is that generally seven to eight times as much fat is derived from the carbohydrates as from all other sources.

J. F.

Proportion of Incompletely Oxidised Phosphorus contained in the Urine. By R. LEPINE, EYMONNET, and AUBERT (*Compt. rend.*, 98, 238—241).—In the urine of patients suffering from apoplexy, epilepsy, delirium tremens, fatty degeneration of the liver, and certain other diseases, the authors have found a greatly increased proportion (as compared with the nitrogen) of incompletely oxidised phosphorus, that is, not in the state of phosphates. R. R.

Physiology of the Formation of Milk. By H. THIERFELDER (*Bied. Centr.*, 1884, 174).—From experiments which he has made, the author believes that lactose is produced in the animal from blood serum through the medium of a ferment which he terms *saccharogen*, but he has not isolated this substance, yet considers it to be soluble in water, insoluble in alcohol and ether, decomposed by boiling, and not identical with glycogen. Caseïn is most probably formed from serum-albumin by an analogous ferment present in the lactic glands.

E. W. P.

Diseases of Animals. By ROLOFF and others (*Bied. Centr.*, 1884, 29—32).—Inoculation against splenic fever with Pasteur's protective lymph is declared to be safe, but a sufficient quantity must be used and certain precautions taken. The increase of the bacterium of this fever is known to take place by division, but sometimes by spores, and both processes are carried on in the organism during the state of fever. The blood of animals in the disease does not contain bacilli until a short time before death, at least 10 hours, and the blood before they appear does not convey the disease if injected into a sound animal.

The author thinks that the bodies of animals even in a healthy state contain the bacteria of splenic fever, but in a third state, dormant, and seeks to identify them with the shining corpuscles of Archangelski, which he thinks are spores.

Gibier contributes notes on the subject of hydrophobia: the disease appears the sooner after the bite the nearer that is to the brain; particles of brain substance convey the disease by inoculation. The disease is also hereditary; rabbits in young inoculated two days before parturition gave it to their young who died of it, and matter from their brains communicated the disease to others. Cold diminishes the effect of the poison; at − 25° it commences to diminish; at − 35° the action is doubtful; at −40° it ceases. In the brain and spinal marrow of animals which have died of the disease, Gibier found small spherical organisms, two of them sometimes united by a long hair-like thread, and others single, bearing a short hair-like appendage, probably a portion of the line which had previously united two of them.

Israël and Wassilieff have made some experiments with the bacilli of glanders. The former cultivated two kinds of fungi from the lungs of a horse dead of the disease; one was active and communicated the disease to rabbits, the other inactive. Wassilieff found in the blood of a postillion who died of glanders, thread-like bacteria similar in size to those of tuberculosis, and containing two to four spores: he also found them in the nasal discharges and the pustules.

J. F.

Irritant Properties of Oats. By SANSON (*Bied. Centr.*, 1884, 20—21).—Experiments made at the agricultural school of Grignon show that oats contain a matter easily soluble in alcohol, which has an irritant action on the motor cells of the nervous system. It is not vanillin, but a nitrogenous substance apparently of an alkaloïdal character, uncrystallisable, granular, and of a brown colour. Its composition is given as $C_{56}H_{21}NO_{18}$, and is called by the author *avenin.* The quantity present varies according to the quality of the grain and soil on which it is grown. The darker varieties contain more than the lighter coloured. When the quantity in air-dried grain does not exceed 0·9 per cent., the irritating action is slight, but beyond that amount it becomes strong. The bruising and milling of oats diminishes the quantity of substance materially, but it is quicker in its action. After the administration of 1 kilo. of oats, the irritation of the motor nerves lasts an hour, gradually increasing to a maximum and diminishing. The importance of the subject to owners of horses lies in the advantage of feeding with grain in the natural state. J. F.

Poisonous Matter of Lupines. By ARNOLD and SCHNEIDEMÜHLE (*Bied. Centr.*, 1884, 32—34).—The preparation of the extract is described—2 to 5 grams are sufficient to kill a dog—the poisonous properties are increased by the presence of alkalis in the solution, diminished by that of acids; the organ first attacked is the liver. The blood vessels appear to convey the poison, as fatal effects rapidly follow hypodermic injection or injection into a blood vessel: the fatal effects of eating lupines are probably caused by wounds in the alimentary or digestive organs. Allowing the poison direct access to the blood, after repeated doses gradually increased, animals gain a certain amount of immunity, and can withstand large quantities. As a cure, acid drinks, plenty of clean cold water, and purges of Epsom salts are recommended. J. F.

Behaviour of "Folia Uvæ Ursi" and Arbutin in the Animal Organism. By L. LEWIN (*Pharm. J.* [3], **14**, 490).—From recent investigations it is shown that the therapeutic value of *Uva ursi* (bear-berry) leaves is due to the quinol (arbutin) they contain; the tannin simply exerting a very slight auxiliary action. From experiments with arbutin, it is observed to split up in the body, in the same way as it does outside it, namely, into sugar and quinol; the whole quantity taken into the system, however, is not decomposed, therefore quinol and also some unchanged arbutin are found in the urine, which on even brief exposure to the air undergoes change of colour, becoming olive-green or brownish, at the same time gradually losing its acidity, until it finally becomes alkaline. These changes are due to oxidation; when the urine becomes alkaline in the bladder, these changes take place inside, and the urine is voided of an olive-green colour. Exactly similar changes take place in human urine after treatment with *Uva ursi* leaves, and hence arises the fact stated above with regard to these leaves. Quinol acts as an antizymotic and antiseptic even in a 1 per cent. solution; urine containing it remains undecomposed for two weeks even when exposed to the air; other urine not containing it undergoes speedy decomposition. Moreover, the dark oxidation-products of quinol act as irritants, and these are beneficial in catarrhal affections of the mucous membrane, making them turgid, and starting reparative action. It is these properties of quinol which make it, and also the *Uva ursi* leaves, of therapeutic value. In conclusion, the author suggests that larger doses than are now given should be administered when *Uva ursi* leaves are used; employing from 30 to 80 grams in 180 of menstruum, removing tannin by agitation with charcoal and filtration.

Or a still greater improvement would be to use arbutin instead of the leaves, making powders with 1·0 gram arbutin and 0·5 gram sugar, or dissolving in water. It may be given hypodermically. Clinical experiments show that arbutin is a valuable therapeutic agent; it is not poisonous and in splitting up does not set free in the body sufficient quinol to exert poisonous action. Arbutin is lævorotatory. D. A. L.

Chemistry of Vegetable Physiology and Agriculture.

Effects of Light on the Respiration of Oxygen by Plants. By J. Reinke (*Bied. Centr.*, 1884, 37—39).—This paper is an examination of Pringsheim's theory (Abstr., 1880, 560), and the author's experiments were limited to the observation of the amount of gas exhaled during varying amounts of sunshine: the evolution of gas begins when the light is fairly strong, and increases as the light becomes more intense, until the maximum is reached. This corresponds with the moment of direct sunlight; further intensification of light prolongs the evolution of gas, but does not increase its rapidity; and when the rays are concentrated by a lens, the process proceeds in this way until the chlorophyll is destroyed. J. F.

Influence of Constant Temperatures in the Soil on Plants. By Hellriegel (*Bied. Centr.*, 1884, 179—190).—The plants were grown in artificial soil composed of sand, to which were added 136·1 mgrms. potassium hydrogen phosphate, 149·2 mgrms. potassium chloride, 24 mgrms. magnesium sulphate, 410 mgrms. calcium nitrate, and 1·6 mgrms. ferric chloride, and placed in glass vessels 26 cm. high and 8 cm. broad, and it was so arranged that the mixture could be kept at a definite temperature, and have always 150 grams water per kilo. sand. It was found that when the temperature remained at 40°, that barley plant roots did not develop themselves; that a temperature of 30° was not fatal to barley, but still the plant did not thrive; that at 20° the results were best; and at 10° certain abnormal results, such as very strong roots of the first and second order, the latter being very short and warty, were observed, but yet no definite damage could be noticed. When other plants were experimented with, such as rye and wheat, it was noticed that a low temperature produced stronger stems and leaves, whilst a high temperature, as it caused the growth to be rapid, produced stems and leaves thinner and weaker. Wheat, for its energetic growth, required a higher temperature than rye; and the assimilation during the young life of rye was most energetic at 20°, barley at 25°, and wheat at 30°. It is also shown that to produce strong growth with fully formed seeds, the period of maximum intensity of light and heat must coincide with that of the maximum period of leaf formation; consequently it should be so arranged that the time of seeding should occur about the end of July. E. W. P.

Influence of Solar Rays on the Temperature of Trees. By E. Ihne (*Bied. Centr.*, 1884, 63).—The author inserted thermometers at different depths into the trunk of a maple tree, also in a branch and twig. He found that in a fine clear day the variations of temperature were not large, the exterior layers were higher than the interior, and the sections of larger diameter were the warmer; but on the whole the variations were slight, and thé temperature at all times of observation a considerable number of dégrees above that of the surrounding atmosphère. J. F.

Formation of Starch-transforming Ferments in the Cells of Highly Organised Plants. By W. Detmer (*Bied. Centr.*, 1884, 69—70).—The experiments recorded were intended to ascertain the influence of atmospheric oxygen on the formation of these ferments.

Seeds and seedlings of *Triticum vulgare* were the subjects of experiment; portions of both were grown in ordinary air, part in an atmosphere of hydrogen. They were then pounded and extracted with water; the solutions obtained from the air-grown plants and grains showed a very much more powerful diastatic effect than those grown in hydrogen, the conclusion arrived at being that the presence of oxygen is a necessary condition of the development of the ferment. J. F.

Lime and Magnesia in Plants. By E. v. Raumer (*Bied. Centr*, 1884, 46—48).—Observations on plants of *Phaseolus multiflorus* show that the functions of lime are connected with the building up of the tissues and the formation of the cell-walls, but is not concerned in the formation or transformation of starch. The office of magnesia, on the contrary, is to assist in the starch-forming process, and the development of chlorophyll. Magnesia is always present in the latter, and its presence is necessary to healthy growth and colour. J. F.

Experiments with Drosera Rotundifolia. By H. Büsgen (*Bied. Centr.*, 1884, 47—49).—The author mentions previous experiments intended to answer the question whether the capture of insects by these and similar plants assists their development. Kellermann, v. Raumer, Rees, and F. Darwin are for the affirmative, but Regel denies that there is any useful effect. The author thinks the difference of opinion is due to the various experiments being made under different conditions, and with plants possibly in different stages of development. To carry out comparative experiments in a trustworthy way, the comparison should commence with the weighing of the seeds and finish with the estimation of the total dry matter of the plant. The seeds of drosera are so extremely minute that they may be left out of account, and the author commenced with the seedlings—they were grown in peats, previously boiled in a nutritive solution; these were placed on saucers and covered with bell glasses; one set were fed with the lice from vine leaves, the other received no such nourishment. The unfed plants were less strong and healthy than the other; the fed plants had 17 flower branches on 14 plants against 9 buds on 16 unfed; 90 seed capsules on 14 plants, against 20 on the 16; the last doubt was cleared up when the total dry weight was taken, the fed plants weighing 0·352, the unfed only 0·119 grams; other trials under less favourable conditions gave similar results, and the author considers it as proved that the plants of drosera are capable of utilising animal food and assimilating it beneficially for the production of seeds. J. F.

Withering of Flowers and Leaves. By J. WIESNER (*Bied. Centr.*, 1884, 43—44).—In most plants, the leaves transpire moisture in larger quantities than the flowers; and, as a rule, cut flowers wither more slowly than leaf twigs. If the transpiration of the leaves is arrested, the flower will remain a long time fresh as when severed, so that it would seem the flowers are deprived of moisture by the leaves. In like manner growing plants, when insufficiently supplied with moisture, either bloom slowly or not all. This action of the leaves explains why in cut twigs the terminal sprout withers even when plunged under water, and why this terminal leaf-bud lasts longer on twigs deprived of their leaves than when they are left on. J. F.

Easily Oxidisable Substances in Plant Sap. By C. KRAUS (*Bied. Centr.*, 1884, 45—46).—The author describes experiments made on the sap contained in the tubers of *Dahlia variabilis*, which he cut into slices. The surfaces gradually became yellow, and with longer time penetrated below the surface; the bulbs swelled, turning green in the light, and pale green chlorophyll bodies appeared. The yellow tinged cells contained a yellow or reddish sap: the surfaces of the slices were not only yellow but showed red points and streaks, whilst in the interior of the cells there was a red colouring matter turned green by alkalis. The author thinks the change of colour is due to oxidation. J. F.

Notes on the Bean of Soja Hispida. By E. MEISSL and F. BÖCKER (*Bied. Centr.*, 1884, 52—53).—The soja bean contains no proteïd matter in the form of gluten, and very little in the form of amides; the albumin, soluble in water or 10 per cent. potash solution, resembles the legumin of leguminous fruits in its behaviour towards reagents, and is put down as caseïn by the author, or possibly a modification thereof; its ash-free composition is C 52·58, H 7·00, N 17·27 per cent. The matter soluble in ether consists of 90 per cent. neutral fat, and 5—10 chlolesterin and other similar substances. In the remaining non-nitrogenous matter, besides cellulose, is found some sugar equal to 10 per cent. dextrin, and less than 5 per cent. starch, in the form of small spherical grains; in round numbers the composition of the bean is: Water 10, soluble caseïn 30, albumin 0·5, insoluble caseïn 7, fat 18, cholesterin, &c., 2, dextrin 10, starch 5, cellulose 5, ash 5, traces of sugar and amido-compound. J. F.

Natural and Renewed Succirubra Bark. By J. Hodgkin (*Pharm. J. Trans.* [3], **14**, 481).—The author publishes the results of the analysis of samples from the same consignment of bark; of quills of entirely natural bark (1), entirely renewed bark (2), and also of quills of natural and renewed bark in juxtaposition; the upper half being renewed bark (3), and lower natural (4). Bark (2) contained largest amount of total alkaloids and quinine, the others being in the following order: (3), (1), and (4). (3) and (4) contained much moisture, 15·96 and 14·61 per cent. respectively. The natural bark (4) seems to have suffered in renewal, which is probably due to injury to the tree caused by the shaving process, which it is suggested was evidently employed in this case. D. A. L.

Seeds of Bassia Longifolia and the Fat contained therein. By E. Valenta (*Dingl. polyt. J.*, **251**, 461—465).—The seeds of this tree are 1 to 2 cm. long, and enclosed in a brown skin. They have a peculiar odour and bitter aromatic taste. 100 parts of the seeds dried at 100° gave—

Fat (light petroleum extract)	51·14
Soluble in absolute alcohol	7·83
Tannin	2·12
Bitter principle soluble in water	0·60
Starch	0·07
Vegetable mucilage	1·65
Albuminous substances soluble in water	3·60
Extractive substances soluble in water	15·59
Insoluble proteïds	4·40
Total ash	2·71
Fibre and loss	10·29

Ash in the soluble portion	0·95 per cent.
Total proteïds	8·00 „

For the extraction of the fat, light petroleum boiling at 40—45° was used. The fat has a yellow colour and greasy consistency; but on exposure to the air and light the colour disappears, and the fat soon becomes rancid. It has a sp. gr. of 0·9175 at 15°, melts at 25·3°, solidifies at 17·5—18·5°. It contains considerable quantities of free fatty acids, but only a small amount of glycerol. 1 gram of the fat requires 192·3 mgrms. KHO for the complete saponification of the fatty acids.' It is partly soluble in alcohol, and perfectly soluble in ether, carbon bisulphide, benzene, &c. The fatty acids obtained by saponifying the fat with potash-ley, and decomposing the resulting soap by means of a 10 per cent. solution of hydrochloric acid, have a white colour, and pleasant odour and taste. They melt at 39·5°, solidify at 38°, and dissolve readily in alcohol.

According to Schädler, Makwah butter consists of 80 per cent.

stearin and 20 per cent. oleïn; the author, however, found that it contained palmitin and oleïn.

The ash of the seeds is yellowish-white and dissolves almost completely in water. It gives by analysis—

Silicic acid and portion insoluble in nitric acid	10·67
Phosphoric acid..................................	15·47
Sulphuric „	6·81
Carbonic anhydride	7·46
Ferric oxide and alumina........................	2·01
Lime	0·64
Potash and soda (the latter is present only in traces)	56·68
Moisture and loss	0·26

D. B.

Suggestions for the Destruction of Phylloxera. By BALBIANI and others (*Bied. Centr.*, 1884, 49—52).—The treatment of vine stems by coal-tar in order to destroy the winter eggs is not found either to injure the growth or impart a disagreeable flavour to the grapes. Lafitte gives statistics which show that the replanting of the injured vineyards is being chiefly carried on with French rather than American vines. Mouillefert gives instructions for the employment of potassium thiocarbonate as an insecticide. He recommends 1 part of the salt to 333 or up to 400 of water; this solution is very effective and destroys the eggs. He says, moreover, that it is the degree of dilution which is of importance in using this substance: as much as a kilogram may be applied to a vine, provided the solution is not stronger than he advises; while 50 grams in concentrated solution would infallibly kill the strongest vine. He recommends plentiful use of pure water after the insecticide has penetrated the soil, and that in the South of France the treatment should be carried out twice in winter from November to April, and again in June or July. Servantie also commends the use of the thiocarbonate as a most useful agent, capable of being used without danger at all seasons of the year, but it must be a pure compound, containing more than 12 per cent. carbon bisulphide, and more than 18 per cent. potash. Contradictory opinions as to the value of pyridine are given, but its high price is against its use. Other experiments, the injection of fluids into the vine-sap are mentioned, but the results are uncertain.

J. F.

American Red Clover. By HARTZ and others (*Bied. Centr.*, 1884, 53—54).—During seasons when native red clover-seed is scarce, the use of American seed is advised, provided it is from Canada, the climate of which resembles that of Steiermark and Tyrol, and seeds produced there should be easily acclimatised. The price of American seed being lower than that of European, experiments were made as to the produce of both, in which the quantity and quality of hay produced was considerably in favour of the higher-priced European. The two kinds are distinguished by the American plant being covered with protruding hairs, whilst on the other the hairs lie flat on the leaves.

J. F.

Cultivation of Sorghum Halepense. By V. BARATTA (*Bied. Centr.*, 1884, 56—57).—Reports of unsuccessful attempts to cultivate this plant in different parts of Austria. In only one case out of four were seeds produced, and an experimenter complains that the very large spreading roots rendered the after culture very difficult. J. F.

Diffusion Residues as Cattle Food. By M. MÄRCKER (*Bied. Centr.*, 1884, 21—28).—The author continues his investigations on the value of these residues (see Abstr., 1883, 695). He has previously shown that the usual mode of storage causes a loss of one-third of the substance, and recommends drying before storing. The present paper is a record of a number of feeding experiments on milch cows, oxen, horses, sheep, and swine. The cows, oxen, and sheep eat it readily, with excellent results. Horses refuse it; swine take to it badly and waste it. The dried substance keeps as well, and is as little hygroscopic as other dry fodders. It can be used as a substitute for a certain quantity of hay, and the milk of cows is not affected injuriously, but the process of fattening is somewhat slower than when animals are fed on hay. J. F.

Sugar-beet Culture and Manuring. By NOWOCZEK (*Bied. Centr.*, 1884, 34—37).—This a report of extensive trials of various kinds of sugar-beet. Certain varieties are recommended: the chief point of interest is the beneficial effect of artificial manures on the yield of sugar in the juice. J. F.

Cultivation of Winter Flax. By A. LEYDHECKER (*Bied. Centr.*, 1884, 55—56).—The author tried the culture of this plant in Northern Bohemia, where the summer variety had hitherto been alone cultivated with good results, and found the loss in steeping, hackling, and other processes but little more than with the early species. He recommends its cultivation. J. F.

Analysis of Soils. By G. LECHARTIER (*Compt. rend.*, **98**, 1339—1342).—When a soil is boiled with a solution of ammonium oxalate containing an excess of ammonia, some of the organic matter and a certain proportion of the inorganic constituents, *i.e.*, phosphoric acid, ferric oxide, alumina, &c., pass into solution. Ammonium citrate exerts the same solvent power, but dissolves some of the calcium existing as carbonate; whereas the ammonium oxalate dissolves only the calcium in combination with the organic matter. The tartrate has less solvent power, except in the case of calcium. Ammonium chloride dissolves a part of the humous substances and some of the inorganic constituents, but has little action on the phosphates. It may be used, however, to dissolve out the calcium existing naturally as carbonate, and that added in manures. The solvent action of these substances varies with the strength of the solution, the presence or absence of an excess of ammonia, and the length of time the liquid is kept in ebullition. If the organic matter is destroyed by roasting the soil at a low temperature, the proportion of phosphoric acid and potassium which dissolve in ammonium oxalate, is not altered, but the proportion of ferric oxide and silica, which becomes insoluble, is much higher than that existing in the decomposed organic matter.

In actual analysis, 20 grams of the dried soil are placed in a flask with 250 c.c. of a solution containing 10 grams of ammonium oxalate and an excess of ammonia; the flask is connected with an inverted condenser, and the liquid boiled for several hours. It is then filtered, evaporated to dryness, the solid matter ignited, the residue treated with hydrochloric acid, and the various substances estimated in the solution. C. H. B.

Influence of a Crop and Shelter on the Physical Properties of a Soil. By E. WOLLNY (*Bied. Centr.*, 1884, 152—160).—Various soils, peat, quartz, loam and chalky sand, were experimented on as regards their temperature when left exposed, covered by straw, or by grass. It was found that during the warm season the bare soil was much warmer than the sheltered, and the soil sheltered by manure (straw) warmer than that covered by grass. At the hour of the daily maximum of the terrestrial temperature, the difference between the temperatures of the shaded and exposed soil is greatest, whilst at the minimum temperature the exposed is generally cooler than the sheltered soil. The daily variations are greater in the exposed than in the sheltered soil, and less in the grass-grown than straw-covered soil. The influence of the coverings on the temperature is so great that it almost completely negatives the specific relations of the several soils themselves towards radiant heat. When soil is covered by vegetation or by dead vegetable matter, as stubble or manure, it is considerably warmer in summer at some distance below the surface, and colder in winter than a fallow; but should a warm period in winter or a cold in summer intervene, then the influence of the covering makes itself felt in the opposite direction. Experiments with quartz sand show that the bare soil is more rapidly warmed by the sun than the covered soil; consequently, in spring it is more quickly heated, and in autumn more rapidly cooled. When land is covered by a crop, the crop exerts a very decided influence on its temperature, dependent on the thickness of sowing, the age of the crop and its character, but when the conditions are similar, then the effects on the temperature are similar; but whether the plant itself has influence is uncertain But when we come to the method of planting, a difference is found, for the thicker the sowing and the stronger the plant, so is the temperature during the warm season lower and the variations less. Soils warm more rapidly when the crop is sown by a drill than when broadcast; an advantage is gained also, when the drills are wider apart and run north and south. With perennials, the temperature rises after mowing. It appears that there is a considerable loss of heat by radiation from a field of, say clover, for below the surface of the crop the temperature is lower than the surface of a fallow. This reduction is due to radiation from the plants themselves, but its effects are considerably counteracted by the absence of radiation from the soil. E. W. P.

Thermal Conductivity of Soils. By F. WAGNER (*Bied. Centr.*, 1884, 145—152).—The research on the thermal conductivity of the soil constituents was commenced, because it was thought that E. Pott's results (*Landw. Versuchs.-Stat.*, 1877, 273) were incorrect, as he did not use pure materials. The apparatus which the author has employed consists of an india-rubber cylinder 32·5 cm. × 10 cm., the heat being communicated by a copper cylinder 12 cm. × 12 cm. placed at right angles to it. Into the india-rubber tube are inserted six thermometers at a distance of 6 cm. from each other, the first being 1 cm. from the commencement of the tube. With dry soils a heat of 70° over the original temperature was employed, but with moist soils a temperature of 35° only. The soils experimented on were washed quartz powder, pure kaolin, precipitated chalk, ferric hydroxide, a peat purified by hydrochloric acid, alcohol, and ether (this contained 8·05 per cent. ash and 3·54 volume per cent. moisture); also humus produced from sugar by the action of sulphuric acid, containing 0·79 per cent. ash and 1·54 per cent. moisture. When the materials lay closely together, the order, as determined by their relative conductivities, was as follows: peat, sugar-humus, kaolin, chalk, ferric hydroxide, and quartz, the mean difference between the thermometers being in the first soil 4·56, in the last 5·66. But when those soils were loosely packed in, the order is altered; chalk, kaolin, ferric hydroxide, sugar-humus, peat, and quartz; thermometric differences, chalk 4·34°, quartz 5·11°. It would be impossible to give a full account of the other experiments which were made with natural soils without introducing various tables of figures, but the chief results may be summed up as follows: the conductivity of any one soil is increased by the closeness of its particles, and it is also raised by increasing quantities of moisture. As a rule, the conductivity in a dry soil increases with the increased size of its particles; finally, the presence of water generally in a soil assists the transmission of heat. E. W. P.

Morphology and Chemistry of Natural and Artificial Ulmin. By J. J. FRÜH (*Bied. Centr.*, 1884, 3—9).—Microscopic preparations of different kinds of turf show two regularly-recurring typical forms, which are similar in colour and transparency, a pale rusty running to a clear yellow, something like softened gutta-percha. One is granular, consists of well-formed spherical and oval grains, mixing readily with water, and easily soluble in 5 per cent. potash solution; the second is the homogeneous form, which the author believes to be derived from the first. It exists in homogeneous plates or layers, and contains various vegetable cells. He thinks this the highest form of ulmin in peat. He then describes the process by which Sestini obtained saculmic acid and saculmin (Abstr., 1880, 865, and 1882, 605), and thinks the natural and artificial products are identical. He traces the similar behaviour of both with reagents, especially towards the 5 per cent. potash solution, in which the granular forms of both contract, and assume the homogeneous form. The author thinks it probable that there are two groups, ulmin and humin, distinguishable from each other with great difficulty. Dopplerite is a modification of ulmin combinations (Abstr., 1883, 160, 427), the formation of dopplerite is described, so-called stone-turf being the intermediate form; the presence of much water and little air are favourable to its production. Dopplerite is not to be confounded with the pitch and shining coal found and described by Zincken. J. F.

Comparative Nitrifying Effect of Various Salts. By PICHARD (*Compt. rend.*, 98, 1289—1290).—In barren soils consisting almost entirely of sand, the nitrogen of organic matter is not converted into nitrates unless a small quantity of nitrifying earth be added. Potassium, sodium, and calcium sulphates, in the proportion of 0·5 per cent., exert an energetic nitrifying action, the effect being especially marked in the case of the calcium sulphate, probably on account of its comparative insolubility. Other things being equal, nitrification is more complete in a fine-grained than in a coarse-grained soil, because of the more regular aëration and moistening of the former. The nitrifying power of equal weights of different salts, that of calcium sulphate being 100, is as follows:—

Calcium sulphate..........	100·00
Sodium „	47·91
Potassium „	35·78
Calcium carbonate........	13·32
Magnesium „	12·52

These ratios may vary with the strength of the solutions in the case of potassium and sodium sulphates, but in the other cases they may be regarded as constant. Under the climate of Central France, nitrification in calcareous soils or in soils which have been treated with calcium sulphate, is very active in September and October. During this time, the proportion of nitric nitrogen to total nitrogen rose to 26·15 per cent. in a soil to which calcium carbonate had been added, and to 46·29 per cent. in a soil which had been treated with calcium sulphate. The nitrifying power of potassium sulphate explains the success which attends its application to tobacco, and the similar but much greater power of calcium sulphate accounts for its beneficial action on lucerne, to which it is applied in the form of plaster of Paris, or of superphosphate rich in calcium sulphate.

The application of plaster of Paris in the proportion of 0·5 to 1 per cent. to soils poor in calcium compounds cannot be too highly recommended, and its effect will be especially marked on clay soils, which do not allow the infiltration of the nitrates. If the presence of calcium sulphate does not confer fertility on soils naturally rich in gypsum, it is because they almost always contain chlorides of the alkalis and alkaline earths, especially sodium chloride, which are well known to be detrimental to nitrification. C. H. B.

Stable Manure. By P. P. DEHÉRAIN (*Compt. rend.*, 98, 377—380).—From the experiments described in the paper, it is inferred that the high temperatures observed in manure are due to the oxidation of organic matter by free oxygen; moreover, this oxidation is only partially induced by a definite ferment (bacilli), whilst the disengagement of marsh-gas in manure deprived of oxygen is exclusively due to the action of the ferment. R. R.

Analysis of Peat Litter. By M. FLEISCHER (*Bied. Centr.*, 1884, 210).—Analyses of three samples of peat litter after use are given; although the samples were moist, they were not sufficiently so to prevent carriage: nitrogen, potash, and phosphoric acid varied considerably. E. W. P.

Manuring Barley and Oats with Nitrogen and Phosphates. By M. MÄRCKER (*Bied. Centr.*, 1884, 162—166).—Pott has previously stated that in Saxony, farmyard manure is not of much value for barley, nor is kainite. The author has applied to barley after sugar-beet 150 kilos. Chili saltpetre per hectare, and to oats 200 kilos.; these crops were grown in at least 20 different districts, the character of the soil varying from sandy to heavy.

It was found that on the average the yield of barley was raised only 7·5 per cent., whilst that of the oats was increased 31·7 per cent.; but as regards the straw, the increase was nearly equal, showing that the nitrogenous manuring exercises a more intense action on the formation of grain in the oat than in the barley plant. In another set of experiments, 40 kilos. of superphosphate were added to the Chili saltpetre, with the result that the yield of barley was very largely increased, whilst though the yield of oats was raised, yet it was only to a small extent: the same may be said for the straw. The analyses of the ash of both plants does not explain the advantage of employing phosphate, but the higher yield is probably due to a deeper ramification of the roots, whereby a better use can be made of the materials present. E. W. P.

Manurial Value of the Lime-waste of Sugar Factories. By F. STROHMER (*Bied. Centr.*, 1884, 210).—Water 33 per cent., $CaCO_3$ 57, other mineral matter 1 per cent., including 0·8 per cent. P_2O_5, organic matter 9 per cent. (0·3 per cent. N). E. W. P.

Use of Superphosphates. By P. P. DEHÉRAIN (*Compt. rend.*, 98, 1286—1289).—A mere determination of the total amount of phosphoric acid in a soil is of little value as a guide to the use of superphosphate. It is necessary to ascertain whether the phosphates are soluble in carbonic acid (calcium and other protoxides), and therefore assimilable by plants, or insoluble in carbonic acid (iron and other sesquioxides), and therefore non-assimilable. For analytical purposes, carbonic acid may be replaced by acetic acid. In comparing the amount of phosphoric acid in different soils, the depth of the latter should be ascertained, and the phosphoric acid stated at so much per superficial area. From the results of recent experiments by different chemists, it would seem that when the total amount of phosphoric acid is more than 4000 kilos. per hectare, a portion being soluble in acetic acid, and the land is treated regularly with farmyard manure, the use of superphosphates is unnecessary. This supposition, however, requires confirmation. C. H. B.

Manuring with Crude Ammonium Superphosphate. By E. WOLLNY (*Bied. Centr.*, 1884, 167—170).—When superphosphate is exposed to coal-gas containing ammonia, but freed from tar, a certain amount of ammonia is absorbed, and a "crude ammonium superphosphate" containing 7·5 per cent. of ammonia is produced; but at the same time a certain quantity of thiocyanate is also retained, and it was thought that this might be injurious to plants; to ascertain this, the ammonium compound was compared with guano as to its action on crops, and several plants were manured with guano to which ammonium thiocyanate was added, but no evil consequences were observed so long as the quantity was not more than 10 kilos. per hectare for rape, peas, and turnips, nor more than 20 kilos. for winter rye. In another set of experiments, crude ammonium superphosphate was tried against superphosphate to which ammonium sulphate had been added, and with a similar result, that no harm was done so long as the thiocyanate did not exceed a definite amount, but rather otherwise; and that of the plants employed, potatoes and maize were the most susceptible to the harmful action of the thiocyanate. E. W. P.

Sulphuric Acid as a Manure. By H. FRESENIUS and STOCKS (*Bied. Centr.*, 1884, 160—162).—Fresenius considers that sulphuric acid is only valuable as a manure in soils which are free from lime, but rich in phosphates (Abstr., 1883, 681). Stocks experimented with rye on sandy soil, meslin and barley on good loam, giving to the first two crops 96 kilos. acid, and 48 kilos. Chili saltpetre per hectare, whilst the third crop received 96 and 360 kilos., the results being that although there was an increase, yet that increase did not compensate for the expense.

Another writer composted dead "Damm" soil with acid, and gave it to barley with clover and to sugar-beet; a good yield was obtained, but this is ascribed to the favourable weather and not to the manure. He proposes to allow the compost to ripen by aid of the atmosphere, and not by acid. E. W. P.

Krugite as Manure for Potatoes. By J. KARBE (*Bied. Centr.*, 1884, 210).—Four centners of krugite applied in addition to a light dressing of farmyard manure and 1¾ centners bone-meal per morgen, brought an increase of tubers but of lower starch-contents; the absolute yield of starch, however, was increased by 2 centners per morgen. E. W. P.

Sodium Chloride as a Manure. (*Bied. Centr.*, 1884, 209.)—Stronger applications than 2 kilos. per fruit tree in moist weather is not advisable, and none should be given in dry weather.

E. W. P.

Analytical Chemistry.

Ammonium Fluoride as a Blowpipe Reagent. By N. W. LORD (*Chem. News*, **49**, 253).—A few grains of ammonium fluoride are added to a drop of sulphuric acid on a piece of platinum, the powdered mineral to be tested is then mixed in to form a paste. This is heated gently near the lower part of the flame in a platinum loop. By this means, and with the aid of a hand spectroscope, boron, potassium, sodium, and lithium are readily detected, if present, even in traces. D. A. L.

Flashing Test for Gunpowder. By C. E. MUNROE (*Chem. News*, **49**, 251—252).—Several methods of testing the quality of gunpowder are described, but in the author's words, the flashing test is the simplest, readiest, and, in the hands of an expert, the best test for the incorporation of powder; therefore, it was deemed desirable to have permanent records of such tests. With this object in view, the following method is recommended:—Pieces of paper coloured with Turnbull's blue (similar to the paper used in the "Blue Print Process" of photography) about 20 cm. square, are moistened, and placed on a sheet of glass or copper; the powder is filled evenly into a truncated leaden cone, 3 cm. capacity; this is inverted on the paper and removed, when the powder is left in a conical heap, and is fired by means of a hot iron, copper, or platinum wire, and after 30 seconds the paper is washed under a jet of water. Good powders produce a blackening and bleaching, where the heap comes in contact with the paper, whilst fine spots (and a few smutches) are uniformly distributed over the whole surface of the paper, which then has the appearance of being a paler blue, with occasional spots and streaks; badly incorporated powders give rise to spots of irregular shape and distribution. This results from the combustion being more regular the finer the ingredients and the more uniform and intimate the mixture is. The action is due to the formation of alkaline carbonates during the combustion of gunpowder. The paper is prepared by sponging it evenly out of contact with sun (day) light, with a mixture of a solution of potassium ferricyanide and ammonium ferrous citrate; it is then allowed to dry spontaneously, and the blue colour is developed by four or five hours' exposure to strong sunlight. For use, the paper is immersed in a stream of water for five minutes, put on the glass plate, and excess of moisture removed by filter or blotting paper.
D. A. L.

Estimation of Moisture in Amylaceous Matters. By L. BONDONNEAU (*Compt. rend.*, **98**, 153—155).—To avoid errors in the estimation of moisture in starches, &c., the substance should, if neutral, be very slowly raised (1 hour required) to the temperature of 100°; but if it be distinctly acid, then that acid should previously be neutralised by mixing the substance with a little distilled water, to which a drop or two of ammonia has been added, and the drying is then effected at a temperature not exceeding 40°, until it is nearly complete, when the heat is slowly increased to 100°.

R. R.

Examination of Potash. By H. HAGER (*Dingl. polyt. J.*, **252**, 86).—On adding silver nitrate to a 5 per cent. solution of potassium carbonate, a yellowish-white precipitate is formed, which is white when potassium hydrogen carbonate is present. On placing the test-tube in hot water, the precipitate should remain unaltered; when however sulphides, traces of sulphites, or thiosulphates are present, it assumes a grey, brown, or black colour. D. B.

Examination of Gas Liquor. By S. DYSON (*Dingl. polyt. J.*, **251**, 457—459).—According to the author, the following substances may be expected to occur in gas liquor:—Ammonium sulphide, ammonium carbonate, ammonium chloride, ammonium thiocyanate, ammonium thiosulphate, ammonium sulphite, ammonium thiocarbonate, ammonium sulphate, ammonium ferrocyanide, ammonium cyanide, and ammonium acetate.

To detect ammonium thiocarbonate, zinc sulphate is added, and the precipitate filtered off and washed with cold water into a small flask connected with a condenser. On heating it, the zinc thiocarbonate is split up, carbon bisulphide being evolved, which is readily recognised by its odour, and if necessary its quantity may be determined with triethylphosphine, and weighed as PEt_3CS_2. For the determination of ammonium thiocyanate, gas liquor is treated with zinc sulphate, the solution filtered, and the filtrate tested with ferric chloride. For the detection of ammonium thiosulphate, gas liquor is treated with zinc sulphate, the solution filtered, and barium chloride added to the filtrate. The filtrate is acidulated with hydrochloric acid and heated. Sulphur separates with evolution of sulphurous anhydride. By precipitating the sulphides with zinc sulphate, acidulating the filtrate with acetic acid, and adding sodium nitroprusside, potassium ferrocyanide gives a purple-red precipitate if sulphites are present. For the detection of chlorine in gas liquor, zinc sulphate is added, the solution filtered, and ferrous and copper sulphate added to the filtrate. The solution is again filtered, acidulated with nitric acid, and tested for chlorine with silver nitrate. To detect ammonium acetate, the liquor is evaporated to dryness, the residue taken up with water, treated with a hot saturated solution of silver sulphate, filtered, washed with hot water, and the filtrate distilled with dilute sulphuric acid. The distillate contains the acetic acid.

A sample of gas liquor from Leeds registered 4·15° Twaddell = 1·0207 sp. gr. at 22°. It contained sulphides, carbonates, chlorides, thiocyanates, thiosulphates, sulphates, and ferrocyanides. For the quantitative determination of the ammonia, 25 c.c. of the gas liquor were distilled with magnesia (Lunge, this vol., 776). For the determination of carbonic anhydride, 50 c.c. of the liquor are precipitated with calcium chloride. The precipitated calcium carbonate is filtered off, dissolved in 50 c.c. standard hydrochloric acid, and the solution titrated back with soda. To determine the chlorine quantitatively, 50 c.c. are evaporated to dryness, the residue is taken up with water and filtered; the filtrate is then mixed with a solution of ferrous sulphate and copper sulphate, filtered, treated with nitric acid and silver nitrate, and the precipitate boiled, collected, and weighed. For the determination of the total sulphur, 25 c.c. of the liquor are treated gradually with water, acidulated with hydrochloric acid, and containing an excess of bromine; the excess of bromine is expelled by boiling, and the solution filtered and precipitated with barium chloride. The sulphides are determined by adding zinc sulphate and ammonium chloride to 25 c.c. of the liquor, filtering, washing the precipitate with water slightly acidulated with hydrochloric acid and containing an excess of bromine, heating to expel the excess of bromine, filtering, and adding barium chloride to the filtrate. For the determination of the thiocyanates, 50 c.c. are evaporated to dryness, the residue heated at 100° for four hours, then extracted with alcohol, the latter expelled by evaporation, the residue taken up with water, filtered, and precipitated with sulphurous acid and copper sulphate: $2NH_4CNS + 2CuSO_4 + H_2SO_3 + H_2O = Cu_2(CNS)_2 + (NH_4)_2SO_4 + 2H_2SO_4$. The precipitated cuprous thiocyanate is dissolved in nitric acid and thrown down with sodium hydroxide; the resulting cupric oxide, when multiplied by 0·96, gives the equivalent amount of ammonium thiocyanate. The sulphates are determined by evaporating 250 c.c. of gas liquor to dryness, adding water, removing the sulphides with zinc oxide, and precipitating the sulphates in the filtrate with barium chloride. To determine the ferrocyanides, 250 c.c. are evaporated, the residue dissolved in water, the solution filtered, and ferric chloride added to the filtrate. The precipitate is decomposed with caustic soda, and the resulting ferric oxide titrated with potassium permanganate. 1 litre of gas liquor treated in this way was found to contain—

Total ammonia		20·45	grams
Total sulphur		3·92	,,
Ammonium sulphide		3 03	,,
,,	carbonate	39·16	,,
,,	chloride	14·23	,,
,,	thiocyanate	1·80	,,
,,	sulphate	0·19	,,
,,	thiosulphate	2·80	,,
,,	ferrocyanide	0·41	,,

D. B.

Estimation of Phosphoric Acid: Oxalic Acid Method as Compared with the Molybdic Method. By D. LINDO (*Chem. News*, **49**, 247—249).—From the results of previous experiments (this vol., 493—497) it is assumed that the molybdic method properly conducted can be safely taken as a standard. Therefore in the present communication several results are published of analyses of phosphatic mineral manures by the oxalic and molybdic methods. From these, it is inferred that as a rule the oxalic acid method does not give strictly accurate results, owing to the practical impossibility of removing all the silica from solution; and a minute quantity of this substance in the presence of alumina is sufficient to impair the result.

Ferric oxide does not act in this way, except when present in notable quantities. Aluminium silicate is slightly soluble in ammonium citrate, but is precipitated by magnesia mixture. Silica should also be removed, as completely as possible, before adding ammonium molybdate. In order to avoid any inconvenience with regard to lime, with the oxalic acid method, the author proceeds as follows: Nearly neutralise with ammonia, precipitate with oxalate, heat, filter, concentrate, filter again, make up filtrate to usual volume, add 1·5 to 2 grams citric acid, then ammonia and magnesia mixture. Ammonium citrate retards the precipitation of calcium oxalate considerably; therefore if the phosphoric precipitate is filtered off after four hours, or when sufficient excess of magnesium mixture is employed, two hours is long enough: there is no fear of any calcium being precipitated. The methods employed are fully described. D. A. L.

Estimation of the Fuel Value of Coal according to Scheurer-Kestner. By F. STOHMANN (*Dingl. polyt. J.*, **252**, 73—78).—This is a reply to Scheurer-Kestner's criticisms that have appeared on the results of some observations made by the author with a new apparatus which Scheurer-Kestner considers to be only a modification of Frankland's calorimeter discarded by the inventor as inaccurate.

D. B.

Estimation of Starch and Glucose in Food. By C. FAULENBACH (*Bied. Centr.*, 1884, 71).—This is a modification of the method of Medicus. In order to obtain the starch in a soluble form, a solution of diastase is prepared in the following manner:—3½ kilos. of new malt is pounded, mixed with 2 litres of water and 4 litres of glycerol, digested for eight days, decanted, pressed, and filtered. 5 drops of this solution is sufficient to transform 1 gram of starch: 15 drops contain 1 mm. of sugar, and the author deducts that proportion from the result. After the transformation of the starch, the liquid is diluted to a determined volume, filtered, and a portion inverted with hydrochloric acid; after exact neutralisation, the quantity taken is diluted so that it may contain 0·1 to 0·2 per cent. sugar; the reduction proportion between Fehling's solution and glucose stands at 100 to 0·509. Titration is first tried with 10 c.c. of sugar solution and varying quantities of Fehling's solution; 40 c.c. are used for the final estimation.

J. F.

Examination of Cane-sugar and Dextrose; Decolorising Dextrose Solutions. By CASAMAJOR and others (*Bied. Centr.*, 1884, 198).—Place the doubtful cane-sugar in a cup, add sufficient water to make it moist, heat to 50—100°. In 10 minutes the adulterated (with dextrose) sugar will form a gummy mass, which when cooled will still remain gummy, whilst the pure cane-sugar becomes drier than when hot. A more exact test is that of polarisation, when dextrose shows rotatory power immediately after solution, which is not the case with cane-sugar. Fehling's solution shows in common solutions the presence of a reducing agent to the extent of 5 per cent., whilst in adulterated sugar 20 per cent. is found. To decolorise grape-sugar solutions, v. Korwin and Rosenblum add potassium permanganate equal to 0·2 per cent. of the weight of starch; this is added to sugar solution at 45°, to which chalk has been added, and then the precipitate is filtered off, and the liquid evaporated down to sp. gr. 1·5 at 45°.

E. W. P.

Testing of Yeast. By E. MEISSL (*Bied. Centr.*, 1884, 205—207).—A mixture of 400 grams pure cane-sugar, 25 grams ammonium hydrogen phosphate, and 25 grams potassium hydrogen phosphate is prepared, and of this 4·5 grams, dissolved in 50 c.c. plain water, is introduced into a light 70—80 cm. flask fitted with a cork, through which two tubes pass. One of these is bent at right angles, the longer portion reaching nearly to the bottom of the flask, whilst the shorter part may be closed by a stopper; the other tube carries a calcium chloride tube. 1 gram of the yeast is then placed in the flask, and the whole well shaken. After weighing and heating at 30° for six hours, the flask and its contents are rapidly cooled, the stopper opened, the carbonic anhydride removed, and the whole again weighed. The results thus obtained (which represent the fermentative power of the yeast) are compared with those obtained by the use of an ideal and normal yeast producing from 4·5 grams of the sugar mixture, 1·75 grams CO_2, thus: CO_2 found $\times \frac{100}{1·75}$ = fermentative power.

E. W. P.

Examination of Olive Oil. By S. CARPI (*Dingl. polyt. J.*, **252**, 87).—The author has found that on cooling cotton-seed oil for three hours at −20° it is less firm in consistence than olive-oil treated in the same manner.

D. B.

Examination of Tannin Extracts. By F. SIMAND (*Dingl. polyt. J.*, **252**, 471).—For the estimation of tannin in tannin extracts the use of Löwenthal's improved method (Abstr., 1883, 391), is

Extract of	Dissolved in cold H_2O. Tannin.	Dissolved in hot H_2O. Tannin.	Difference on 100 pts. of extract.	Calculated on 100 pts. tannin.	Remarks.
	Per cent.	Per cent			
Quebracho wood (solid)	70·09	73·08	2·99	4·09	The commercial product dried before analysis.
Valonia (solid)	68·59	70·44	1·85	2·62	Prepared by the author and dried before analysis.
Oak wood	15·09	15·47	0·38	2·45	18° B., prepared by the author.
Fir wood......	13·72	14·31	0·59	4·13	32° B. Commercial extract.
Oak bark......	23·72	24·37	0·65	2·67	32° B.
Chestnut wood.	22·68	23·52	0·84	3·57	31° B.
Sumach.......	10·75	13·38	2·63	19·66	34° B.

strongly recommended. It is shown, however, that when the solution is prepared with hot water, a larger percentage of tannin is obtained than when the extract is dissolved in cold water. Hence in investigating tannin extracts, it should always be stated whether hot or cold water has been used for dissolving the extract. The subjoined table (p. 931) gives the author's results.

D. B.

Technical Chemistry.

Self-purification of Sewage-contaminated Rivers. By F. Hulwa (*Bied. Centr.*, 1884, 1—2).—This paper is the result of investigations made by the author on the water of the River Oder before it entered and after it had passed through the city of Breslau, receiving in its transit the sewage of the city. The standard of purity adopted was a minimum (in 100,000 parts) of 50 parts total residue, 1·5 nitric acid, 3 chlorine and traces of ammonia and albuminoïd ammonia, 0·25 of oxygen to oxidise organic matter, and 18° to 20° of hardness (German scale).

According to this scale, the water of the river before entering Breslau, although slightly contaminated, yielded an excellent drinking water after being filtered. In its progress through the city the river shows increasing pollution, and at its exit was greatly polluted; a short distance down the river the effects of dilution became evident; the self-purification of the river by the combined action of the oxygen of the air and of vegetable and animal life in the stream itself were very marked, the impurities diminishing so rapidly that at 14 kilos. distant from the city the water was as pure as when it entered it, neither chemical nor microscopical tests showing serious impurity. The author thinks it a mistake to forbid the outflow of sewage into rivers, provided that the outfall is below the city, and the rapidity and volume of the stream are sufficient to carry the sewage to such a distance as will allow the operation of natural causes of purification.

J. F.

Preservative Effect of Ether- and Chloroform-vapour on Organic Substances. By R. Dubois (*Bied. Centr.*, 1884, 72).—Pears were placed under bell-glasses, the air of which was saturated with the vapour of chloroform, ether, alcohol, or water. The fruit in the first two vapours became discoloured in a few hours; in alcohol-vapour after two or three days, in the water-vapour they preserved their appearance many days. Weighed after many months the loss was: Chloroform, 6·75 per cent.; ether, 2·5 per cent.; alcohol, 0·6 per cent.; and water-vapour, 1·14 per cent. The fruit in the latter case was covered with a coat of mould.

In other experiments with anatomical preparations and whole animals, under glasses filled with ether-vapour, there was no decomposition, only a loss of moisture. Blood so treated showed no alteration of the corpuscles after a long time—they were only drawn together somewhat more closely. J. F.

Influence of Calcination and of Carbonic Anhydride on the Setting of Hydraulic Cements. By E. LANDRIN (*Compt. rend.*, **98**, 1053—1055. Compare Abstr., 1883, 754, 830).—The silicate, $SiO_2,2CaO$, was prepared by heating pure lime and silica in the proper proportions at a bright-red heat for several hours. The product remained pulverulent, but was completely soluble in hydrochloric acid. In one case only was it scoriaceous as described by Berthier. When this silicate is moistened with water, no heat is developed, and after 24 hours it acquires the consistency of soap, but its hardness is not increased even after many months. If, however, the substance, either freshly prepared or after it has been in contact with water for some time, is brought in contact with water charged with carbonic acid, it rapidly sets and the hardness of the mass increases as the absorption of carbonic anhydride progresses.

The silicate, SiO_2,CaO, was obtained in three forms by roasting its constituents at a high temperature for different lengths of time, viz., A, pulverulent; B, fritted; and C, fused. All these products were readily and completely soluble in hydrochloric acid. When finely powdered and moistened with water, A and B set without development of heat in exactly the same manner as mixtures of hydraulic silica and lime, but C did not set even after immersion in water for several years. If, however, they are placed in water charged with carbonic acid, *all three* varieties set and become extremely hard.

It is evident that calcium silicates set with difficulty after being heated to a high temperature, and in all cases do not harden under water. In order to obtain the maximum hydraulicity, the process of calcination should be continued sufficiently long to convert all the silica into hydraulic silica without fusing the product. The absorption of carbonic anhydride is an essential factor in the setting of hydraulic cements, and is the only factor which determines the ultimate hardening of the mass. C. H. B.

Application of Electricity in Chemical Industry. By F. FISCHER (*Dingl. polyt. J.*, **251**, 418—424).—Hermann (Ger. Pat. 24,682, April, 1883) recommends the electrolytical deposition of zinc from dilute solutions of the sulphate by the aid of potassium, sodium, ammonium, strontium, magnesium, or aluminium sulphates, used singly or mixed together. Kiliani states that during the electrolysis of a solution of zinc sulphate of 1·38 sp. gr. (the anodes and cathodes consisted of zinc plates), the evolution of gas is greatest with a weak current, diminishing with an increasing current, and ceasing when 3 mgrms. of zinc are deposited on 1 square centimetre pole surface per minute. The deposits obtained with strong currents were firm. From a 10 per cent. solution, the precipitate was obtained in the best form with a current of from 0·4 to 0·2 mgrm. zinc. From weak solutions, the zinc was always deposited in a spongy condition with evolution of much hydrogen. Kiliani concludes that the size of the pole surfaces depends on the intensity of the current and the concentration of the solution.

For the extraction of metals from ores, Blas and Miest employed a process which depends on the fact that the natural sulphides conduct electricity when they are rolled into plates whilst hot. These plates are then suspended as anodes in a suitable bath. For the separation of zinc from blende the bath consists of zinc sulphate, and the following reaction takes place:—$ZnSO_4 + ZnS = Zn + S + ZnSO_4$. The advantages of this process are (1) the ores do not require to be roasted; (2) the sulphur is obtained as such; (3) less current energy is required for the decomposition of zinc sulphide. In the case of galena, a bath of lead nitrate is used. Marchese has patented a similar process, the essential difference being the suspension in the depositing tanks of the ores in lumps or small pieces filled into iron baskets.

Referring to the electrolytic extraction of copper, the author states that the firm of Siemens and Halske of Berlin have five machines C_1, each with 12 baths in action at the Oker Works. Each machine is worked with a water power of 4 to 5 e. and deposits 1 kilo. copper per cell per hour, *i.e.*, about 300 kilos. per diem. At the North German Refining Works in Hamburg, six Gramme machines (No. 1) and one Wohlwill machine are in operation precipitating 2500 kilos. of copper daily. Oescher and Mesdach have constructed a Gramme machine according to Wohlwill's instructions, which yields 800 kilos. of copper daily. Hilarion Roux in Marseilles works with a No. 1 Gramme machine (5 e.) connected with 40 baths having 900 square meters anode surface; the cathodes are only 0·5 mm. thick, and are 5 cm. from the anodes. The machine makes 850 revolutions a minute, consumes 240 kilos. coal per day, and deposits with 8 volts and 300 ampères 250 kilos. of refined copper.

Keith's process for refining lead is worked by the Electro-metal Refining Company in New York. The bath consists of lead sulphate dissolved in sodium acetate; gold, silver, and antimony are retained by the anode.

The deposition of aluminium by electrolytic means is discussed by the author. According to Weldon, the cost of preparing alumina from bauxite at Pechiney's works at Salindres, amounts to 9·7 per cent., that of the preparation of double chloride of aluminium and sodium 33·4 per cent., and for the decomposition of the double chloride with metallic sodium 56·9 per cent. of the total expenditure. The manufacture of 1 kilo. sodium costs about 7 shillings, the largest item being for the costs of the vessels in which the sodium carbonate is heated with powdered charcoal, and which are so rapidly destroyed that their cost stands for one-half the total cost of sodium, and a third of the total cost of aluminium. It is further considered an impossibility to reduce alumina by carbon, for the reactions which occur correspond with the following numbers:—

$$\begin{aligned}
2Al_2O_3 + 3C &= 2Al_2 + 3CO_2\\
-783{,}200 + 291{,}000 &= -492{,}200 \text{ cal.}\\
Al_2O_3 + 3C &= Al_2 + 3CO\\
-391{,}600 + 85{,}770 &= -305{,}830 \text{ cal.}\\
Al_2Cl_6 + 3H_2 &= Al_2 + 6HCl\\
-321{,}870 + 132{,}000 &= -189{,}870 \text{ cal.}
\end{aligned}$$

That in spite of these unfavourable thermochemical relations, sodium can be formed from sodium carbonate and carbon is explained by Weldon as follows:—When a mixture of sodium carbonate and carbon is heated intensely, some of the sodium oxide becomes dissociated, and the carbon then combines with the oxygen, sodium being liberated. The temperature required for the dissociation of Al_2O_3 is, however, considered to be unattainable on a large scale.

The author is of opinion that if this explanation is correct there should be no difficulty in obtaining this dissociation temperature by the aid of the electric furnace. Moreover the reaction $C + 2H_2O = CO_2 + 2H_2$ corresponds with $-136{,}800 + 97{,}000 = -39{,}890$ cal., and yet it takes place when steam is passed over lignite coke heated to 300—350°, a temperature at which steam could not undergo dissociation; the reaction $ZnO + C = Zn + CO$ yields $-85{,}430 + 28{,}590 = -56{,}840$ cal. If therefore heat be supplied by external means reactions accompanied by the absorption of heat would be possible.

For the separation of iron from the solutions of aluminium sulphate, sodium sulphate, &c., Löwig and Co. in Goldschmieden deposit the iron electrolytically. When treating solutions of sulphates, the anode is to be of lead. The separation of the iron does not take place unless the production of oxygen at the anode can be almost entirely prevented. This is effected either by using an anode with a large surface or by causing as much resistance as possible to be offered to the passage of the current at the anode. D. B.

The so-called Burning of Iron and Steel. By A. LEDEBUHR (*Dingl. polyt. J.*, **251**, 506—509).—The author attributes the burning of iron to prolonged exposure to the action of red-hot fuel gases. A cast-iron plate which had been exposed for several years to the flame of a coal fire had the following composition:—

Graphite	0·960
Combined carbon	—
Iron	68·386
Sulphur	0·079
Arsenic	0·056
Phosphorus	0·269
Copper, nickel	0·125
Oxygen combined with iron, sulphur, arsenic, phosphorus, copper, and nickel	27·804
Manganous oxide	0·030
Silicic acid	2·328

When wrought iron is heated to or near its fusing point and cooled slowly, without being welded, it becomes burnt iron. A piece of melted wrought iron taken from the bottom of a gas-mill furnace at Riesa gave on analysis—

C.	Si.	P.	S.	O.	Mn.	Cu.	CoNi.
0·052	—	0·223	—	0·177	—	0·450	0·157

From a series of experiments on the burning of iron and steel, the author infers that the carbon in steel containing small quantities of manganese and silicon, burns away and thus reduces the hardness, firmness, and elasticity of the steel, whilst the carbon in steel rich in silicon and manganese does not burn away but is probably oxidised, which operation alters the properties of steel. Iron, however, is not oxidised in a similar manner. D. B.

Process for Phosphorising Bronze or Brass. By J. WHITING (*Dingl. polyt. J.*, **251**, 431).—Bronze or brass wire is placed for some time in a solution of 0·125 to 5 per cent. phosphorus dissolved in ether, carbon bisulphide, or olive-oil, 5 to 10 per cent. of sulphuric acid, and 85 to 95 per cent. water. The metal takes up phosphorus. The wire is then drawn a size finer and introduced into a closed retort, the bottom is covered with a thin layer of phosphorus so that the resulting vapours come in contact with the wire. After this the wire is packed in wood-charcoal and ignited, and heated until it softens, and can be drawn a size still smaller. This treatment is alternately repeated until the wire has been reduced to the desired fineness. Wire prepared in this manner is said to be more indestructible, takes a higher polish, and is less subject to corrosion.

D. B.

Researches on Russian Petroleum and Petroleum Lamps. By J. BIEL (*Dingl. polyt. J.*, **252**, 119—123).—It is shown that the smaller the amount of luminosity afforded by a petroleum lamp the greater is the consumption of oil calculated on 100 units of illuminating power produced. A lamp burns proportionately the smallest quantity of petroleum when it develops its full degree of brilliancy. The length of wick up which the petroleum has to travel, that is, the capillary attraction of petroleum, depends on the boiling point or the percentage of oils boiling above 270°, and is influenced by the diameter of the wick. In order to adapt the German round burners to Russian petroleum it is necessary to shorten the lower part of the glass chimney. Flat burners consume from 34 to 38 per cent. more oil than round burners, the luminosity being the same in each case. Efforts should be made to induce the Russian petroleum industry to produce a petroleum oil for general use which shall not give off an inflammable vapour under 35°, and contain at the same time up to 30 per cent. of heavy oils. It is further recommended to determine the quality of petroleum by distillation according to a uniform standard. D. B.

Fractional Distillation of Mineral Oils in a Current of Steam. By F. RASINSKI (*J. pr. Chem.* [2], **29**, 39—41).—The steam is introduced by means of a tube passing to the bottom of the distillation flask. The mixture of water and hydrocarbon vapours is passed through long cooling tubes and then washed in Mendelejeff's flasks. When the flasks become full, the steam is shut off and their contents are returned to the distillation flask. The mixture of vapours issuing from the last of the series of flasks is, after cooling, collected in portions of 65—70 c.c., and the sp. gr. determined. Also the proportion between the weights of water and oil is ascertained. The numbers obtained are used for coordinates in describing the curve by which each distillation is represented. The relative volume for the same sp. gr. becomes less each successive distillation, until a certain point is reached when for some time it exhibits no marked alteration. The deflection of the curves corresponds very closely with that observed in the ordinary process of distillation. The relative volume at first increases rapidly for the same sp. gr., then falls slowly, as is exemplified by the following table:—

	0·7700	0·7800	0·7900	0·8000	0·8100	0·8200	0·8300	0·8400	0·8500	0·8550
1	—	—	—	135	215	330	570	1100	2500	—
2	—	37	56	90	140	212	420	960	1850	3300
3	30	36	54	84	127	208	343	825	1625	—

J. I. W.

Caoutchouc and its Applications. (*Dingl. polyt. J.*, **251**, 459—461.)—For the manufacture of sets of elastic teeth, Bentelrock uses soft vulcanised caoutchouc for the gum, whilst the teeth and chewing surfaces are made of hard caoutchouc. According to De Tour-du Brueil the vulcanising of articles prepared from caoutchouc and sulphur can be performed in a boiling solution of calcium chloride.

Kent works up india-rubber waste by grinding and mixing it with water, and thereby separates the india-rubber from the specifically heavier impurities.

According to Burghardt caoutchouc is gradually oxidised in the air, forming a hard resin soluble in alkalis and containing 27·3 per cent. oxygen and a resinous mass containing 20 per cent. oxygen and insoluble in alkalis and benzene. Perfectly new and fresh vulcanised caoutchouc contains about 3 per cent. of the first resin, but is free from the insoluble resin described above. Good caoutchouc should not contain more than 0·5 per cent. water; brittle and hard caoutchouc contains from 5 to 10 per cent., which is given off on heating at 100° to 120°. The carbon in decomposed caoutchouc is reduced and the quantity of oxygen increased as may be seen from the following analyses. No. I is a normal sample; Nos. II to IV were more or less damaged and brittle, No. V was very hard and brittle:—

	I.	II.	III.	IV.	V.
Carbon	77·91	72·53	70·43	65·09	64·00
Hydrogen ..	10·33	11·31	10·59	10·04	9·26
Sulphur	5·15	1·97	3·14	1·95	2·28
Oxygen	6·61	14·19	15·84	22·96	24·46

The destruction of caoutchouc is facilitated by painting it with oil, especially olive-oil or palm-oil, as they promote oxidation. Certain dyes are also injurious to caoutchouc, particularly if they contain copper compounds. If caoutchouc is vulcanised with more than from 2 to 2·5 per cent. of sulphur, the excess is oxidised by the oxygen of the air into sulphuric acid which then attacks the caoutchouc. The process of boiling the caoutchouc in caustic alkalis with a view to eliminate the excess of sulphur is injurious on account of its rendering the surface porous, so that the oxygen of the air can more easily act thereon. A better method has been worked out by Rowley who mixes only the theoretical amount of sulphur (2 to 2·5 per cent.) with caoutchouc, and vulcanises either in an aqueous solution of ammonia (12 per cent. NH_3) or in the gas itself in the presence of steam.

Gernez has patented methods of making and treating various mixtures of either india-rubber or gutta-percha with sulphur, camphor, gum kauri, and the farina of mustard deprived of its oils and husks.

D. B.

Purification of Glycerol. By C. Moldenhauer and C. Heinzerling (*Dingl. polyt. J.*, **252**, 86).—The authors evaporate crude glycerol or soap-leys to dryness at a low temperature, treat the residue with 1—2 parts absolute alcohol, add 1—10 per cent. anhydrous sodium carbonate, and separate the deposited salts by filtration. The resulting alcoholic solution is then acidulated with sulphuric acid, the sodium salt separated, and the solution treated with lead oxide or lead salts, in order to remove the chlorine. The alcohol is then expelled from the solution by distillation in suitable stills.

D. B.

Improvement of Inferior Wine by Addition of the Husks of Superior Grapes. By J. Nessler (*Bied. Centr.*, 1884, 59—60).—The wine of 1882 was deficient in alcohol and contained much acid. The endeavour to improve it by the addition of the mark or pressed residue of the 1883 grapes was very successful. The percentage of alcohol was raised, the acid diminished, and many impurities removed. Certain precautions as to removal of stalks, &c., are recommended.

J. F.

Reduction of Extractive Matter by Clearing of Wine. By K. Portele (*Bied. Centr.*, 1884, 57—59).—The author found that when red wine is cleared with gelatin the percentage of extract is considerably reduced, and so really good natural wines may be reduced below the minimum, 65 per cent. of solid extract.

The clearing of wine by gelatin has a considerable effect on the colour of inferior qualities, some of these being quite decolorised.

The treatment of red wine by Pasteur's method also affects the colour, but the author's opinion is different from that of other authorities, and the question remains undecided. J. F.

Fermentative Strength of Beer Yeast in Distillery Mash. By K. Kruis (*Bied. Centr.*, 1884, 72).—The experiments were made in order to find if beer barm could be used to replace the artificial ferments used by distillers, and it was found that it produced a tolerably energetic fermentation, and in a moderately short time accommodates itself to the temperature and conditions of distillers' mash. J. F.

Action of Air on Beer Yeast. By D. Cochin (*Bied. Centr.*, 1884, 203—205).—The cellular membrane of the yeast permits the passage of sugar solution, and after a short time fermentation commences; if this endosmose occurs at the ordinary pressure, the solution within is of the same strength as that without, but if the air be removed, then the internal solution is richer in sugar than the external. When there is no free admission of air to yeast, its action on sugar is considerably reduced. E. W. P.

Beet Sugar. By E. v. Lippmann and others (*Bied. Centr.*, 1884, 201—203).—From the incrustation of lime salts in the evaporating pans, Lippmann has obtained, amongst other acids, a new acid which he believes to be closely allied to, if not identical with, hydroxycitronic acid.

A. Nord states that to prepare strontianite in a proper condition for purifying sugar, it must be powdered, mixed with sawdust and "a small quantity of a cheap vegetable glutinous material," and worked into bricks, which when dried are burnt. Steffens recovers the ammonia contained in the alcohol employed for the removal of molasses, by adding sulphuric acid, when the sulphate formed is precipitated after the alcohol has been sufficiently concentrated.

E. W. P.

Employment of Magnesium Sulphite and Ferric Chloride in Sugar Factories. By R. Bergreen and O. Licht (*Bied. Centr.*, 1884, 201).—Basic magnesium sulphite, $MgSO_3 + 2Mg(OH)_2$, is employed in preference to the free acid, and it is prepared by passing sulphur dioxide into water, holding magnesia in suspension. Licht prefers to use ferric chloride instead of barium chloride for purifying crude syrups, because the organic acids are more easily precipitated, and the separation by means of lime facilitated.

E. W. P.

Recovery of Sugar from Molasses by Means of Lime. (*Dingl. polyt. J.*, **251**, 373—380 and 415—418.)—In order to diminish the quantity of insoluble lime salts produced in the preparation of calcium saccharate, and also during the washing, Manoury boils the molasses with lime and decomposes the resulting lime salts with sodium carbonate, calcium carbonate and alkaline salts being formed. The latter, however, are soluble, so that a certain amount of organic non-saccharine matter is removed from the saccharate; had this been in combination with lime it would have been insoluble in dilute alcohol, and have contaminated the sugar after saturation. The loss of sugar is mainly due to the fact that a portion of the sugar does not combine with sufficient lime to form tri-saccharate. It is shown that in the preparation of calcium saccharate, according to Eissfeldt's method, the smallest loss of sugar takes place. The purity of the saccharate depends largely on the mechanical procedure of the extraction. The impurity caused by the decomposition of the saccharate by potash salts of organic acids is unavoidable in all processes, and depends on the perfect combination of the sugar with the lime in the saccharate; but the further contamination of the saccharate by the action of the excess of caustic lime in the saccharate on the potash salts depends on the rapidity of the extraction. As the caustic lime is but sparingly soluble in dilute alcohol, it is possible to remove the potash salts, which are more readily soluble, before appreciable quantities of lime are dissolved. In the first portions of the liquors, the largest quantities of non-saccharine matter and sugar are dissolved in the following order:—

Non-saccharine.	Sugar.
Eissfeldt.	Manoury.
Manoury.	Weinrich.
Weinrich.	Scheibler-Seyferth.
Scheibler-Seyferth.	Eissfeldt.
Drevermann.	Drevermann.

For dissolving approximately equal quantities of non-saccharine matter at the commencement of the extraction, the parts of ley required are given, and the amount of sugar dissolved under it—

According to	I. Parts.	II. Parts.
Manoury	1·00	2·89
Eissfeldt	1·18	1·00
Weinrich	1·81	2·79
Scheibler-Seyferth ..	7·01	3·97
Drevermann	8·18	3·20
Eissfeldt	1·00	—
Weinrich	2·79	—
Manoury	2·89	—
Drevermann	3·20	—
Scheibler-Seyferth ..	3·97	—

The first leys at the same time contain the largest quantities of free potash, so that here the largest quantities of lime salts are formed, but owing to the different solubilities of the potash salts and the calcium saccharate in dilute alcohol, the first leys also contain the largest amount of undecomposed alkali salts, which gradually disappear, owing to the fact that in the subsequent portions of the leys enough lime and calcium saccharate is dissolved to decompose the alkali salts still in solution. The production of free potash in the leys is mainly caused by the action of soluble monobasic saccharate on the alkali salts, although to some extent it depends also on the action of the dissolved calcium hydroxide on the alkali salts.

Whilst according to Lippmann in the substitution process for the production of tribasic saccharate by continued agitation of a solution of molasses and milk of lime, a soluble monobasic calcium saccharate is formed, which, on boiling, deposits part of the sugar in a tribasic form, it was found that on introducing finely-divided lime into a sugar solution an immediate formation of the same saccharate was effected. On examining this, Steffen has discovered a new reaction and based a new process thereon. In order to completely precipitate the sugar from a solution, it was found necessary to employ a solution of sugar saturated with lime, containing not less than 33 parts dissolved lime to 100 parts sugar. On introducing a fresh quantity of lime into this solution, the sugar contained therein is immediately precipitated in a granular form as tribasic calcium saccharate.

Wolters has patented a process for the recovery of sugar from aqueous solutions in the form of an insoluble tetrabasic calcium saccharate. For its production, it is necessary to avoid a rise of temperature during the mixing of the lime with the molasses. Over-burnt lime is ground and mixed with a quantity of an 8 or 10 per cent. solution of sugar, of which 1 mol. equals 3 mols. of lime. The mixture is then filtered, and the filtrate treated with 0·5 mol. lime. After careful agitation the mixture is decanted, when a precipitate is deposited composed of 1 of sugar and 4 of lime. D. B.

Dubrunfaut's Lime Osmose Process. By J. DE PUYDT (*Bied. Centr.*, 1884, 60—61).—This process has been tried in a factory and somewhat modified, with good results. The leading feature of the process is the addition of lime to the molasses or syrup, the sugar forms with it a sparingly soluble monocalcic saccharate, whilst the alkalies are expelled from their organic combinations, and are easily diffused. The modification now suggested is that instead of lime, calcium chloride should be used, which combines with potash and soda, the chlorides of which are so soluble. The syrup purified by osmose is then added to fresh juice, which is treated with lime and carbonic acid; sugar is obtained, and new syrup formed, the process being continuous. J. F.

A Physical Property of Milk. By G. RECKNAGEL (*Bied. Centr.*, 1884, 16—18).—The thickening of milk is irrespective of its temperature, and hitherto has not been much investigated; it cannot be assigned to the escape of gases, because old milk which has been boiled and cooled behaves in the same manner. In view of the importance of the sp. gr. of milk to public analysts and general control, the German Government directed the author to investigate the subject. He found that when milk was kept at a temperature of 15° the thickening process proceeded slowly and took two days to complete. The density of the milk was increased 0·8° to 1·5° of Quevenne's lactodensimeter, and varied with the richness of the milk; by cooling below 15° the process is hastened and is completed in six hours if the temperature is kept at 5° or below it.

When thickened milk is warmed, it breaks up into fragments; on cooling, it again thickens. As to the cause, the author does not think it due to the formation of acid, as milk which has become acidified is of less sp. gr. than before; nor does he think it due to a breaking up of the milk globules, as a low temperature delays that operation and hastens the thickening: he thinks it is caused by the swelling of the caseïn, and finds an analogy in the behaviour of glue, which at low temperatures absorbs much water, which is expelled when the temperature is raised. J. F.

Blue Milk, Blue Cheese, and Ropy Milk. By M. SCHMÖGER and others (*Bied. Centr.*, 1884, 196—198).—Cheese made from milk separated from centrifugal machines turns blue: this is not due to bacteria, but to iron removed from the drum; the same result can be obtained by adding ferric chloride to ordinary cheese: the blueing of milk is doubtless produced by the same cause. Schmitt prevents the blueing by disinfecting by means of sulphur dioxide. J. Reiset prevents the above mentioned appearance by adding to 10 litres milk 1 litre 1 per cent. acetic acid; this does not prevent the rise of cream nor damage the flavour of the butter. Another writer attributes the ropyness of milk to the use of bran as fodder. E. W. P.

Cheese from Skim-milk, with Foreign Fats added. By C. HANSEN and others (*Bied. Centr.*, 1884, 199).—Skim-milk containing 0·15 per cent. fat is made into cheese with the addition of 1·5—2 per cent. oleomargarine. Schrodt finds such artificial cheeses are not to be readily distinguished from pure cheese. Langfurth finds less volatile fatty acids in artificial American cheese than in pure sorts of English, Dutch, &c., origin. E. W. P.

Application of Electrolysis in Preparing Indigo Vats. By F. GOPPELSROEDER (*Dingl. polyt. J.*, **251**, 465—467).—In furtherance of his former researches on the use of electrolysis in dyeing and printing, the author gives a description of the method adopted by him for the preparation of the alkaline indigo vat. He mixes finely-divided indigo with a concentrated solution of caustic potash and fills a copper vessel half full with this mixture as also a porous cell, which is then placed into the copper vessel. The latter communicates with the negative pole of a galvanic battery or dynamo machine, whilst into the solution contained in the porous cell a large platinum plate is placed, which forms the positive pole. The apparatus is then warmed gently, and the current passed through for 3—4 hours. At the negative pole, *i.e.*, in the copper vessel, hydrogen is liberated with the formation of much froth and the characteristic odour of the indigo vat. The indigo-blue is converted into indigo-white, which dissolves in the alkaline solution. The resulting yellowish-green vat is then used for dyeing cotton fabrics indigo-blue. D. B.

Dyeing Cotton-yarn with Aniline-black in the Cold. By A. RENARD (*Dingl. polyt. J.*, **251**, 425—428).—The author describes a process for producing aniline-black on cotton without the application of heat. The ordinary method of dyeing cotton-yarns with aniline-black consists in introducing the material into a cold bath containing aniline, hydrochloric acid, sulphuric acid, and potassium dichromate, and heating at 50—60° as soon as the colour begins to develop. In the author's process, the same substances are used, but the proportions are different. The best results are obtained with the following mixture :—For 100 kilos. cotton, 16 to 20 kilos. hydrochloric acid, 21° B; 20 kilos. sulphuric acid, 66° B.; 8 to 10 kilos. aniline oil; 14 to 20 kilos. potassium dichromate; and 10 kilos. ferrous sulphate. The presence of the latter is not absolutely necessary, but it helps to increase the stability of the colour. The amount of water used is much smaller than in the ordinary process, as the reaction must take place in a shorter time and without the help of heat: hence the form of the dye vats has to be altered, to admit of the smallest quantity of solution being employed. The aniline is mixed in the vat with hydrochloric acid previously diluted with an equal volume of water, the sulphuric acid diluted to the same degree is then added, and finally the solution of ferrous sulphate. The dichromate is dissolved in another portion of water. The yarns are boiled, washed, and wrung out, after which they are placed on reels fixed over the vat. The solution in the vat is diluted with water, and to it half the dichromate solution is added. The reels are then rotated for 1 to 1½ hours. The goods are now taken out of the vat; the remaining half of the chromium solution is added and the dyeing continued, until the desired shade is produced. The dyed fabric is then washed and boiled in a soap solution containing 5 grams of soap per litre, and about 2 per cent. sodium carbonate. The resulting black is sufficiently fast for all purposes, being unaltered in the air or when exposed to the action of dilute sulphurous acid. Bronze and blue blacks are produced in a similar manner: it is necessary, however, to use a smaller amount of chemicals and reduce the time of dyeing. The bronze colour is obtained by washing and drying the unsoaped cotton, whilst the blue-black is formed by treating the soaped fabric with sodium carbonate.

D. B.

Preparation of Blue Colouring-matters. (*Dingl. polyt. J.*, **252**, 78—82.)—For the preparation of blue sulphuretted dye-stuffs, 10 kilos. dimethylaniline are dissolved in 10 litres hydrochloric acid of 21·5° B. and 50 litres water, and treated gradually with a solution of 7 kilos. sodium nitrite in 25 litres water. The product is mixed with an excess of ammonium sulphide (about 20 litres), heated, and agitated until the unattacked ammonium sulphide has been expelled. The mixture is then cooled, and the aqueous liquor separated from the resulting resinous sulphur compound by filtration (*Actien. Ges. f. Anil. Fab. Berlin*).

Bernthsen obtains a blue colouring-matter by heating 10 parts of diphenylamine with 4 parts of sulphur at 250—300°. Hydrogen sulphide is evolved and thiodiphenylamine obtained. The latter is purified by distillation and several crystallisations from alcohol. It is converted into a nitro-compound by treatment with 5 parts nitric acid of 40° B. On treating the nitro-derivative with acid stannous chloride (or other reducing agent), a colourless liquid is obtained containing the stannochloride of a leuco-base, and on oxidising this a violet colouring-matter is obtained. The dye-stuff may be fixed directly on the animal fibre, and is adapted to the dyeing of animalised or tanned cotton fabrics.

For the preparation of orange dye-stuffs and their conversion into blue sulphuretted colouring-matters, Möhlau dissolves 14 kilos. nitrosodimethylaniline hydrochloride and 8·5 kilos. dimethylaniline in 45 kilos. warm hydrochloric acid of 1·16 sp. gr. On adding water to the mixture and neutralising the acid, the colouring matter is deposited. For the formation of the blue dye, the acid aqueous solution of rubifuscin is treated with a reducing agent (zinc, tin, iron, sulphurous anhydride, thiosulphates, ammonium sulphide, hydrogen sulphide) at the ordinary or an elevated temperature, until the conversion into a leuco-compound is completed.

Fischer treats trichlorobenzaldehyde (m. p. 100—110°) with dimethyl- or diethyl-aniline, and obtains crystallisable leuco-bases, which produce bluish-green colours on oxidation. On heating 1 part trichlorobenzaldehyde with from 2 to 3 parts dimethylaniline in the presence of zinc chloride, a new leuco-base is obtained, which has the composition $C_{23}H_{23}Cl_3N_2$, is sparingly soluble in water and alcohol, and crystallises from hot alcohol or benzene in needles melting at 128—129°. When this leuco-base is oxidised in an acid solution, it yields a colour base having the formula $C_{23}H_{23}Cl_3N_2O$. It forms crystalline salts, and imparts a bluish-green colour to the fibre.

Meyer describes the preparation of substituted isatins and their conversion into substituted indigo. He subjects aniline, toluidine, xylidine, cumidine, naphthylamine, their alkyl or halogen substitution products, or the corresponding diamines to the action of dichlor- (dibrom- or diiodo-) acetic acid or its amides. The direct products of the reaction are substituted imesatins, which readily give up the imido-group for oxygen when treated with strong acids or bases, yielding isatin or substituted isatin. The reactions are explained by the following equations :—

$$\underset{\text{Dichloracetic acid.}}{C_2H_2Cl_2O_2} + \underset{\text{Aniline.}}{4NH_2Ph} = \underset{\text{Phenylimesatin.}}{C_{14}H_{10}N_2O} + 2NH_3PhCl + H_2O + H_2;$$

$$C_{14}H_{10}N_2O + H_2O = \underset{\text{Isatin.}}{C_8H_5NO_2} + NH_2.C_6H_5.$$

$$C_2H_2Cl_2O_2 + \underset{\text{Toluidine.}}{4(NH_2.C_7H_7)} = \underset{\text{Substituted imesatin.}}{C_{16}H_{14}N_2O} + 2[NH_3(C_7H_7)Cl] + H_2O + 2H;$$

$$C_{16}H_{14}N_2O + H_2O = \underset{\text{Substituted isatin.}}{C_9H_7NO_2} + NH_2.C_7H_7.$$

The resulting isatin or the substituted isatin may be converted into indigo or substituted indigo by reducing the hydrochloride with zinc and glacial acetic acid. D. B.

Quinoline and Pyridine Compounds. (*Dingl. polyt. J.*, **252**, 123—126.)—Jacobsen states that for the preparation of yellow dye-stuffs from pyridine and quinoline bases the phthalic anhydride may be replaced by chlorinated phthalic acids. The yellow dye obtained by the action of phthalic acid on the coal-tar bases boiling at 235—240° is identical in properties and composition with that obtained from quinaldine and phthalic acid. The same dye is formed from methylquinoline obtained by the reduction of orthonitrobenzylidenacetone. Yellow dyes are obtained also by converting cumidine into cumoquinaldine or trimethylquinaldine by treatment with aldehyde and hydrochloric acid, and heating with phthalic anhydride, phthalimide, nitrophthalic acid, or chlorinated phthalic acids.

Pure quinoline does not form a yellow dye with phthalic acid. Yellow dyes are obtained, however, by methylating (ethylating, amylating, &c.) quinoline and treating the product with phthalic anhydride or substituted phthalic acids.

For the preparation of hydroxyquinolines, the Farbwerke treats sulphonic acids of primary aromatic amines with glycerol and sulphuric acid, and adds aromatic nitro-compounds.

Knorr obtains quinoline derivatives, whose pyridine nucleus is hydroxylated, from ethyl acetoacetate and its alkyl and halogen substitution products on the one hand, and aromatic monamines (aniline, toluidine, xylidine, cumidine, naphthylamine, amidoanthracene, amidobenzoic acid, or their alkyl or halogen substitution products, chlorine, bromine, iodine, methyl, ethyl derivatives, as well as their azo-derivatives) on the other hand, by heating them in equivalent quantities at 120° for several hours and treating with sulphuric acid.

Ladenburg and Roth show that the piperidine prepared from pyridine by synthesis is identical with the base obtained from pepper.

Königs and Geigy describe the preparation of hydroxypyridinecarboxylic acid from hydroxyquinolinic acid as well as the formation of pyridinedisulphonic acid, by heating piperidine with concentrated sulphuric acid. On treating this with phosphorus pentachloride, trichloropyridine is obtained. D. B.

Preparation of Anthraquinone Compounds. By H. ENGELSING (*Dingl. polyt. J.*, **252**, 183).—On heating 1 part anthraquinonesulphonic acid with 2 parts fuming nitric acid and 3 parts sulphuric acid, the temperature rises rapidly towards the completion of nitration, and sulphurous anhydride is evolved; as soon as this ceases, the mixture is heated for 10—15 minutes at 180—185°. The resulting mass consists of a red and blue colouring-matter, the red being more soluble in alcohol than the blue. The blue dye is readily soluble in water, and forms blue salts with bases (basic and normal), the red dye forming red normal and blue basic salts. Both dyes are fixed by mordanted vegetable fibres. D. B.

Preparation of Ammonium Albuminate. By E. MUTH (*Dingl. polyt. J.*, **252**, 86).—The author uses a compound of caseïn with ammonia—called ammonium albuminate—as a substitute for ordinary paper size. He mixes 100 kilos. dry caseïn with 10 kilos. pulverised ammonium carbonate and 1 kilo. ammonium phosphate until the mixture assumes a uniform appearance and pale yellow colour. The reaction is completed in from 15—20 hours.

D. B.

Composition of Turkey-red Oil and its Mode of Action. By A. MÜLLER-JACOBS (*Dingl. polyt. J.*, **251**, 499—506, and 547—552).—The following is a summary of the researches which form the subject of this paper. Turkey-red oil is a saturated solution both of unaltered oil (triglyceride), and of decomposition products of sulpholeic acid in the alkali salts of this or an analogous acid, *e.g.*, sulphoricinoleic acid. It acts as a mordant, inasmuch as it gives up its oil in a finely divided form to the fibre. In the process which gives the best results, the sulpholeates are removed as much as possible by means of washing, whilst in the less complicated processes the property possessed by sulpholeic acid—to form insoluble salts with aluminium hydroxide—is simultaneously utilised for the fixation of the mordant. The preference given to the product from castor-oil depends on the presence of a larger amount of oil in the corresponding sulpholeic acid, so that such Turkey-red oil gives up a greater proportion of oil to the fibre than the analogous products of other triglycerides. It is evident, therefore, that the "new process" which has revolutionised Turkey-red dyeing could not have been discovered until the most suitable conditions for preparing this product had been fully and completely attained. The experiments made by Runge, Mercer, and Greenwood, as well as those of Keyser, failed owing to the fact that the methods which they adopted for obtaining the mordant were accompanied by the evolution of sulphurous anhydride. The so-called "Acide sulfoleique" mordant used for the fixation of aniline dyes also made but little progress, since the characteristic feature of a Turkey-red oil, *i.e.*, complete solution in water of a definite amount of an unaltered oil was disregarded in its preparation.

In 1873 the author published the results of some experiments made with a view to simplify the Turkey-red mordanting process, based on the conversion of the triglycerides into a finely divided emulsion by the addition of a solution of gum and an alkaline hypochlorite. The experiments were very successful, as by the use of the resulting mordant once passing replaced the usual oft-repeated soap-baths, a bright and permanent colour being obtained. Subsequently, the author took out a patent for the preparation of a mordant known in commerce under the name of Turkey-red oil, and in his specification he described minutely the conditions required for the successful preparation of a mordant. Thus far, the author claims a share in the "new Turkey-red process." D. B.

Tincture of Nux-Vomica. By M. CONROY (*Pharm. J.* [3], **14**, 461—462).—In order to study the effect of alcohol of various strengths on nux-vomica, several lots of the same sample of finely-powdered nux-vomica were extracted by the British Pharmacopœia process with alcohol of different strengths: (1) proof spirit; (2) a mixture of half proof and half rectified spirit; (3) rectified spirit as recommended in the British Pharmacopœia; (4) stronger rectified spirit; (5) a mixture of equal parts of absolute alcohol and rectified spirit; (6) absolute alcohol. The table given below shows the specific gravities of these menstrua, and the results of the analysis, &c., of the tincture:—

No. of experiment.	Specific gravity of menstruum at 60° F.	Specific gravity of tincture at 60° F.	Per cent. dry extract from tincture.	Total alkaloids per cent.	Strychnine, per cent.	Brucine, per cent.
1	0·920	0·924	1·353	0·209	0·083	0·126
2	0·882	0·886	1·320	0·209	0·084	0·125
3	0·838	0·842	1·056	0·190	0·077	0·113
4	0·830	0·834	0·957	0·119	0·045	0·074
5	0·820	0·823	0·803	0·081	0·030	0 051
6	0·795	0·798	0·748	0·032	—	—

From these results, it is evident that the rectified spirit of the Pharmacopœia, and alcohols of greater strength, are unsuitable as menstrua for the extraction of nux-vomica; the reason is that the strong spirit hardens the cell-walls, by coagulating albumin and absorbing water, and therefore impedes osmotic action, whereas dilute spirit softens the cell-walls, causing them to swell up, promotes osmose, and consequently solution. The best menstruum is No. 2 spirit (sp. gr. 0·882). D. A. L.

Purgative Principle of Croton-oil. By H. Senier (*Pharm. J.* [3], **14**, 446).—By means of alcohol, commercial croton-oil may be separated into two portions, one soluble, the other insoluble in this medium (this vol., p. 909); the former contains the vesicating principle, whilst the latter is non-vesicating, and constitutes the purgative principle which may be obtained, therefore, by simply washing croton-oil with alcohol until nothing more is dissolved. It is administered in the form of pills with extract of hyoscyamus. In doses equivalent to the non-vesicating oil in $\frac{1}{16}$ minim of ordinary croton-oil, it gives rise to slight nausea, uncomfortable sensation, but no appreciable effect; in doses equivalent to the amount of this oil in a half minim of ordinary croton-oil it acts as a very powerful purgative. The vesicating principle irritates the alimentary canal, gives rise to nausea, but does not purge. D. A. L.

Spontaneous Decomposition of "Explosive Gelatin." By C. E. Munroe (*Chem. News*, **49**, 259).—A sample of camphorated explosive gelatin was wrapped in paraffin-paper, and this parcel in light brown paper. After some time, more than a year, the volume had diminished considerably, nitrous fumes were evolved, and had attacked the paper, whilst clusters of fine crystals were found on the outside of the paper. The mass was friable, and after a short immersion in water disintegrated; and the camphor odour, which was quite strong up to this stage, soon disappeared. The water was straw coloured, gave a strongly acid reaction, contained traces of nitrous (but no nitric) acid along with oxalic acid, and a sugar-like substance giving glucose reaction with Fehling's solution. The paraffin remained unchanged, but neither glycerol, nitroglycerol, nor gun-cotton could be detected. D. A. L.

Experiments with Compressed Gun-cotton. By W. v. Forster (*Dingl. polyt. J.*, **251**, 371—373).—In replying to a criticism by O. Guttmann, the author states that he is able to determine how far his experiments in which the explosion took place in an open space are of use as a basis of inferring what took place in a confined space. He is of opinion that the experiments hitherto made and the theories hitherto advanced, do not fully explain this point, and although his experiments do not completely develop the theory of explosion, they establish additional principles. His process for rendering gun-cotton and gun-cotton cartridges waterproof is effective, inasmuch as gun-cotton which has hitherto been considered insoluble is dissolved, and forms the coating of the substance itself. He is aware that points of entrance are left open to the water, and to make the surfaces perfectly impervious to water he varnishes the pieces of gun-cotton after treatment, with acetic ether. In regard to the spontaneous decomposition of gun-cotton, the author states that gun-cotton even when badly prepared under ordinary conditions, will not decompose with production of fire or even explosion. D. B.

Three Processes for Obtaining the Albuminoïd Matter from Potato Waste. By W. Kette (*Bied. Centr.*, 1884, 172—174).—A considerable amount of albuminoid matter is contained in the liquid from which the potato-starch has separated; to recover this, and to use it as fodder, 12 to 14 litres of sulphuric acid is added to 45,000 litres of liquid, or 4 litres sodium silicate solution mixed with 12 litres sulphuric acid, or else acid dextrin solution; this is prepared from the waste pulp in the cylinders, 102 litres of this pulp (which contain about 6 kilos. starch) are mixed with 9 litres acid and 34 litres water, and the whole is heated with steam in a large vessel. The author proceeds with the description of the apparatus employed, and states that the precipitate so obtained, after neutralisation with soda, may be given to cattle, and although it contains sodium sulphate, no unpleasant effects have been observed. When dried, the mass contains over 40 per cent. of albuminoids, and about 0·4 per cent. fat.

General and Physical Chemistry.

A Mercury Galvanometer. By J. CARPENTIER (*Compt. rend.*, **98**, 1376—1377).—In 1881 the author made experiments similar to those described by Lippmann (this vol., p. 881), and constructed a galvanometer on the same principle. C. H. B.

A Mercurial Electrodynamometer. By G. LIPPMANN (*Compt. rend.*, **98**, 1534—1535).—A small parallelopipedal chamber, filled with mercury and communicating laterally with the two branches of a manometer, is supported in the centre of a bobbin of copper wire. The current passes through the wire and then through the mercury, and the manometer shows a permanent deviation due to the electrodynamic action exerted on the mercury by the remainder of the circuit. The deviation is strictly proportional to the square of the intensity of the current, and the apparatus can be used to measure alternating currents. All the parts of the apparatus are rigid and immoveable with the exception of the mercury, and even in this latter case the points at which the current enters and leaves the mercury have an invariable position with respect to the rest of the apparatus. In consequence of this rigidity, the form and sensibility of the apparatus remain perfectly constant.

This instrument can be constructed to measure currents in absolute measure, for the pressure p indicated by the manometer is connected with the intensity I by the formula

$$p = \frac{C}{E} I_2.$$

where E is the thickness of the layer of mercury and C is the intensity of the magnetic field produced at the centre of the bobbin by a current of unit intensity. The former is measured directly; the latter is deduced from the dimensions of the bobbin and increases indefinitely with the number of turns of the copper wire. In the mercurial galvanometer (this vol., p. 881) both the numerator and denominator in the expression $\frac{H}{E}$ have a maximum limit. The author criticises Carpentier's note (preceding Abstract). C. H. B.

Heat liberated by the Compression of Solid Bodies. By W. SPRING (*Ber.*, **17**, 1215—1217).—Jannettaz states (*Ber.*, **17**, 98) that a block of bell-metal subjected to a pressure of 6000 atmospheres showed signs of melting on its surface, and inferred from this that a considerable liberation of heat had been caused by the pressure. Spring has subjected acephorone (m. p. 28°) and also azoxybenzene (m. p. 36°) to a pressure of 7000 atmospheres, but in neither case has the least sign of fusion been apparent. In order to prove that no local heating takes place, he substituted gunpowder for these substances, so that any local heating would cause the ignition of the whole mass: no ignition took place. The author believes the effect observed by Jannettaz to be due to friction. In Jannettaz's experiments, the metal was pressed between two plates, so that lateral motion (with friction) was possible; whereas Spring's experiments were conducted with a closed pressure chamber, thus preventing any lateral movement. L. T. T.

Relation between Molecular Weight and Velocity of Evaporation of Liquids. By C. Schall (*Ber.*, 17, 1044—1058).—In a former paper (this vol., p. 551) the author states that the time of evaporation of equal weights of liquids, each heated in its own vapour, is inversely proportional to their molecular weights; or that quantities by weight of different liquids proportional to their molecular weight, when heated in their own vapours, evaporate equally quickly; or lastly, that equal weights of two substances, when heated in their own vapours, evolve quantities of vapour which, when sufficiently heated, occupy, according to Avogadro's law, equal spaces in equal times. A complete description of the complicated apparatus, by means of which these propositions were proved, is given in this paper, and also an account of a large number of estimations. Eleven substances have been tried, and if the time of evaporation of benzene be taken at 1, the time of evaporation of equal volumes of vapour (which represents quantities in proportion to the molecular weight) is as follows:—

Sulphide of carbon = 1·00
Ether .... = 0·99
Ethyl bromide.... = 0·97
Chloroform ...... = 0·94
Ethyl iodide...... = 0·98
Tetrachloride of carbon = 0·945
Ethyl acetate .... = 0·98
Acetone .... = 0·99
Methyl alcohol ...... = 1·00
Water .... = 1·00

A. B.

Dependence of Boiling Point on Pressure. By G. W. A. Kahlbaum (*Ber.*, 17, 1245—1262; and 1263—1272).—These papers are in continuation of the author's earlier communication on this subject (this vol., 141), and give the results of the careful examination of about 50 compounds. The influence on the resultant numbers due to error of experiment is believed not to exceed 0·001 in the case of the specific remission,* and 1·5° in the case of boiling points.

A comparison of the results obtained leads to the general law that at 0 mm., "the specific remission and also the reduction in boiling point vary in direct proportion to the boiling point;" or, in other words, the specific remission and reduction in boiling point in homologous compounds vary with the introduction of CH_2 in a manner similar to that in which the boiling point varies. This law has a special interest, as likely to be of service in determining the constitution of a substance and the size of its molecules. For—as the change of boiling point is caused by the reduction in pressure—the different reduction in boiling point of various compounds for the same reduction of pressure shows that the pressure on each molecule of one liquid, caused by the pressure of the air, is different from that on each molecule of another liquid. But since the *absolute* reduction in pressure is the same in both cases, the different reduction in boiling point would appear to be due to the different size of the single molecules in the two liquids; and therefore the difference in the reduction of temperature for the same reduction of pressure would be a measure of the relative size of the molecules.

---

* Specific remission (sp. r.) is the relation of the reduction in boiling point to the reduction in pressure.

In homologous series, the average numerical results obtained are, that a variation in composition of CH_2 causes a variation in specific remission of 0·01, and in the reduction of boiling point of 7·6° for 0 mm. pressure. These numbers agree with the observations in 17 cases, but disagree in 3 cases, but the author is not prepared at present to regard these numbers as having more than a subordinate signification.

Attention is called to the fact that the difference in boiling point between various substances is less at a low pressure than at the ordinary pressure of the air. The reputed fact that different substances are more easily separated by fractional distillation under low than under ordinary pressures, cannot have its origin in the boiling points lying further apart in the former than in the latter case; but, if really a fact, must be due to some entirely different cause.

In the numbers obtained certain regularities are, as already said, to be observed, but still there are many irregularities. And this was to be expected, for we may express the equation for the boiling point of a substance as

$$S = C + A + D + O + H + Z,$$

where C is the cohesion, A the adhesion, D the pressure of air and vapour, O the surface tension, H the pressure of liquid on itself, and Z the increase of cohesion caused by D, O, and H. In every case, boiling will commence when the heat given to the liquid exceeds the value of S. In the present case, therefore, it is only one of the elements determining the boiling point which has been eliminated, and that the simplest one. It is thus clear that most, if not all, the irregularities to be observed at ordinary pressures will still be observed at 0 mm. pressure, and many perhaps in a more marked degree. Probably the most important of the elements of the above equation beyond D are C and A. The results obtained by other investigators show that adhesion does influence the boiling point, and that it varies with the material composing the boiling vessel; but little is at present known as to the extent of such influence. It would however appear that it is the cohesion of the liquid which chiefly determines the boiling point when the pressure is removed, and tends to hinder the change of aggregation from the liquid to the gaseous state.

A generally accepted definition of boiling point is "the temperature at which the vapour tension of the liquid is sufficient to counterbalance the pressure of the air." But the author shows that this definition of boiling point is quite wrong, as the effect of cohesion in hindering change of aggregation is entirely omitted. The tension of the molecules given off from the surface of a liquid is sufficient to counterbalance the pressure of the air, at a temperature decidedly below that necessary for entirely overcoming the cohesion. This is shown to be experimentally true by a comparison of the author's numbers with those of Landolt. Landolt determined the vapour tension; the author the actual boiling point; and in each case his numbers were higher, in many cases very considerably higher, than those obtained by Landolt. The author defines as boiling point "the temperature of the vapour of a liquid in motion at which all its molecules pass from the liquid to the gaseous state without change of pressure." L. T. T.

Dissociation of Salts containing Water and Relation of the Dissociation to the Molecular Volume of the Combined Water. By W. Müller-Erzbach (*Ber.*, 17, 1417—1421).—In these experiments, the vapour-tension of the water in the salt is compared with that of pure water; the ratio of these tensions gives a measure of the energy with which the water is held in combination in the salt. In many cases the tension diminishes after a portion of the water is lost, *e.g.*, sodium phosphate, $Na_2PO_4 + 12H_2O$, tension ratio at 17° = 0·67; after loss of 25 per cent. of water, tension ratio at 16° = 0·30. The vapour-tension appears to decrease with a decreased molecular volume for the water in the salt: for instance, with three salts containing 10 molecules of water of crystallisation:—$Na_2SO_4 + 10H_2O$, mol. vol. of water = 16·7, tension ratio = 0·78; $Na_2CO_3 + 10H_2O$, mol. vol. of water = 15·2, tension ratio = 0·67; $Na_2B_4O_7 + 10H_2O$, mol. vol. of water = 14·8 to 13·2, tension ratio = 0·28. A. J. G.

General Law of Freezing of Solvents, and Deductions therefrom. By F. M. Raoult (*Ann. Chim. Phys.* [6], 2, 66—125). —In this extensive memoir are collected together the results obtained in an investigation on the lowering of the freezing point of liquids by the solution in them of various substances; the sources of experimental error are also discussed, and deductions drawn from the results as to the determination of molecular weights, and the subdivision of a base between two acids (comp. Abstr., 1880, 523; 1882, 1260; 1883, 7, 278, 952).

Part I. *Experimental.*—If A represent the *coefficient of lowering*, *i.e.*, the lowering of freezing point produced by 1 gram of substance dissolved in 100 grams of solvent, M the molecular weight of substance dissolved, and T *the molecular lowering of freezing point*, *i.e.*, the lowering of freezing point produced by the solution of 1 molecule of substance dissolved, then MA = T. Practically it is found advisable to experiment with very dilute solutions in order to avoid errors arising from arbitrary evaluations of the water of crystallisation or combination of the substance dissolved. The solvents employed were water, benzene, nitrobenzene, ethylene dibromide, acetic and formic acids. The method of experiment consisted, in outline, of determining the freezing point of the solvent with and without the substance dissolved within a short interval of time. If P be the weight of the solvent, P′ that of the substance dissolved, K the lowering of the freezing point, then the coefficient $A = K\frac{P}{P' \times 100}$. The liquid is cooled, while constantly stirred, to about $\frac{1}{4}$° below the freezing point. The thermometer quickly rises, and then remains stationary at a certain point for a short time. This point is taken to be the freezing point. The magnitude of errors due to reading the thermometer scale, radiation, incomplete immersion of the stem of the thermometer, displacement of zero point, and alteration in the liquid during the experiments, are fully discussed. The conditions necessary in order to obtain comparable results are also carefully examined.

The conclusions arrived at, illustrated by a selection of examples in the memoir, are given below.

(1.) All substances, solid, liquid, or gaseous, when dissolved in a liquid which can be solidified, lower the point of solidification.

(2.) In the case of the solvents examined, the molecular lowering of freezing point, due to the solution of different substances, approximates to one of two values, one of which is double the other; these vary with the nature of the solvent.

These mean values are 117 and 58 for ethylene dibromide, 72 and 36 for nitrobenzene, 49 and 24 for benzene, 39 and 18 for acetic acid, 28 and 14 for formic acid, 47—37 and 18·5 for water. The higher of each of these pairs of values is the more common, and is designated by the author the *normal* value, and the lower the *abnormal* value.

EXAMPLES.

Solvent.	Substance dissolved.	Molecular weight.	Coefficient A.	Molecular coefficient T = M A.
Acetic acid	Methyl iodide....	142	0·273	38·8
" "	Naphthalene	128	0·306	39·2
" "	Formic acid	46	0·793	36·5
" "	Sulphuric acid ..	98	0·189	18·6
" "	Hydrochloric acid	36·5	0·471	17·2
Benzene	Methyl iodide....	142	0·335	50·4
"	Naphthalene	128	0·391	50·0
"	Ethyl formate ..	74	0·666	49·3
"	Methyl alcohol ..	32	0·791	25·3
"	Formic acid	46	0·504	23·2
Water	Hydrochloric acid	36·5	1·071	39·1
"	Ammonium sulphate, potassium chromate, sulphate and carbonate	—	—	38·0

These results will serve as a means for fixing the molecular weight of a substance, for if A is determined experimentally, then in the case of water T = 38 divided by A will give the molecular weight.

It is further shown that in a constant weight of a given solvent, every molecule, of whatever nature it may be, produces the same lowering of freezing point. For example, if the higher of the two values for T given above are divided by M, the molecular weight of the solvent, then the quotients are, with the exception of water, practically equal.

Solvent.	Molecular weight M.	Maximum value for T.	M ÷ T.
Water	18	47	2·61
Formic acid	46	29	0·63
Acetic acid	60	39	0·65
Benzene	78	50	0·64
Nitrobenzene	123	73	0·59
Ethylene dibromide	188	119	0·63

It would appear that the molecule of liquid water does not consist of isolated chemical molecules of the simple formula H_2O, but probably of four such molecules combined or condensed together. From the results in the table above, the general law of the freezing of solvents may be ennunciated as follows:—

(1.) *If a molecule of any kind be dissolved in* 100 *molecules of a liquid of a different kind, there is produced a lowering of freezing point of the solvent approximately equal to* 63. *Consequently the lowering of freezing point of a dilute solution is approximately equal to the product obtained by multiplying* 63 *by the ratio existing between the number of molecules dissolved and the molecules of the solvent.*

PART II. *Deductions.*—It is remarkable that the acids, as regards the effect produced by them on the lowering of the freezing point of water, are separable into two groups; the value for T of members of one group is approximately 40, of the other 20. The members of the former group are powerful acids, whilst those of the latter are the weaker acids. It is here shown that *equivalents of the acids of the first group displace almost completely equivalents of the acids of the second group from their combinations with bases.* To illustrate this proposition, examples are given, such as the action of hydrochloric acid on neutral sodium sulphite, nitric acid on sodium iodate, sulphuric acid on sodium arsenite, hydrochloric acid on potassium arsenate, the first of which may be taken in order to show the method used.

If by x be denoted the fraction of the molecule of sulphurous acid liberated by the action of 2 molecules of hydrochloric acid on 1 molecule of sodium sulphite, then at the end of the change the composition of the mixture may be represented by the formula—

$$x(2NaCl + H_2SO_3) + (1 - x)(NaHSO_3 + HCl + NaCl).$$

The lowering of freezing point due to each of the components of the above formula is as follows:—

A.	1 molecule NaCl in 2 litres water	1·7
B.	1 ,, H_2SO_3 ,, ,,	0 955
C.	1 ,, $NaHSO_3$,, ,,	1·62
D.	1 ,, HCl in 2 litres water	1·835
E.	1 ,, Na_2SO_3 ,, ,,	2·105

The liquid obtained by mixing solution D with half E causes a lowering of freezing point of 1·472, or referred to the same standard of 2 litres = 1·472 × 3 = 4·416; hence

$$a(2 + 1{\cdot}7 + 0{\cdot}955) + (1 - x)\,(1{\cdot}62 + 1{\cdot}835 + 1{\cdot}7) = 4{\cdot}416$$
$$\text{or } x = 0{\cdot}958.$$

i.e., $\frac{958}{1000}$ of the sulphurous acid are liberated by the action of the hydrochloric acid. The results in this memoir are in accordance with those obtained by Berthelot in his thermochemical investigations, and point to a correlation between the lowering of the freezing point and the chemical energy of the acids. Similarly it is shown that the bases can be separated into two groups. The value for T of members of one group varies between 33 and 48, mean 39, and for the other group the value varies from 16 to 20, mean 19. Included in the first group are the hydroxides of the metals of the alkali and alkaline earth groups, together with those of tetramethyl- and trimethylethylammonium, while in the second group are the organic bases, together with ammonia. As in the case of the acids, so also it is shown that the members of the first group completely eliminate the members of the second group from their combination with acids. The results are strictly in accordance with the observations of Berthelot, that ammonia and aniline are completely displaced by soda, and with those of Menschutkin, that ammonia and the organic bases are displaced by soda in alcoholic solution.

Examples are given to illustrate the action of the hydroxides of barium and rubidium on ammonium chloride, and of trimethylethylammonium hydroxide on ammonium iodide. There is thus a similar correlation to that observed in the case of acids between the lowering of the freezing point and the chemical energy of the bases.

In conclusion, the author traces out an analogy existing between the phenomenon of the lowering of the freezing point and that of the heat of dilutions of the acids and bases. This may be stated generally thus: those acids and bases which lower the freezing point of the solvent to the greater degree possess the greater affinity for that solvent. It is proposed to illustrate this analogy in a future memoir. V. H. V.

Displacement of Chlorine by Bromine, and Reactions accompanied by the Absorption of Heat. By A. POTILITZIN (*Ber.*, 17, 1308—1324).—The author has previously shown (Abstr., 1882, 457) that the displacement of chlorine in metallic chlorides by bromine takes place according to a simple rule, which may be expressed by the equation $\frac{A}{BE^2} = \text{Const.}$, where A is the atomic weight of the metal, B the percentage of chlorine displaced, and E the valency of the metal. The correctness of this equation has been confirmed by the results of the examination by the author of the action of bromine on the chlorides of 14 metals, whose valency varied between 1 and 6, and atomic weights between 7 and 207. Amongst these were cobalt and nickel, which, having equal valencies and atomic weights, formed good examples to test the correctness of the law.

The author disputes the soundness of the arguments used by Berthelot (Abstr., 1883, 8) to show that this displacement of chlorine by bromine may be fully explained according to his "*principe du travail maximum*," and denies the possibility of the existence, under the conditions of the experiments, of the perbromides and bromine chloride, the formation of which Berthelot assumes. The author considers that this reaction must be classed amongst those reactions which take place at certain temperatures, notwithstanding that they are accompanied with an absorption of heat, and that the work of chemical change in these cases is completed at the expense of the heat of the surrounding medium. He believes that the real cause of the reaction must be sought in intramolecular conditions, and is probably due to the varying velocity of the molecules, in accordance with Clausius' generally received theory.

The author has repeated the experiments with silver, potassium, and sodium chlorides at ordinary temperatures, and is unable to confirm Berthelot's results. He finds that there is a very slight displacement of chlorine in silver chloride (about 0·8 per cent. after six days' treatment), that with potassium chloride the displacement is much less (less than 0·1 per cent.), and with sodium chloride is scarcely perceptible. L. T. T.

Vapour-density Apparatus. By V. Meyer (*Ber.*, 17, 1334—1335).—The author disputes the advantages (except perhaps in special cases) claimed by Schwarz (Abstr., 1883, 899) for his modification of the author's apparatus. In such an apparatus, the neck should be as small (to hinder diffusion), the gas space as large as possible. The unheated portion should be small, and the vertical position of the apparatus is to be preferred so as to minimize diffusion. Finally, it is important to have a constant temperature, and for easily decomposible substances it is advantageous to know that temperature. The author contends that these conditions are not so completely fulfilled in Schwarz's apparatus as in his own. L. T. T.

Specific Volume of some Double Chlorides. By R. Romanis (*Chem. News*, 49, 273).—The author has observed that a great contraction takes place in the specific volumes of some anhydrous double chlorides. For example, the sp. vol. of ammonium platinochloride, $(NH_4)_2PtCl_6$, is 148, and that of $PtCl_4$ being 114·7, and of $2(NH_4)Cl$ 71·32, there is a contraction equal to 38. A similar contraction is observed with the platinochlorides of zinc, cobalt, nickel, &c., whilst the contraction in the case of potassium platinochloride amounts to 54·5. The stannochlorides behave in a similar manner, *e.g.*, potassium stannochloride, K_2SnCl_6, sp. gr. is 2·948, and sp. vol. 138·6, the contraction being 52·5; ammonium stannochloride, $(NH_4)_2SnCl_6$, sp. gr. = 2·511 and sp. vol. 146·1, contraction = 39·8. On the other hand, combinations of $PtCl_2$, $ZnCl_2$, and $SnCl_2$ exhibit an expansion, *e.g.*, $(NH_4)_2PtCl_4$, sp. gr. = 2·84, sp. vol. = 132, and sum of sp. vols. of $PtCl_2$ and $2NH_4Cl$ = 116·8; $(NH_4)_2ZnCl_4$, sp. gr. = 1·77, sp. vol. = 137, expansion = 17. Sp. vol. of K_2SnCl_4 = 136·6. As an example of a trichloride, $K_3S_6Cl_6,2H_2O$, sp. gr. = 2·42, sp. vol. = 200·8.

D. A. T.

Spheroidal State. By J. LUVINI (*Compt. rend.*, **98**, 1536).—Water boils at −18° to −20° under a pressure of 1 mm., and the temperature of water in the spheroidal state under this pressure must be less than −18°. It is easy to see, therefore, that the temperature of very volatile liquids in the spheroidal state under very low pressures must be very low. In Despretz's experiment with nitrous oxide in the spheroidal state, under a pressure of 20 mm., the temperature of the nitrous oxide must have been below −200°.

A platinum capsule previously heated in boiling water was placed on a hot brick, and 13—15 c.c. of ether poured into it. A tube containing water was placed in the ether, a receiver placed over the whole, and the pressure reduced to 100—120 mm. The water froze in about one minute. Under a pressure of 6—7 mm., water could be frozen in alcohol, and at 8—10 mm. mercury can be frozen in ether.

C. H. B.

Colloïds. By E. GRIMAUX (*Compt. rend.*, **98**, 1434—1437).—*Schweizer's Solution.*—When the solution obtained by the action of ammonia on copper turnings is dialysed in a porous vessel, ammonio-copper nitrite and the excess of ammonia pass through, and after six or seven days the porous vessel contains a blue solution of ammonio-cupric oxide, which will not pass through the dialyser. This solution has properties similar to those of other colloids. It yields a gelatinous precipitate of cupric hydroxide on the addition of water, decomposition being partial with 1—2 vols. of water, and complete with 5—6 vols., and it is also precipitated by magnesium, calcium, aluminium, and copper sulphates, and by dilute acetic acid, but not by sodium chloride or potassium sulphate. When the solution is heated to 40—50°, it yields a precipitate of cupric hydroxide, which redissolves on cooling, the action of heat causing true dissociation. When a solution of cellulose in Schweizer's reagent is dialysed, the liquid left in the dialyser is much less highly coloured than the original solution. It yields a gelatinous precipitate of cellulose when mixed with water, but this precipitate is dissolved on adding a few drops of ammonia, and yields a perfectly transparent and but slightly coloured solution. If dialysis is carried too far, the solution is decomposed, and a firm deep blue jelly forms in the dialyser, and can be freed from mother-liquor by washing with water. This jelly consists of cellulose and cupric oxide, and is not soluble as a whole in ammonia; the latter dissolves out the cupric oxide from it.

Pyruvic Ureïdes.—The solutions obtained by dissolving in alkalis the white powders which are formed when crystallised pyruvic ureïdes are heated at 150°, have the properties of other colloïdal solutions, and yield a precipitate when treated with a current of carbonic anhydride, but become limpid again when treated with a current of air. They differ, however, from the colloïds of the animal organism by the fact that they are not affected by boiling nitric acid.

Amido-aspartic Colloïd.—This substance is obtained by heating aspartic anhydride with urea at 125°, or by the action of a current of ammonia-gas on aspartic anhydride at 150°. Its solution gelatinises on evaporation, and yields bulky precipitates with baryta-water, calcium chloride, &c. The precipitate formed by nitric acid dissolves on heating, and is reprecipitated on adding water. Sodium chloride produces only a slight precipitate in the cold, but an abundant precipitate on heating. The precipitate produced by magnesium sulphate is dissolved on gently heating, but is permanently reprecipitated on boiling.

This colloïd readily undergoes hydration, yielding a non-colloïdal substance; with copper salts this forms a derivative, which dissolves in potash and produces a rose-violet solution exactly similar to that of the analogous derivatives of albuminoids.

Soluble silica is easily obtained by boiling 8 grams of methyl silicate with 200 grams of water in a flask provided with an inverted condenser. The liquid is evaporated to three-fourths of its bulk in order to expel methyl alcohol, and the solution thus obtained contains 2·26 per cent. of anhydrous silica. It is very stable, and is not coagulated by the action of carbonic anhydride even on heating, but is precipitated by a somewhat large quantity of sodium chloride or potassium sulphate at 100°. The properties of the solution agree with those previously described by Graham. C. H. B.

Simple Method of Demonstrating Spring's Compression Experiments. By B. Tollens (*Ber.*, 17, 662—664).—The author employs the press on the knee-joint principle already described by him (*Ber.*, 9, 488). His results in general confirm those already described by Spring. Potato-starch gave a cylinder, in part transparent, in part opaque. In the transparent parts starch granules could no longer be recognised under the microscope. A. J. G.

History of the Periodic Law. By J. A. Newlands (*Ber.*, 17, 1145—1150).—A question of priority.

Mixed Crystallisation. By H. Kopp (*Ber.*, 17, 1105—1121).—The author criticises Brügelmann's statement (*Chem. Centr.*, 1882, 522; 1883, Nos. 30—32; and this Journal, Abstracts, 1883, 147—148) "that compounds of dissimilar atomic constitution can assume the same crystalline form, and that such compounds crystallise together in varying proportions."

In a series of experiments on the crystallisation of mixed salts, in which small quantities of the saturated solutions were allowed to crystallise on watch-glasses coated with a thin film of paraffin, it was observed that the salts of dissimilar constitution crystallised separately. When a solution of potassium nitrate with permanganate, chromate, or dichromate crystallises, the crystals of potassium nitrate which are deposited are coloured by the small quantities of chromate or permanganate contained in the cavities in which these crystals abound. Potassium chloride and sulphate also exhibit these cavities, and consequently behave in a similar manner. The chromate or permanganate is only mechanically enclosed in these crystals, and their presence cannot be regarded as a proof that these salts of dissimilar constitution crystallise together. W. C. W.

Influence of Repeated Compression on the Amount of Sulphides formed by Pressure. By W. SPRING (*Ber.*, 17, 1218—1220).—The author subjected the mixtures of metals and sulphur to repeated compressions, the block obtained being powdered between each two applications of pressure. The following results were obtained:—

	One compression.	Two compressions.	Four compressions.	Six compressions.
Silver sulphide	4·51 p.c.	12·43 p.c.	46·74 p.c.	69·41 p.c.
Lead „	1·32 „	19 34 „	28·08 „	45·54 „
Cuprous sulphide*	14·09 „	28·20 „	40·08 „	56·89 „
Cupric „	8·49 „	16·95 „	24·02 „	34·60 „

The mere powdering also slightly increases the amount of sulphide formed. Time plays an important part in the completion of the reaction. A block of silver and sulphur, which had twice been subjected to pressure, and contained 12·43 per cent. silver sulphide, was re-analysed after an interval of a year, and was then found to contain 41·63 per cent. of sulphide. These experiments therefore show that the amount of sulphide formed depends on the degree of pressure, the amount of surface contact of the two constituents, and the time during which such contact lasts. L. T. T.

Inorganic Chemistry.

Action of Sulphur on Oxides. By E. FILHOL and SENDERENS (*J. Pharm.* [5], 7, 480—482).—Sulphur acts on potassium and sodium hydroxide, even at normal temperatures, forming polysulphide and thiosulphate. When sulphur is mixed with aqueous solutions of potash or soda, the chemical action is inversely as the quantity of water present, and directly as the temperature. A solution containing 200 grams of sodium oxide in a litre of water was acted on by sulphur at the normal temperature; the reaction was complete in 24 hours. When the quantity of sodium oxide was reduced to 40 grams per litre, the reaction commenced after about 20 hours, but was not completed after one month. Heating the solution at 100° very much hastened the reaction, which was then complete in a few hours. A solution containing 4 grams of sodium oxide per litre was not sensibly acted on by sulphur, even after many months, but the reaction takes place when the solution is heated at 100°. A solution of sodium oxide containing 0·4 gram per litre of water was not acted on by sulphur, either at ordinary temperatures or when heated. These observations are strictly in accordance with the laws of thermo-chemistry. The calculations in the original paper indicate that whilst the heat of combination of sodium oxide in the solid state is 152 cals., the heat of formation of sodium tetrasulphide and thiosulphate, also in the solid state, is 224·1, that is 72 cals. in favour of the second reaction. On the other hand, the thermo-chemical equivalents of the same bodies when dissolved in water are 232·8 cals. in the first reaction, and 232·9 cals. in the second, that is, the two reactions are thermochemically identical. W. R. D.

---

* The author is uncertain whether the copper is present in the cupric or cuprous state, or in both.

Solubilities of Haloïd Salts. By A. ÉTARD (*Compt. rend.*, **98**, 1432—1434).—*Sodium Bromide.*—The author's results agree with those of Kremers. Between −20° and + 40° the solubility is given by the equation $S = 40 + 0{\cdot}1746t$, but between 40° and 50° the curve changes in direction, and from 50° to 150° the equation is $S = 52{\cdot}3 + 0{\cdot}0125t$. The hydrate $NaBr,2H_2O$ loses its water of crystallisation at 50°. When the ratio between anhydrous salt and water in a saturated solution is represented in molecules, numbers are obtained in the case of the majority of very soluble salts closely approaching those given by solid hydrated salts, and it would seem as if salts of the first class behaved like fused hydrates. For sodium bromide at −20°, the ratio is $NaBr : 8H_2O$; at + 40° $NaBr : 5{\cdot}5\ H_2O$; whilst from 50—150° the ratio only varies from $NaBr : 4{\cdot}5\ H_2O$ to $NaBr : 4{\cdot}3\ H_2O$, or approximately $2NaBr + 9H_2O$ through an interval of 100°.

Sodium Iodide.—From 0° to 80° $S = 61{\cdot}3 + 0{\cdot}1712t$, with extreme ratios $NaI : 5H_2O$, and $NaI : 3H_2O$. From 80—160°, $S = 75 + 0{\cdot}02586t$; with ratios $NaI : 3H_2O$ and $NaI : 2H_2O$. Below zero the solubility appears to diminish very rapidly. According to Coppet (*Ann. Chim. Phys.*, 1884) the solubilities of the hydrates $NaBr,2H_2O$ and $NaI,2H_2O$ should be represented by curved lines, but the author's results show that the inflection of the curve near the point at which the hydrates are dissociated can be regarded as an inclination of the whole curve towards the axis *x* only when the curve is not sufficiently prolonged.

Potassium Chloride.—The solution freezes at about −9°. Between −9° and 110°, $S = 20{\cdot}5 + 0{\cdot}1445t$, with $KCl : 15H_2O$ and $KCl : 6H_2O$.

Potassium Bromide.—According to Kremers, the curve consists of two straight lines, but according to Coppet (*loc. cit.*), the solubility is represented by a single straight line. The author's results agree with those of Kremers between −12° and + 165°, and Coppet's numbers are represented by this curve with greater accuracy than by the curve which he himself gives. The ratios are, at −12° $KBr : 13H_2O$; at 30°, $KBr : 11H_2O$; at 120°, $KBr : 5H_2O$.

Potassium Iodide.—The author's results agree with those of Coppet between 0° and 100°, but according to the latter the curve is a straight line below 0°, whilst the author finds that it is inflected, as in the case of the bromide. Between 0° and 165° the equation is $S = 55{\cdot}8 + 0{\cdot}122t$, with ratios at 0°, $KI : 7H_2O$; at 120°, $KI : 3{\cdot}7H_2O$.

The curves of the six haloïd salts already described are almost parallel. The curves of potassium bromide and iodide show perturbations strictly comparable with those observed in the case of the hydrated salts, although no definite hydrates of these salts have been prepared.

Calcium Chloride.—Between −18° and + 6° the proportion of anhydrous salt in a solution of the hydrate is given by the equation $S = 32 + 0{\cdot}2148t$; with extreme ratios, $CaCl_2 : 13H_2O$ and $CaCl_2 : 10H_2O$. Between 6° and 48° the curve is modified, whilst from 50° to 170°, an interval of 120°, the equation is $S = 54{\cdot}5 + 0{\cdot}0755t$. The alterations in the curve do not take place suddenly at a point, as in the case of sodium sulphate. Up to + 6°, and even up to 40°, the crystallisation of saturated solutions takes place readily, but above 40°—the melting point of the hydrate—crystallisation takes place with difficulty, and the solution remains supersaturated for a long time.

When a cold saturated solution of calcium or magnesium chloride is mixed with cobalt chloride solution, the latter becomes blue, and a solution of nickel chloride becomes yellow, thus showing that all the water in these solutions is utilised in some way, and that the solution even exerts a dehydrating action. A saturated solution of zinc chloride has not this property. Saturated solutions in fact undergo double decomposition, independently of any definite hydrates which they may contain. Barium and strontium chlorides are completely precipitated from their solutions by a saturated solution of hydrated calcium chloride, $CaCl_2,6H_2O$. C. H. B.

Permeability of Silver to Oxygen. By L. Troost (*Compt. rend.*, 98, 1427—1429).—A silver tube of 10 mm. internal diameter, with walls 1 mm. thick, was heated in cadmium vapour in an iron muffle, provided with an internal platinum lining. A slow current of oxygen was passed into the muffle, and the silver tube was rendered vacuous. Under these conditions oxygen passes through the walls of the tube with a velocity corresponding with 1·7 litre per square metre per hour. If the walls of the tube are only 0·5 mm. thick, the velocity of transfusion increases to 3·33 litres per hour. When a current of air is led into the muffle instead of oxygen, oxygen passes into the silver tube free from any trace of nitrogen, but the velocity of transfusion is only 0·89 litre per hour if the walls of the tube are 1·0 mm. thick.

Instead of maintaining a vacuum in the silver tube, a current of carbonic anhydride or some other gas may be led into it, but in this case the rate of transfusion is considerably lower. With a silver tube with walls 0·5 mm. in thickness, the rate of transfusion at the boiling point of cadmium is 0·4 c.c. per hour per square metre for carbonic anhydride; 0·1 c.c. for carbonic oxide; and less than 0·1 c.c. for nitrogen. This difference between the rates of transfusion of oxygen and nitrogen may possibly be utilised as a means of obtaining oxygen from the air.

The transfusion of oxygen through silver can be distinctly recognised at the boiling point of selenium. C. H. B.

Soldering of Aluminium. By Bourbouze (*Compt. rend.*, 98, 1490).—Aluminium can be readily soldered by means of an alloy of in and zinc, or better, of tin, bismuth, and aluminium. The best esults are obtained with alloys of tin and aluminium. A good solder for articles which have to be beaten, turned, &c., is composed of 45 parts of tin and 10 parts of aluminium. Softer solders are obtained by using a smaller proportion of aluminium. The surface of aluminium requires no special preparation, but it is advisable to give surfaces of other metals a preliminary coating of pure tin. C. H. B.

Melting Points of Beryllium Chloride and Bromide. By T. CARNELLEY (*Ber.*, **17**, 1357—1360).—In a paper on the vapour-density of beryllium chloride by Nilson and Pettersson (this vol. p. 820), some doubt is thrown on the accuracy of the author's determination of the melting point of beryllium chloride, inasmuch as the vapour-density of the chloride could be determined at the ordinary pressure at temperatures 100—150° lower. The author has therefore felt it necessary to publish the details of his determinations in order to show their correctness. He points out that many substances are known to sublime at temperatures considerably below their melting points.

A. J. G.

Purification of Arseniferous Zinc. By L. L'HOTE (*Compt. rend.*, **98**, 1491—1492).—Zinc containing arsenic or antimony can be easily purified by projecting into the fused metal 1 to 1·5 per cent. of anhydrous magnesium chloride, and agitating so long as white fumes are given off. Arsenic and antimony are volatilised as chlorides, and the metal is granulated in the usual way. C. H. B.

Action of Copper Chlorides on Metallic Sulphides. By F. RASCHIG (*Ber.*, **17**, 697—698).—The results given below were obtained by boiling the freshly-precipitated metallic sulphides with solutions of cuprous or cupric chloride. The following sulphides, FeS, CoS, ZnS, CdS, PbS, Bi_2S_3, SnS, and SnS_2, when boiled with a solution of cuprous chloride in sodium chloride, yield cuprous sulphide and the chlorides of the respective metals, or the products of their decomposition by water. When boiled with a dilute solution of cupric chloride, they yield cupric sulphide and the metallic chloride, except in the case of SnS, when cuprous sulphide, cuprous chloride, and a stannic compound are obtained, some sulphur being separated and some oxidised to sulphuric acid. Mercuric sulphide gives with cuprous chloride a yellow addition product of the formula HgS,CuCl; with dilute solutions of cupric chloride, it yields the same product, in addition to the compound, $2HgS,HgCl_2$, already known.

A. J. G.

Cupric Iodide. By M. TRAUBE (*Ber.*, **17**, 1064—1067).—On adding a very dilute solution of potassium iodide to a dilute solution of cupric sulphate, the separation of iodine, with precipitation of cuprous iodide, takes place very slowly. A solution of $\frac{1}{3}$ per cent. potassium iodide, when added to a 1 per cent. solution of cupric sulphate, only produces a precipitate in 10 minutes; one of $\frac{1}{4}$ per cent. becomes yellow in one hour; and one containing $\frac{1}{20}$ per cent. remains clear and colourless, does not give a blue coloration with starch solution, but gives the reaction of a cupric salt with caustic potash and potassium ferrocyanide. The author also finds that on sufficiently diluting a liquid containing a suspended precipitate of cuprous iodide and free iodine, in time the whole of the cuprous iodide is dissolved and the clear solution gives no reaction with starch solution; and that an aqueous solution of iodine may be freed from iodine by shaking it with an excess of cuprous iodide, owing to the formation of cupric iodide. This solution of cupric iodide is decomposed by ferrous sulphate in presence of hydrogen peroxide in acid solution, and in this it may be distinguished from other metallic iodides.

A. B.

Action of Cupric Sulphide on Potassium Sulphide. By A. DITTE (*Compt. rend.*, 98, 1429—1432).—When freshly precipitated cupric sulphide is mixed with a cold concentrated solution of potassium monosulphide, the liquid becomes orange-yellow, and after some hours the precipitate is converted into a mass of crystals, partly quadratic or octagonal plates, deep red by transmitted light, partly long slender needles with brilliant greenish facets. If the liquid is boiled, the cupric sulphide changes almost instantly into a bulky mass of slender needles, with a bronze colour and metallic lustre. All these crystals have the composition $K_2S,4Cu_2S$. If the alkaline sulphide solution is below a certain degree of concentration, the cupric sulphide is not altered even after several months.

This reaction is similar to that already observed in the case of mercuric sulphide, but the cupric sulphide is at first decomposed into cuprous sulphide and sulphur. The reaction $6CuS$, solid $+ K_2S$, dissolved $= 3Cu_2S$ solid $+ K_2S_4$ dissolved, develops approximately $+ 4{\cdot}6$ cal., but the concentration of the solution may change the sign of the thermal disturbance, and hence below a certain degree of concentration the cupric sulphide is not attacked. That the cupric sulphide is first decomposed in this manner is shown by the fact that when it is brought in contact with the colourless solution of potassium monosulphide, the latter becomes orange-yellow and behaves with acids like solutions of polysulphides. The precipitated cupric sulphide is not a mixture of cuprous sulphide and sulphur as Thomsen has supposed, for when brought in contact with an alkaline sulphide solution too dilute to convert it into the compound $K_2S,4Cu_2S$, the alkaline sulphide does not take up sulphur, although a solution of the same strength readily dissolves free sulphur.

The double sulphide can also be obtained in long needles by immersing metallic copper in a solution of the alkaline sulphide. If the liquid is exposed to air, the amount of the double compound gradually increases, but if it is contained in a closed vessel, the formation of the double sulphide ceases after a time. The action of the alkaline sulphide on the copper is due to the presence of oxygen, for if the solution is perfectly free from oxygen and the latter is carefully excluded, the copper is not attacked. The first reaction consists in the formation of potassium hydroxide and cupric sulphide, and the latter as fast as it is formed splits up into cuprous sulphide, which forms the double compound $K_2S,4Cu_2S$, and sulphur, which forms polysulphides. The reaction K_2S diss. $+ O + Cu = K_2O$ diss. $+ CuS$

solid, develops + 62·4 cal., and continues until all the oxygen is used up. The polysulphide which is formed, in its turn acts on the copper with formation of the double sulphide and potassium monosulphide, and at the end of the reaction the solution is quite colourless.

A solution of potassium sulphide too dilute to decompose cupric sulphide attacks metallic copper in presence of air or oxygen, but the product is the simple sulphide CuS. C. H. B.

Action of Mercuric Sulphide on Potassium Sulphide. By A. Ditte (*Compt. rend.*, **98**, 1380—1382).—The compound $K_2S,5HgS$ can be obtained in red needles similar in every respect, except colour, to the black crystals previously described (this vol., p. 893). These red crystals are formed when a solution of the alkaline sulphide containing an excess of mercuric sulphide is gradually heated to 35—40°, especially if a small quantity of vermilion is added. In such a solution, heated at 35—40°, but still clear, the formation of red or black needles is determined by adding a small quantity of vermilion or of the black crystals. The colour of the crystals varies from bright red to deep cinnabar-red, according to the concentration of the solution and the temperature. When a mass of the black needles is allowed to stand in the alkaline sulphide solution in a closed vessel for some time, those crystals which are in contact with the sides of the vessel are gradually converted into the red variety. These are stable in the alkaline liquid in the cold, but if heated they are reconverted into the black variety, the change being more rapid the more concentrated the solution.

If the alkaline sulphide solution at the ordinary temperature contains but a small quantity of the compound HgS,K_2S, it yields on boiling a black deposit, which contains not only black crystals of $K_2S,5HgS$, but also mercuric sulphide in black hexagonal plates. If such a solution is gradually heated in a water-bath and mixed with a trace of vermilion, a red deposit is obtained consisting of red needles of the composition $K_2S,5HgS$, and red transparent rhomboidal lamellæ of mercuric sulphide. With a certain degree of concentration of the solution, the latter is practically the sole product.

It is evident, therefore, that the simple sulphide HgS and the double sulphide $K_2S,5HgS$ can be obtained simultaneously in either red or black crystals, but when one is red the other is red, and when one is black the other is also black.

These facts explain the wet process for the manufacture of vermilion. In this process precipitated black mercuric sulphide is digested with potassium sulphide solution, care being taken that the temperature does not rise above 45°. A certain quantity of the double sulphide $K_2S,5HgS$ is formed, but as the temperature of the liquid, which is not constant, rises slightly, the double compound is decomposed and yields red crystalline mercuric sulphide. When the temperature falls somewhat, a further quantity of the double compound is formed at the expense of the more easily attacked amorphous sulphide. This in its turn is decomposed by the next rise of temperature, and so on until the whole mass is converted into vermilion.

C. H. B.

Arsenotungstic Acids. By M. Fremery (*Ber.*, **17**, 296—297).—By decomposing barium tungstate, $BaWO_4$, suspended in an aqueous solution of arsenic acid, with the calculated quantity of sulphuric acid and digesting on the water-bath, the author obtained a golden-yellow solution, which, when concentrated in a vacuum over sulphuric acid, yielded crystals of an *arsenotungstic acid* in the form of long hexagonal plates. These crystals are stable, and the saturated solution at 16° has a sp. gr. of 3·279. Carbonates, when added to the aqueous solution of this acid, cause it to split up again into its constituents, but crystallisable salts were obtained by adding the nitrates of the metals and concentrating on the water-bath. The *potassium, sodium, ammonium, copper, cobalt,* and *nickel salts* crystallise well; the *barium salt* is microcrystalline, and the *silver salt* forms a brown precipitate. The analytical results obtained for the ammonium salt correspond approximately with the constitution

$$19WO_3,As_2O_5,3(NH_4)_2O,18H_2O;$$

and for the potassium salt with $19WO_3,As_2O_5,3K_2O,16H_2O$.

The author also obtained a second arsenotungstic acid differing from the first in crystalline form, and in the density of its saturated solution, which is 2·241 at 16°. L. T. T.

Action of Hydrogen Peroxide on Molybdates. By C. Baerwald (*Ber.*, **17**, 1206).—Commercial ammonium molybdate,

$$(NH_4)_6Mo_7O_{24} + 4H_2O,$$

dissolves in hydrogen peroxide, forming a yellow solution, which deposits lemon-coloured crystals belonging to the monoclinic system—

$$a : b : c = 1·4727 : 1 : 1·0268. \quad \beta = 74° 32'.$$

Similar compounds of potassium, sodium, magnesium, barium, silver, and lead were prepared. W. C. W.

Reduction of Molybdenum Sulphide. By O. F. v. d. Pfordten (*Ber.*, **17**, 731—736).—Both the bisulphide and trisulphide of molybdenum are completely reduced to metal when strongly heated in a current of dry hydrogen. In the case of the native sulphide (molybdenum glance), whose reduction is slightly more difficult to effect than that of the artificial sulphides, the metal is obtained in pseudomorphs of the mineral. It appears to be more convenient to prepare the metal in this way from the sulphide than by reduction of the oxide, the method usually employed. In estimating molybdenum, it is better to weigh as metal than as bisulphide, as there is some fear of the latter being partially reduced during the heating in hydrogen.

A. J. G.

Ferrous Chloride. By V. Meyer (*Ber.*, **17**, 1335—1338).—The author has redetermined the vapour-density of this substance, using a porcelain vessel and an atmosphere of hydrochloric acid gas. The hydrochloric acid prevents the decomposition, which was previously noted, of a trace of the ferrous chloride into iron and ferric chloride. The numbers obtained were 6·67 and 6·38. $FeCl_2$ requires 4·39, Fe_2Cl_4 8·78. It would seem, therefore, that ferrous chloride, like stannous chloride, has the double molecule Fe_2Cl_4 at low temperatures, the simple one $FeCl_2$ at high temperatures, but that the temperature employed (bright yellow heat) was not high enough to cause the complete formation of the simpler molecules. L. T. T.

Colloidal Derivatives of Ferric Hydroxide. By E. GRIMAUX (*Compt. rend.*, **98**, 1485—1488 and 1540—1542).—When potassium hydroxide is added to a mixture of glycerol and ferric chloride, a precipitate is formed soluble in excess, and the solution has the characteristic properties of the colloidal solutions previously described (this vol., p. 905). The tendency to coagulate is diminished by the presence of a large amount of glycerol, and increased by the presence of sodium chloride or of potash in excess. If the proportion of glycerol is very large, coagulation is entirely prevented. When solutions rich in glycerol are dialysed, they first lose their excess of potash, then their excess of glycerol, and become coagulable by heat, and finally they form a firm thick jelly containing glycerol, ferric hydroxide, and potash. Similar solutions are obtained by substituting either ammonia or soda, or sodium or potassium carbonate for potash. They seem to be compounds of glycerol, ferric hydroxide, and alkalis, and are easily dissociated by water into glycerol and insoluble compounds richer in ferric hydroxide. With acetic acid, they yield a precipitate soluble in excess, and this solution gives a greenish precipitate with potassium ferrocyanide, converted into Prussian blue by the action of a mineral acid.

Mannitol, erythrol, and sugar yield solutions having precisely similar properties.

Ferropotassium tartrate also forms colloidal solutions with similar properties, but they are not precipitated by potash in the cold, and the precipitate with carbonic anhydride is ochreous, and resembles ferric hydroxide. Potassium ferrocyanide produces a violet coloration, and Prussian blue is precipitated from this solution on adding an acid.

When a solution of ferric chloride is added to a solution of sodium arsenate, a precipitate of ferric arsenate is formed, but redissolves in excess of ferric chloride, forming a colloidal solution, which yields an opaque yellowish-white coagulum of the composition $Fe_2(AsO_4)_2$. In preparing this solution, excess of ferric chloride must be avoided, since this substance prevents coagulation by heat. If the solution is dialysed, it loses sodium chloride, and the jelly which forms is perfectly transparent and of a pale yellow colour, but by prolonged dialysis it becomes reddish-yellow.

Potassium arsenite and ferric chloride yield a similar solution, which is very unstable, and coagulates spontaneously. With potash, it forms a precipitate soluble in excess, and when this solution is dialysed it yields a colloidal solution of ferropotassium arsenite, which does not gelatinise on heating unless mixed with potash solution, when a thick brown jelly resembling ferropotassium tartrate is formed. Arsenious acid therefore resembles tartaric acid in its behaviour with ferric salts.

Boric acid and sodium phosphate behave like arsenic acid, but in the case of the phosphate the solution shows less tendency to coagulate.

A 2·26 per cent. solution of silica, obtained by the decomposition of methyl silicate, forms with ferric chloride and excess of potash a limpid solution, which becomes turbid after a few minutes.

C. H. B.

Hydrates of Cobaltous Chloride. By A. POTILITZIN (*Ber*, **17**, 276—283).—As is well known, hydrated cobaltous chloride changes in colour under varying conditions of temperature, &c. Bersch (*Sitzungsber. d. Wiener Akad.*, **56**, 724) states that three hydrates exist, namely, $CoCl_2 + 6H_2O$, which is red in colour at ordinary temperatures, melts at 86°, and begins to lose water at 111°; a rose-coloured $CoCl_2 + 4H_2O$, formed from the hexhydrate at 116°; and $CoCl_2 + 2H_2O$, formed from the two last-named hydrates by heating them at 121°. He further states that all these hydrates when heated turn blue, the dihydrate existing in two modifications, even at ordinary temperatures; the one mentioned above being of a dark violet colour, the other, obtained by drying the hexhydrate over sulphuric acid, forming a rose-coloured crystalline powder having a slight violet tint, and finally that all lose water at 140° and yield the anhydrous salt.

The author has reinvestigated this subject, and cannot confirm Bersch's statements. Crystals of the hexhydrate begin to lose water at about 30—35°, and at 45° effloresce tolerably quickly, about four hours' heating at the latter temperature converting them into the dihydrate, which is of a rose colour, having a slight tint of violet. This same dihydrate is obtained if the hexhydrate is kept four or five days over sulphuric acid under a bell-jar. The colour, &c., is identical in both cases. The dihydrate absorbs moisture when exposed to the air, and becomes reconverted into the hexhydrate. At a little below 100°, the dihydrate is very slowly converted into a dark violet monohydrate, which is exceedingly hygroscopic, absorbing moisture from the air, and being reconverted into the hexhydrate. When a solution of $CoCl_2 + 6H_2O$ in absolute alcohol is slowly evaporated in an air-bath at 90—95°, it deposits the same monohydrate in the form of fine silky violet-coloured needles. In very thin layers, this salt is almost colourless, and as the thickness of the layers increases the colour passes through various shades of violet, until with a thick layer it is almost the same as that of a concentrated alcoholic solution of cobaltous chloride. At 110—120° the monohydrate loses its last molecule of water, but this is always accompanied by a slight loss of hydrochloric acid, the anhydrous salt thus formed always leaving a slight brown residue of oxide when dissolved. The anhydrous salt rapidly absorbs moisture if exposed to the air.

The author draws the following conclusions from the results obtained:—The temperatures given by Bersch for the decomposition and formation of the various hydrates are arbitrary and incorrect. The dihydrate $CoCl_2 + 2H_2O$ exists only in one form, and is of a rose colour with a slight shade of violet. There are three distinct hydrates of cobaltous chloride, $CoCl_2 + 6H_2O$, $CoCl_2 + 2H_2O$, and $CoCl_2 + H_2O$. The change of colour which occurs on heating is due to the separation of the water; all dehydrating agents (as alcohol, hydrochloric acid, &c.) may therefore cause change of colour even at low temperatures.

The author suggests that the incorrectness of Bersch's results is probably due to his not allowing time for the dissociation to be completed. Even porous hygroscopic substances, such as filter-paper, cause dehydration of these salts; a drop of a concentrated aqueous solution of cobaltous chloride placed on filter-paper always shows a blue edge as it dries. L. T. T.

Compounds of Gold Chlorides with Phosphorus Chlorides. By L. LINDET (*Compt. rend.*, **98**, 1382—1384).—*Aurous phosphorous chloride*, $Au_2Cl_2,2PCl_3$, is obtained by heating aurous chloride (prepared by reducing auric chloride at 185—190°) with excess of phosphorous chloride in sealed tubes at 110—120° for an hour. The aurous chloride dissolves in the phosphorous chloride, and on cooling the double chloride is deposited in large colourless oblique prisms. The double chloride is stable in dry air, and is infusible and non-volatile, but it decomposes above 100° with evolution of phosphorous chloride, and a complex residue is left. When treated with water or exposed to moist air, it is decomposed with formation of phosphorous acid and metallic gold. Chlorine and phosphoric chloride convert it into the double auric phosphoric chloride.

Auric phosphoric chloride, $AuCl_3,PCl_5$, can be obtained by the direct combination of auric chloride and phosphoric chloride, but it is most easily prepared by heating aurous chloride in sealed tubes at 120—130° for several hours with a solution of two equivalents of phosphoric chloride dissolved in phosphorous chloride. It forms citron-yellow microscopic needles, which are insoluble in and are not attacked by phosphorous chloride, but in contact with metallic gold and phosphorous chloride, they are reduced to aurous phosphorous chloride. At about 120°, it dissociates into auric chloride and phosphoric chloride; it is decomposed by water.

Both these compounds can be produced simultaneously by treating auric chloride with phosphorous chloride at 120°, or by treating metallic gold with phosphoric chloride. In the latter case, one or the other double salt can be obtained alone by using proper proportions of gold and of phosphoric chloride. C. H. B.

Mineralogical Chemistry.

Rubidium, Cæsium, Lithium, and Boric Acid in Chili Saltpetre. By DIEULAFAIT (*Compt. rend.*, **98**, 1545—1548).—Grandeau found in 1863 that the beetroots in the north of France contain a relatively large proportion of rubidium, but are free from cæsium and lithium, but in beetroots from Lower Normandy, where no foreign substances had been used as manure, the author found neither cæsium nor rubidium, but distinct traces of lithium. In the north of France, Chili saltpetre is largely used as a manure, and the author finds that sodium nitrate from Chili and Peru, even after being once refined, contains sensible quantities of rubidium, mere traces of lithium, little or no cæsium, and an unusual quantity of boric acid. The source of the rubidium in the beetroot is obvious.

C. H. B.

Minerals from Upper Silesia. By B. KOSMANN (*Jahrb. f. Min.*, 1884, 2, Ref., 15—17).—The author has already published a paper on the same subject (Abstr., 1883, 955). He now describes at some length the minerals occurring in the ore deposits of the Muschelkalk of Upper Silesia. The minerals described are—zinc blende, iron pyrites, cerussite, dialogite, tarnowitzite, and calcite. Analyses of markasite from the Apfel Mine (1) and from Bleischarley (2) are given:—

	Fe.	Ni.	Pb.	Zn.	As.	S.	SiO_2.
I.	43·51	0·25	0·51	0·078	2·12	48·55	1·32
II.	42·27	0·185	0·124	0·147	0·71	50·15	1·30

	Al_2O_3.	CaO.	Total.
I.	0·89	2·78	100·008
II.	0·87	2·06	99·816

This the author believes to be a mixture of markasite, arsenical pyrites, nickel pyrites, blende, galena, and a silicate, $CaAl_2SiO_6$.

B. H. B.

Thenardite. By O. MÜGGE (*Jahrb. f. Min.*, 1884, 2, Mem., 1—10).—By observing the optical properties, at various temperatures, of natural and artificial thenardite (Na_2SO_4), as well as those of the mixed crystals of K_2SO_4 and Na_2SO_4, the author arrives at the conclusion that the theory of morphotropic relations between glaserite (K_2SO_4) and thenardite is, to a certain extent, correct.

In order to obtain artificial thenardite, Glauber's salt was heated not much above 45°; the interior of the crystals then fused, and, on cooling, a cavity was formed, lined with small transparent crystals of thenardite. Glauber's salt crystals, dried below 35°, give up their water, and pass over into amorphous thenardite. The mixed salt of equal parts of potassium and sodium sulphates crystallises optically uniaxial, and is positively doubly refracting. When heated, however, it becomes first isotropic and then optically negative. Pure potassium sulphate presents two similar modifications; the rhombohedral crystals are positive, whilst glaserite, on being heated, passes over into a hexagonal modification with negative double refraction. The author has also no doubt that thenardite, on being heated to 180—250°, passes over into a hexagonal modification, the true nature of which is observed with greater difficulty than in the salts previously mentioned, on account of its very weak double refraction. Similar weak double refraction has been observed in the double salt of potassium and lithium sulphates, whilst the double salt of potassium and sodium approaches an isotropic state only at a much higher temperature.

It is more difficult to explain how it is that the uniaxial modification of sodium sulphate, produced by heating the rhombic salt, is just as irregularly disposed as that obtained by fusion. The geometrical deviation from hexagonal symmetry is greater with thenardite than with glaserite. The slight variation of the refractive indices of the uniaxial modification, like their change in the mixed salt, perhaps indicates at the same time an approach to regular symmetry.

In conclusion, the author is of opinion that it is not merely by chance that the majority of the substances hitherto examined approach with increasing temperature a higher symmetry, or reach it, as in the case of arragonite, nitre, glaserite, silver iodide, leadhillite, and cryolite, but not of sulphur and mercury iodide; these substances pass over gradually, from the most highly differentiated crystalline state into the amorphous fluid state, so far as they can reach it without decomposition.

B. H. B.

Triclinic Potash Soda Felspar (Microclase). By F. J. Wiik (*Jahrb. f. Min.*, 1884, 2, Ref., 20).—The author proposes to apply the name microclase to the triclinic felspars, which stand nearer to orthoclase than albite, but are distinguished from the former by the crystal system, and from microline by the small extinction angle on the base, and from both by the percentage of soda. He describes a felspar of this class from St. Gotthard. The angle $0P : \infty P\breve{\infty}$ gave on an average 90° 24′. Sp. gr. 2·567. The analysis gave the following results (I) :—

	SiO_2.	Al_2O_3.	K_2O.	Na_2O.	Total.
I.	(66·40)	16·23	11·90	5·47	100·00
II.	(66·20)	18·87	10·37	4·56	100·00

A combination of $3K_2Al_2Si_6O_{16}$ with $2Na_2Al_2Si_6O_{16}$, would require the figures given under II.

B. H. B.

Analysis of the Foyaite from the Serra de Monchïque, Portugal. By P. Jannasch (*Jahrb. f. Min.*, 1884, 2, Mem., 11—13).—The analysis gave the following results :—

SiO	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CaO.	MgO.
54·20	1·04	21·74	0·46	2·36	0·11	1·95	0·52

K_2O.	Na_2O.	Li_2O.	Loss on ignition.	Total.	Sp. gr.
6·97	8·69	trace	2·32	100·36	2·578

B. H. B.

New Locality for Andesine at Orijärvi, in Finland. By H. Gylling (*Jahrb. f. Min.*, 1884, 2, Ref., 19).—On the crystals, the following planes were observed :—$0P$, $\infty P\breve{\infty}$, $\infty P\bar{\infty}$, $\infty P'$, $\infty' P$, $\infty P'\breve{2}$, $\infty' P\breve{2}$, ${}_{,}P_{,}\bar{\infty}$, $'P_{,}\breve{\infty}$, $2'P_{,}\breve{\infty}$, $'P$, P', ${}_{,}P$, $2P$, $2P\bar{2}$.

The analysis gave :—

SiO_2.	Al_2O_3.	CaO.	Na_2O.	Loss.	Total.	Sp. gr.
57·37	26·09	8·13	7·96	0·70	100·25	2·68

B. H. B.

Solubility of the Labradorite from St. Paul Island. By P. JANNASCH (*Jahrb. f. Min.*, 2, Mem., 42—44).—These experiments were undertaken to solve the question whether the felspars, regarded as an isomorphous mixture of sodium-aluminium and calcium-aluminium silicates, when treated with hydrochloric acid, give up the anorthite portion, or whether the whole of the felspar substance is partially soluble. The results are in favour of the latter view. I is the analysis of the labradorite (sp. gr. 2·688); II, that of the acid solution; and III, that of the felspar remaining insoluble in hydrochloric acid:—

	SiO_2.	Al_2O_3.	FeO.	MnO.	CaO.	MgO.	Loss on ignition.	K_2O.
I.	54·09	27·82	1·50	trace	11·20	0·05	0·19	0·43
II.	52·23	26·96	1·98	trace	13·25	0·12	—	0·23
III.	54·34	29·36	0·22	trace	10·79	—	—	0·46

	Na_2O.	Li_2O.	Total.
I.	4·76	trace	100·04
II.	5·23	trace	100·00
III.	5·49	—	100·66

B. H. B.

Relation between the Optical Properties and Chemical Composition of Pyroxene and Amphibole. By F. J. WIIK (*Jahrb. f. Min.*, 1884, 2, Ref., 21).—The following data serve as an addition to the former paper on the same subject (Abstr., 1883, 560):—

	FeO per cent.	Extinction angle on clinopinacoid.
Diopside from Achmatowsk	2·00	37° 30′
Diopside from Pargas	2·25	38
Diopside from Ala	—	39
Diopside from Zillerthal	2·51	38°—39°
Augite from Nordmarken	17·31	45° 45′
Augite in the olivine diabase of Ewra (West Finland)	18·35	46°

The examination of a number of augites from basaltic rocks gave results which do not agree with the series.

	FeO per cent.	Extinction angle on clinopinacoid.
Augite from basalt tuff from Teplitz	5·45	46° 30′
Augite from Monti Rossi	7·89—11·39	48° 50′
Augite from Vesuvius	4·55— 9·08	45° 30′ and 49°
Augite from Frascati	10·80	54°

The author is therefore of opinion that a basaltic augite must be distinguished analogous to the basaltic hornblende. The latter also seems to have optical properties different from the ordinary hornblende occurring in older rocks. The hornblende from the basalt-wake of Schima, with an alumina percentage of 17·59, gave an extinction angle on the clinopinacoid of only 10°. B. H. B.

Kelyphite. By A. SCHRAUF (*Jahrb. f. Min.*, 1884, 2, Mem., 21—26).—If the large amphibole group be divided into two classes of nearly equal form and optical symmetry, namely, the actinolite division, $RSiO_3$, and the hornblende division, $x(RSiO_3) + y(R_2SiO_4)$, in which y is greater than x, kelyphite may be identified with hornblende. B. H. B.

Ganomalite. By A. SJÖGREN (*Jahrb. f. Min.*, 1884, 2, Ref., 23—24).—This mineral, discovered by Nordenskiöld at Laangban (Abstr., 1879, 22), has recently been obtained from Jakobsberg, in Nordmarken. System tetragonal. Columnar crystals with the planes: ∞P, P, $\infty P4$, $0P$. $\infty P : P = 135°$. Cleavage distinct, parallel to ∞P and $0P$. Fracture uneven. H. = 3. Sp. gr. 5·738. Colourless, greasy to glassy lustre. Becomes dull and whitish on exposure by the oxidation of the lead. Optically positive. Strong refraction. Weak interference colours. Fuses in thin splinters in candle flame. Soluble in warm nitric acid. The analyses, made with impure material, lead to the formula $2PbO,CaO,2SiO_2$. B. H. B.

Analysis of Ganomalite. By G. LINDSTRÖM (*Jahrb. f. Min.*, 1884, 2, Ref., 25).—Ganomalite, from Jakobsberg, carefully purified by the magnet and by iodide solution, gave on analysis the following results:—

SiO_2.	PbO.	CuO.	MnO.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.
18·33	68·80	0·02	2·29	0·07	0·12	9·34	0·11

Alkalis.	P_2O_5.	Cl.	Ignition.	Total.
0·10	0·04	0·24	0·57	100·03

From this the formula $3PbO,2SiO_2 + 2RO,SiO_2$ is deduced.

B. H. B.

Tephroite. By A. SJÖGREN (*Jahrb. f. Min.*, 1884, 2, Ref., 24—25).—Crystals of tephroite from Laangban were found to belong to the rhombic system. Colour, grey; transparent; glassy to greasy lustre. Fracture conchoidal to splintery. H. = 5·5 to 6. Sp. gr. 3·95—4·02. Fuses before the blowpipe with difficulty to a brownish cloudy glass. Gelatinises with warm hydrochloric acid. The following forms were observed:—$\infty P\bar{\infty}$, ∞P, $\infty P\breve{2}$, $\infty P\bar{\tfrac{10}{9}}$, $P\breve{\infty}$, P, $2P\breve{2}$, $3P\breve{3}$. The analysis gave:—

SiO_2.	MnO.	MgO.	Total.
31·39	65·34	3·15	99·88

B. H. B.

The Rocks of Noyang. By A. W. HOWITT (*Jahrb. f. Min.*, 1884, 2, Ref., 59—61).—The author describes the eruptive rocks occurring at Omeo, Gippsland, Victoria. The rocks in the district are quartz-mica diorites (Analysis I), traversed by porphyritic masses. In contact with these dykes, porphyritic varieties of quartz-mica diorites (Analyses II and III) occur. Somewhat more recent than the quartz-mica porphyrites are dykes of quartz-porphyrite (Analysis IV), and quartz-felsophyrites. The diorites and porphyrites are traversed by dykes of "greenstone." A greenstone dyke (Analysis V), about 30 inches wide, is described by the author as a diorite, not far removed from the amphibolised diabases. A true diabase dyke, the only one observed by the author, occurs in the quartz-mica diorite at Navigation Creek.

Rock from the Volcano Yate. By H. ZIEGENSPECK (*Jahrb. f. Min.*, 1884, 2, Ref., 58).—Four specimens were examined from the Volcano Yate, south of the Boca de Reloncavi, South Chili. The first, from the northern foot of the volcano, is a porphyritic rock (Analysis II) containing felspar (Analysis I), olivine, augite, and magnetite. The ground-mass consists principally of felspar with augite crystals, and but little granular isotropic basis. The second sample, of a slag-like structure, contains felspar, augite, and magnetite in a brown isotropic basis. The third rock (Analysis III) contains plagioclase, augite, magnetite, and apatite in a dark ground-mass, poor in glass. The fourth rock (Analysis IV) is compact, and weathered on the surface. It contains plagioclase, augite, magnetite, and apatite in a microlithic ground-mass.

	Na_2O.	Loss on ignition.	Total.	Sp. gr.
I.	4·43	0·48	99·94	2·74
II.	2·38	0·28	99·45	2·76
III.	6·54	2·23	99·52	2·55
IV.	4·90	2·88	99·56	2·52

In Analyses II, III, and IV, traces of HCl, P_2O_5, and SO_3 were detected, and in III and IV also traces of copper. The author classes the first rock as basalt, the others as augite-andesite. B. H. B.

Krakatoa Ashes. By A. v. Lasaulx, A. Sauer, J. H. Kloos, A. Renard, and A. Daubrée (*Jahrb. f. Min.*, 1884, 2, Ref., 53—58).—There can be no doubt that the Krakatoa eruption yielded ashes of enstatite-andesite. All the observers give labradorite, augite, magnetite, and apatite. Hornblende and iron pyrites are also stated to be present by one observer. The principal mass of the ashes consists of a pumiceous glass.

The chemical composition of the ashes which fell in Batavia is determined by an analysis (I) by Sauer, and also by Renard (II). Sauer also found 0·82 substance soluble in water, consisting principally of lime and sulphuric acid, with traces of potash and soda. He also analysed the ashes carefully freed from crystalline substances, and found the composition given under III. Both Renard and Sauer also analysed a sample of ashes, collected from His Majesty's ship "Elizabeth," 300 nautical miles from the Sunda Straits. This was found to be identical with the material from Batavia.

Krakatoa Ashes. By K. Oebbeke (*Jahrb. f. Min.*, 1884, 2, Mem., 32—33).—The author gives analyses of the ashes which fell on the ship "Barbarossa," on the 27th August, 1883. The results obtained by him were as follows:—I, complete analysis; sp. gr. 2·38. II, portion soluble in hydrochloric acid, 7 per cent. III, portion insoluble in hydrochloric acid, 93 per cent.

	SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CaO.	MgO.
I.	68·06	0·38	15·03	0·28	3·66	trace	2·71	0·81
II.	50·45	trace	14·05	17·10		—	5·65	3·80

B. H. B.

Analysis of Volcanic Ashes from Krakatoa. By D. DE LOOS *Ber.*, **17**, 999—1000).—These ashes were collected after the eruption f August, 1883, in Java, and were found to consist of 0·80 per cent. f matter soluble in water (silica, sulphuric acid, chlorine, calcium, otassium, sodium), 5·70 per cent. soluble in acid (chiefly ferric oxide nd alumina), and 93·50 per cent. of insoluble matter. This insouble part consisted of 64·05 per cent. silica, 6·54 per cent. ferric xide, and a trace of ferrous oxide, 13·08 per cent. alumina, and ·80 per cent. calcium oxide. A. B.

Classification of Meteorites. By G. TSCHERMAK (*Jahrb. f. Min.*, 884, **2**, Ref., 25—28).—The author proposes the following classification:—

I. Meteorites, consisting principally of iron.
    Meteoric iron.

II. Iron ground-mass, with enclosed silicates.
    Pallasite—iron and olivine,
    Mesosiderite—iron, olivine, and bronzite,
    Siderophyr—iron and bronzite,
    Grahamite—iron, plagioclase, olivine, bronzite.

III. Olivine and bronzite, with subordinate iron.
    Chondrite.

IV. Olivine, bronzite, pyroxene.
    Chassignite—olivine,
    Amphoterite—olivine and bronzite,
    Diogenite—bronzite or hypersthene,
    Bustite—diopside and enstatite.

V. Augite, bronzite, and lime-felspar.
    Howardite—augite, bronzite and plagioclase.
    Eukrite—augite and anorthite. B. H. B.

Peculiar Concretions in Iron Meteorites. By L. SMITH (*Amer. J. Sci.*, 25, 417—423).—The author calls attention to the more or less globular concretions in the interior of meteoric iron, which seem but rarely to be absent. These concretions consist of troilite, schreibersite, graphite, daubréelite, lawrencite, or chromite. Each of these concretions is almost as characteristic of meteoric iron as the nickeliferous alloy of the metal. The troilite concretions are often somewhat complex in their character. 8 grams from the Cranbourne iron were treated with petroleum ether, dilute hydrochloric acid, and nitric acid, and the magnet was applied to the residue. In this way, celestialite, sulphur, a compound of sulphur and carbon, schreibersite, daubréelite, graphite, silica, and a cobalt mineral were determined.

B. H. B.

The Bishopville and Waterville Meteorites. By M. E. WADSWORTH (*Amer. J. Sci.*, 26, 22—38).—The meteorite of Bishopville, South Carolina, was found on microscopic examination to consist of the following minerals: enstatite, felspar, monoclinic pyroxene, olivine, pyrrhotine, and nickel-iron. The enstatite contains many glass inclusions, microliths, chromite and metallic grains. The felspar is mostly plagioclase, with exceedingly fine twinning bands. It contains numerous yellowish-brown, dark, or almost colourless inclusions, and minute crystals of enstatite in rosette-like forms. In its mineralogical composition and its structure the meteorite resembles gabbro (norite).

The doubtful meteorite of Waterville, Maine, proves to be a laminated ash-grey, cellular, cinder-like slag, consisting of a cellular, glassy mass, which has begun to devitrify, and has been long exposed to the action of atmospheric agencies. B. H. B.

The Alfianello Meteorite. By H. v. FOULLON and W. FLIGHT *Jahrb. f. Min*, 1884, 2, Ref., 30—32).—This meteorite has already been described in detail (Abstr, 1883, 1071).—I gives the results of Foullon's analysis of material from six specimens; II, the composition of the portion soluble in acid; III, that of the insoluble silicates. II*a* and III*a* give the results obtained by Flight:—

	I.	II.	II*a*.	III.	III*a*.
SiO_2	39·14	35·05	35·12	56·22	56·12
Al_2O_3....	0·93	0·41	1·52	1·64	$[Cr_2O_3 = 8·28]$
FeO	17·42	28·53	51·43	12·16	13·40
CaO	1·96	0·55	4·64	4·16	6·71
MgO....	25·01	35·46	7·27	23·76	17·26
Na_2O....	0·75	—	—	2·06	—
K_2O	0·10	—	—		
Fe......	11·31	—	—	—	—
Ni......	1·09	—	—	—	—
S	2·71	—	—	—	—
Totals...	100·42	100·00	99·28	100·00	101·77

From these results the mineralogical composition is calculated (IV) by Foullon, and (V) by Flight.

IV.		V.	
Bronzite and felspar..	41·37	Insoluble silicates..	40·12
Olivine	43·77	Soluble silicates....	50·86
Nickel iron	7·66	Nickel iron........	2·11
Magnetic pyrites	7·45	Troilite	6·92

The results given under II and II*a*, III and III*a*, do not agree very well, and the high percentage of chromium in III*a* is especially remarkable. In the analysis III*a*, the percentage of silica is also too high for an olivine so rich in iron. B. H. B.

The Rowton and Middlesbrough Meteorites. By W. FLIGHT (*Jahrb. f. Min.*, 1884, 2, Ref., 28—30).—The iron meteorite of Rowton is the first whose fall has been observed in Great Britain. It took place on April 20th, 1876, at 3.40 p.m. Analysis I gives the composition of the nickel iron; II, that of the troilite. The iron yielded 6·38 times its volume of gas, an analysis of which is given (III):—

	I.		II.		III.
Fe....	91·15	Fe....	63·93	CO_2....	5·15
Ni....	8·67	S	36·07	H	77·78
Co....	0·34			CO....	7·34
Cu....	trace			N	9·72

The Middlesbrough meteorite fell on the 14th of March, 1881, at 3.35 p.m. The sound resembled the boom of a gun, but no luminous or cloud-forming phenomena are reported. The stone weighed 3 lb. 8¼ oz., and forms a low pyramid. It has a greyish-white colour, and is for the most part composed of silicates. The metallic particles (9·38 per cent.) obtained by treating with mercuric chloride gave on analysis the following results:—

Fe.	Ni.	Co.	Total.
76·99	21·32	1·69	100·00

Of the remaining constituents 59·94 per cent. were soluble silicates (Analysis II), and 40·06 per cent. insoluble (Analysis III). The analysis of the soluble portion indicates the presence of

$$2(Mg,Fe)O,SiO_2.$$

No lime and no alumina were found. The insoluble portion is bronzite, or, as is more probable, augite with labradorite.

	SiO_2.	Al_2O_3.	FeO.	CaO.	MgO.	Total.
II.	41·10	—	27·96	—	30·94	100·00
III.	55·39	4·77	23·58	4·37	11 04	99·15

B. H. B.

The Nogoya Meteorite. By WEBSKY and DAUBRÉE (*Jahrb. f. Min.*, 1884, 2, Ref., 32).—The meteorite fell at Nogoya, in the Argentine Republic. in the winter of 1880, with distinct luminous phenomena. The form is that of a spheroid, 15—13 cm. in diameter. The weight is 4½ kg. It belongs to the carbonaceous meteorites, and resembles most closely that of Cold Bokkeveld. B. H. B.

Mineral Water from Aruba. By D. de Loos (*Ber.*, 17, 999).—This mineral water, from Antikroeri, in the West Indian island of Aruba, has been analysed, and found to contain no copper salts, as was supposed. One litre of the water contains 11·16 grams mineral salts, of which 2·13 grams are magnesium chloride, and the remainder chlorides and sulphates of the alkalis, along with a little calcium sulphate. A. B.

Composition of Borhegyer Water. By M. Ballo (*Ber.*, 17, 673—674).—This mineral water, from the vicinity of Bibarczfalva, in the Siebenbürgen, contains in grams per litre:—

Calcium carbonate	0·65040
Magnesium carbonate	0·42075
Sodium carbonate	0·37489
Lithium carbonate	0·00646
Ferrous carbonate	0·07428
Manganous carbonate	0·01824
Potassium sulphate	0·00034
Sodium chloride	0·10971
Potassium chloride	0·05820
Sodium bromide	0·00046
Sodium iodide	0·00018
Alumina	0·00952
Phosphoric acid	traces
Silica	0·08454
	1·80797
Total carbonic anhydride	3·13008
Carbonic acid present as bicarbonates	1·4023
Free carbonic anhydride	1·72778

Organic Chemistry.

Monobromomethyl Chloroform (Bromotrichlorethane). By L. Henry (*Compt. rend.*, 98, 370—372).—This compound, $CCl_3.CH_2Br$, may be obtained by heating the trichlorethane, $CCl_3.CH_3$, with bromine at 150—160° in sealed tubes, but higher brominated derivatives are formed at the same time. It is more conveniently prepared by the action of antimony pentachloride on $CCl_2Br.CH_2Br$ or $CClBr_2.CH_2Br$. It is a colourless mobile liquid of ethereal odour boiling at 151—153°, Its sp. gr. at 0° is 1·8839. When treated with alcoholic potash, it is decomposed, the elements of hydrochloric acid being eliminated and the compound $CCl_2 : CHBr$ formed; this is a colourless liquid which boils at 114—116°. It has a powerful odour and rapidly absorbs oxygen on exposure to the air.

The following table gives the properties of the chlorinated bromethanes:—

	B. p.	Density.
$CH_2Br.CH_3$	38°	1·4733
$CH_2Br.CH_2Cl$	108	1·7387
$CH_2Br.CHCl_2$	138	1·8587
$CH_2Br.CCl_3$	151	1·8839

C. E. G.

Propargyl Iodide. By L. Henry (*Ber.*, **17**, 1132—1133).—Propargyl iodide, prepared by the action of sodium iodide on propargyl bromide in alcoholic solution, is a pale-yellow liquid boiling at 115°, sp. gr. at 0° 2·0177, non-miscible with water. It unites with mercury forming a yellow crystalline compound, C_3H_3HgI, and with iodine, yielding propargyl triiodide, $C_3H_3I_3$, which is deposited from a warm ethereal solution in colourless needles melting at 40°. An addition-product of the composition $(C_3H_3I_2)_2HPO_2$ is formed by the action of iodine and amorphous phosphorus on propargyl alcohol (*Ann. Soc. scientifique Bruxelles*, 1878). W. C. W.

Second Anhydride of Erythrol, $C_4H_6O_2$. By S. Przybytek (*Ber.*, **17**, 1091—1096).—This dioxide has been obtained by the action of potassium hydroxide on erythrol dichlorhydrin, and is a complete internal anhydride of erythrol as shown by the formula  $CH_2—CH.CH—CH_2$. Erythrol dichlorhydrin, melting at 124°, was prepared by the action of concentrated hydrochloric acid on erythrol at 100°. The dichlorhydrin was dissolved in ether, and powdered potassium hydroxide added as long as any reaction took place; this reaction was observed by the precipitation of potassium chloride and the slight boiling of the ether. After the separation of the precipitate, the ether was evaporated off, and the new oxide distilled. It is a colourless mobile liquid boiling at 138°, and has a disagreeable peculiar odour and a burning taste. The sp. gr. at 0° is 1·1322, at 18° 1·1132. It is extremely volatile, passing over with the vapour of ether.

Analysis leads to the formula $C_4H_6O_2$. The estimation of the vapour-density by Meyer's method with aniline vapour gave it as 3·12—3·20, whilst that calculated for $C_4H_6O_2$ is 2·91.

The chemical properties of this compound show that it has the above constitutional formula. It combines with water, acids, and ammonia, to form addition-products in the proportion of 1 mol. to 2 mols. water or 2 mols. monobasic acid. It mixes in all proportions with water, and combines with it to form erythrol, somewhat slowly at the ordinary temperature, more quickly at 100°. Hydrochloric acid converts it into the original dichlorhydrin. It combines with dry hydrocyanic acid at 50—55° to form the nitrile of dihydroxyadipic acid, $C_4H_6(OH)_2(CN)_2$. When heated with 2 mols. hydrocyanic acid at 50—55° for four or five hours, it forms an amorphous mass of nitrile, and this when treated with potash gives ammonia, and is converted into the potassium salt of dihydroxyadipic acid. The capacity of this oxide to combine with acids is so strong that it will precipitate magnesia and cupric oxide from their soluble salts. With ammoniacal silver nitrate, it gives a silver mirror. It combines with 2 mols. of aniline to form an addition-product, $C_{16}H_{20}N_2O_2$, insoluble in water and ether, and combining with mineral acids to form salts. The hydrochloride of this aniline compound, $C_{16}H_{20}N_2O_2,2HCl$, forms large colourless plates. The same salt can be obtained by heating the dichlorhydrin with aniline at 100°.

The properties of this oxide are analogous to those of the series $C_nH_{2n}O$. It is the first member of a series of dioxides which would have the general formula $C_nH_{2n-2}O_2$. The author is at present engaged in preparing the dichlorhydrin, $C_6H_{12}O_2Cl_2$, by the action of hypochlorous acid on diallyl, and hopes to obtain a dioxide from it by the action of potassium hydroxide.
A. B.

Lactose and Mucic Acid. By W. H. Kent and B. Tollens (*Ber.*, **17**, 668).—In preparing lactose from milk-sugar, hydrochloric acid gives better results than sulphuric acid. The action of nitric acid in systematically increased amounts on milk-sugar and on lactose has been investigated. In favourable cases there has been obtained from milk-sugar 38 per cent., and from lactose 77 per cent. of mucic acid. 10—15 per cent. solutions of lactose show a rotary power $[\alpha]_D = 81·4—81·7°$. Lactose yields lævulinic acid when heated with hydrochloric acid.
A. J. G.

Lactosin: a New Carbohydrate. By A. Meyer (*Ber.*, **17**, 685—692).—Lactosin is a crystalline carbohydrate occurring largely in the Caryophyllaceæ, in which it plays the same part as inulin in the Compositæ. It is best prepared from the roots of *Silene vulgaris*, those gathered in autumn being richest in lactosin. The grated roots are pressed, the juice mixed with an equal volume of alcohol (95 per cent.), and allowed to stand twelve hours; the precipitated proteïds are then filtered off, the filtrate mixed with an amount of alcohol equal to three times the original volume of the juice, and allowed to stand 24 hours. The precipitate is dissolved in a little water and again precipitated with alcohol; the crude lactosin so obtained still contains 2·1 per cent. of ash. It is best purified by precipitation from aqueous solution by lead acetate and ammonia; the sparingly soluble lead compound is decomposed by hydrogen sulphide, the aqueous solution concentrated, and, whilst still hot, precipitated by alcohol; the precipitate is dissolved in water, evaporated on the water-bath, and dried over sulphuric acid. Amorphous lactosin so obtained is free from ash, and shows all the properties of the crystalline form, except that the specific rotation = +105°. Probably lactosin exists in two modifications mainly distinguished by the difference in their rotary powers.

Crystalline lactosin is prepared from the amorphous form by boiling it for some days in a vessel provided with a reflux condenser with an amount of alcohol of 80 per cent. insufficient for complete solution. It forms small colourless, lustrous crystals of the formula $C_{36}H_{62}O_{31} + H_2O$, loses its water on long heating at 100°, and has the specific rotation $[\alpha]_D = +211\cdot7°$. It is moderately soluble in water, the colourless solution resembles an aqueous solution of dextrin in its physical properties, is not precipitated by lead acetate, basic lead acetate, or lime-water, but is precipitated by lead acetate and ammonia. It does not reduce Fehling's solution of the ordinary strength, but appears to exert a slight reducing action on weak solutions. An alcoholic solution is precipitated by basic lead acetate and by lime-water, but not by normal lead acetate. Addition of alcoholic potash or soda precipitates the potassium or sodium derivatives of lactosin.

On inversion, lactosin yields lactose and a sugar of rotary power equal to about +17°, whose investigation will be continued.

A. J. G.

Gallisin, the Unfermentable Part of Commercial Glucose. By C. Schmitt and A. Cobenzl (*Ber.*, **17**, 1000—1015).—Neubauer and other authors have stated that in wine, which in its preparation has been subjected to Gall's treatment with glucose and fermented, a certain portion of the glucose remains in the wine as an unfermented substance which is neither glucose nor dextrin. Owing to the interest that has arisen as to the possible unwholesomeness of gallinated wines, the authors have been led to investigate the subject, and have succeeded in separating from fermented glucose (prepared from potato-starch) an intensely hygroscopic substance which they have named *gallisin*. A physiological investigation of this compound is in progress, but at present for purposes of priority, the purely chemical part of the research is published.

Preparation of Gallisin.—A solution of 5 kilos. of glucose was fermented at 18—20° for five or six days with yeast and filtered. The solution thus obtained was then evaporated to a thick syrup on the water-bath and shaken in a flask with a large excess of absolute alcohol: it became thicker, but did not mix with the alcohol. After a second treatment with absolute alcohol (by means of which water, sugar, organic acids, &c., are extracted) the syrup was found to be converted into a crumbling yellow-gray mass, which by pounding in a mortar with a mixture of absolute alcohol and ether can be obtained as a gray powder. This powder may be purified by dissolving it in water, repeating the above treatment, and drying over sulphuric acid.

Gallisin when viewed under the microscope is found to be amorphous and without any characteristic structure. It is intensely hygroscopic, more so than calcium chloride, but yields no definite compound with water. It is insoluble in ether, chloroform, and benzene, very sparingly soluble in glacial acetic acid and in absolute alcohol, but slightly more so in methyl alcohol, and in this it differs from glucose which is readily soluble. It dissolves when boiled in a mixture of glacial acetic acid and absolute alcohol, but it is precipitated from this solution by ether. In concentrated aqueous solution, it has an acid reaction to litmus-paper; and undergoes no change, either by heat or when treated with lead acetate, mercuric nitrate or chloride, ferric chloride, tincture of iodine, or calcium or barium chloride. Barium hydroxide precipitates a small quantity of a white barium compound. With silver nitrate, it undergoes no change until it is heated or ammonia is added, when metallic silver is precipitated. It rapidly reduces potassium permanganate, especially in slightly alkaline solution, with separation of peroxide of manganese. Potassium dichromate in dilute acid solution is also rapidly reduced. Fehling's and Knapp's solutions are reduced by it (in this it differs from dextrin), and 0·05 g. glucose are equal to 0·109784 g. gallisin in reducing power. A concentrated solution of gallisin prevents the precipitation of iron salts by ammonia or caustic alkalis. With acetic anhydride, it gives an acetyl compound, and it is converted into glucose by treatment with dilute mineral acids on the water-bath. On treating an aqueous solution with fresh yeast it is not fermented, nor does it undergo lactic fermentation, but if a dilute aqueous solution is allowed to stand for a time it decomposes with formation of a mouldy fungus. At 100° it gives off water and carbonic anhydride. It has a slightly sweet taste at first, but in time becomes insipid. A solution of gallisin turns the plane of polarisation to the right, and this power increases according to the dilution of the solution. A very pure white specimen, when analysed with every care to prevent access of moisture, was found to contain 43·50 per cent. C and 7·36 per cent. H, and these results lead to the formula $C_{12}H_{21}O_{10}$ (C, 43·9 : H, 7·32).

Gallisin-barium, $C_{12}H_{22}BaO_{10} + 3H_2O$, may be obtained by precipitating a concentrated aqueous solution of gallisin by barium hydroxide in alcoholic solution, and is purified by dissolving the precipitate in water, reprecipitating with alcohol, and washing with ether. The pure substance readily absorbs carbonic anhydride, is slightly alkaline, and reduces Fehling's and Knapp's solutions. It loses its water of combination over sulphuric acid.

Hexacetylgallisin is formed by heating gallisin with acetic anhydride for two and a half hours at 130—140° under pressure. The resulting brown mass is soluble in alcohol, and after driving off the excess of acetic anhydride on the water-bath, may be purified by boiling with charcoal; the acetyl-derivative is obtained on evaporation of its alcoholic solution as a colourless glass-like mass of the formula $C_{12}H_{15}O_{10}\overline{Ac}_6$. It is insoluble in water, but soluble in alcohol and similar solvents. If gallisin be heated for several hours at 170—180° with an excess of acetic anhydride, it is decomposed with formation, amongst other products, of ethyl acetate.

Gallisin-potassium, $C_{12}H_{23}KO_{10}$, is precipitated from an alcoholic solution of hexacetylgallisin by boiling it with alcoholic potash, ethyl acetate being formed simultaneously. It is a hygroscopic powder soluble in water, with alkaline reaction. In a similar way a precipitate of gallisin-lead may be obtained, $C_{12}H_{22}PbO_{10} + PbO$.

Conversion of Gallisin into Grape-sugar.—Equal parts by weight of gallisin and oxalic acid were heated on the oil-bath at 103° for two to three hours. On separating the oxalic acid with lime and evaporating the solution, a thick sweet syrup was obtained which in a few days formed a crystalline mass of glucose. The whole of the gallisin, however, could not be converted into glucose: by the prolonged action of oxalic acid on an aqueous solution of gallisin, it becomes yellow, and smells strongly of caramel.

Oxidation of Gallisin.—On pouring a solution of 100 grams gallisin in 50 c.c. water into 400 grams strong nitric acid, a powerful reaction takes place, and the solution becomes heated to boiling, with evolution of nitrous fumes. On cooling, neutralising with potash, and afterwards strongly acidifying with acetic acid, an acid potassium salt crystallises out in beautiful groups of white needles soluble in hot water but sparingly in cold. About 20 grams of these were obtained and the results of analysis agreed with the formula $C_6H_9KO_5$. From this acid salt a neutral silver salt, $C_6H_8Ag_2O_8$, was prepared, and from the lead salt by the action of sulphuretted hydrogen the free acid was obtained as a thick, acid, uncrystallisable syrup, soluble in water and alcohol but insoluble in ether. On distilling the ammonium salt, besides ammonia, pyrroline, &c., a sublimate was obtained which is soluble in water, alcohol, and ether, and at present is under investigation.

Action of Heat on Gallisin.—On heating gallisin in a current of hydrogen gas on the water-bath at 65°, carbonic anhydride and water are given off, and at 100° it melts to a thick amber-coloured syrup; 17·2 per cent. of water (4 mols. = 18 per cent.) and 13·7 per cent. of carbonic anhydride (1 mol. = 13·4 per cent.) were given off. This syrup has many of the properties of gallisin, as has also its barium compound, which is found on analysis of the barium derivative to have the formula $(C_{11}H_{23}O_8)_2Ba$. This may mean that gallisin, when heated, gives up water and carbonic anhydride, but when the resulting substance is treated with water the water is again taken up, and, as the barium derivative shows, a compound is formed containing 1 mol. of carbonic anhydride less than gallisin.

The authors succeeded also in preparing pure gallisin from a wine which had been prepared by Gall's process in 1873, and identified it by the above reactions and by analysis. In conclusion, the authors mention that a physiological investigation of gallisin is being made, and already it has been found by numerous trials that there is no direct or indirect unwholesomeness in the use of gallisin or of the glucose which is formed along with it. A. B.

Invertin. By E. BOURQUELOT (*J. Pharm. Chim.* [5], 7, 131—134).—Experiments were made in reference to the action of the soluble ferment of yeast (invertin) on gelatinised starch. The invertin was obtained from the yeast now largely used by bakers (brewers' yeast gives a bitterness to the bread), which is prepared by sowing yeast in a mixture of rye or maize meal with malt: this yeast has a little diastase mechanically adhering to it. 50 grams of the yeast were mixed with 100 c.c. of distilled water, and, after standing, the solution was filtered. The residual yeast was treated with water in this way four times in succession. The four solutions were all found to be rich in invertin, indicated by its hydrolytic action on cane-sugar. Berthelot and Bechamp have previously shown that yeast furnishes large quantities of invertin to water when isolated from nutrient matter. The above liquids were allowed to act for some hours on gelatinised starch, after which it was found by testing with iodine that the first solution alone exercised a hydrolytic action on the starch, and this only to a feeble extent, which the author supposes is due to adherent diastase; the other liquids had no action on the starch. The author therefore concludes that invertin, unlike diastase, has no hydrolytic action on starch. W. R. D.

Direct Conversion of Alcohols of the Ethyl Series into Amines. By V. Merz and K. Gasiorowski (*Ber.*, 17, 623—640).—Although it is known that phenols when heated with ammonia, best in presence of dehydrating agents, are converted into primary and secondary amines, the reaction has not yet been worked out with alcohols of the ethyl series. Ammonia alone has no action, and but slight action in presence of calcium chloride; good yields were obtained only in the presence of zinc chloride at high temperatures.

Methyl alcohol, heated in sealed tubes at 200—220° for 16 hours with the compound of zinc chloride and ammonia, yields mono- and tri-methylamine. The formation of dimethylamine also was highly probable, although it was not proved.

Absolute alcohol and ammonio-zinc chloride react but slightly at 200—220°; on further heating for eight hours at 260°, mono-, di-, and tri-ethylamine are formed, the yield of mixed amines being about 50 per cent. of the alcohol employed. Ethylene and pyridine bases appear also to be formed.

Isobutyl alcohol and ammonio-zinc chloride react but slightly at 200—220°, even after being heated for 16 hours; at 260—280° from 50—75 per cent. of the alcohol is converted into amines. Mono-, di-, and tri-isobutylamine were isolated from the product. Isobutyl alcohol and ammonium chloride react but slightly at 280°.

Normal octyl alcohol and ammonio-zinc chloride on being heated at 280° for 16 hours give a large yield of amines (over 75 per cent. of the alcohol used). Monoctylamine has been described by Eichler (Abstr., 1880, 229). *Dioctylamine*, $NH(C_8H_{17})_2$, crystallises in long white needles having an odour like that of tallow. It melts at 36·5°, boils at about 297—298°, is practically insoluble in water, readily soluble in alcohol and ether. The *hydrochloride*, $NH(C_8H_{17})_2,HCl$, crystallises in colourless plates, is sparingly soluble in water or ether, soluble in alcohol. The *platinochloride*, $[NH(C_8H_{17})_2]_2,H_2PtCl_6$, forms clear yellow plates practically insoluble in water. *Trioctylamine*, $N(C_8H_{17})_3$, after long purification forms a white crystalline mass, but was usually obtained as a nearly colourless oil of agreeable ethereal odour. It boils at 365—367°, is readily soluble in ether and absolute alcohol, but very sparingly soluble in ordinary spirit. Most of its salts are liquid. The *platinochloride*, $(NC_{24}H_{51})_2,H_2PtCl_6$, forms a glutinous mass insoluble in water.

In order to ascertain the nature of the reaction in the case of a secondary alcohol, capryl alcohol was heated with ammonio-zinc chloride. The yield of amines was much less than with the primary alcohols, being only about 25 per cent. of the weight of the alcohol employed. Monocaprylamine has long been known. *Dicaprylamine*, $NH(C_8H_{17})_2$, forms a colourless oil of aromatic odour. It boils at about 270°; vapour-density = 8·49 (calc. 8·33). The *hydrochloride* is a white crystalline substance soluble in alcohol. The *platinochloride*, $(NC_{16}H_{35})_2,H_2PtCl_6$, crystallises in fine yellow plates; the *aurochloride*, $NC_{16}H_{35},HAuCl_4$, crystallises in golden-yellow plates. *Tricaprylamine* is also an oil of aromatic odour. It boils a little above the boiling point of mercury. The *platinochloride*,

$$(NC_{24}H_{51})_2,H_2PtCl_6,$$

was obtained as a compact resinous mass showing slight signs of crystallisation. A. J. G.

Action of Zinc-ethyl on Amines and Phosphines. By H. GAL (*J. Pharm.* [5], 7, 484—485).—Zinc-ethyl has been found by the author to be without action on tertiary amines, while it acts violently on primary and secondary amines, the unsubstituted hydrogen being replaced by zinc with disengagement of ethane. The same appears to be the case with the phosphines. The bodies used in these experiments were triethylamine, dimethylphenylamine, methyldiphenylamine, and trimethylphosphine, all of which were unacted on by zinc-ethyl. The author proposes to utilise this reaction for the diagnosis of primary, secondary, and tertiary amines. The body is mixed with zinc-ethyl in ethereal solution to moderate action, when the amines of the first two classes will give rise to a reaction in which ethane is continuously and regularly evolved, while the tertiary amines will be unacted on. The action of zinc-ethyl on alkaloïds was also examined. No reaction occurred with nicotine or with quinoline; hence these bases contain no hydrogen which is replaceable by zinc. The alkaloïds that contain oxygen were generally attacked, yielding metallic derivatives, which were easily isolated. These new compounds are only slowly altered by exposure to the air, but are rapidly decomposed by water, forming zinc oxide and regenerating the alkaloïd; they form crystalline salts with sulphuric and hydrochloric acids. W. R. D.

Glyoxalisoamyline and its Derivatives. By B. RADZISZEWSKI and L. SZUL (*Ber.*, 17, 1291—1296).—Radziszewski has already described (Abstr., 1883, 1086) the preparation of glyoxalisoamyline from glyoxal and the ammonio-compound of isolvaleraldehyde. The authors now find that it may be obtained by passing a current of dry ammonia into a mixture of crude glyoxal and isovaleraldehyde in alcoholic solution. Care must be taken not to allow the temperature to rise to any extent during the reaction. The *hydrochloride* is a colourless deliquescent body crystallisable from alcohol with difficulty, and melting at 135—136°. The *hydrobromide* is similar in properties, and melts at 100°. The *sulphate* is so deliquescent that it could not be obtained pure, but is a neutral sulphate. The *oxalate* was obtained in fine rhombic crystals having the axial relations $a : b : c =$ 0·4784 : 1 : 0·4603.

If bromine be gradually added to an ethereal solution of glyoxalisoamyline at 0° until it is no longer *completely* decolorised, the product yields glyoxalisoamyline hydrobromide and dibromoglyoxalisoamyline. The weight of bromine added then equals the weight of the glyoxalisoamyline employed. If three times this quantity of bromine be added the liquid remains of an orange colour, and dibromo- and tribromoglyoxalisoamyline are obtained, together with a good deal of resinous matter not investigated.

Dibromoglyoxalisoamyline crystallises in colourless scales melting at 157—158°, and with silver nitrate gives a white precipitate, which rapidly turns black on exposure to the light, and decomposes at 300° without previous fusion. *Tribromoglyoxalisoamyline* crystallises from alcohol in colourless needles, which blacken at 200° and melt at 216—217°. It is soluble in alcohol and ether, and sparingly so in water. It is converted into the dibromo-compound when treated in aqueous solution with sulphurous acid; it also gives up a third of its bromine to silver nitrate. *Oxalmethylisoamyline* was obtained by the action of glyoxalisoamyline on methyl iodide, but in quantity too small for investigation. Its *methiodide*, $C_7H_{11}MeN_2,MeI$, was obtained in rhombic prisms. When heated to 136°, the crystals from an alcoholic solution lose their transparency, and melt at 169—170°; the crystals from an aqueous solution do not show this loss of transparency.

Oxalethylisoamyline was obtained by the action of ethyl bromide on glyoxalisoamyline. It forms a colourless liquid of unpleasant pungent odour, boils at 224—225° (B. = 743 mm., t_B = 19·4°); its sp. gr. is 0·9291 at 19·6°. The *platinochloride* crystallises in orange-coloured prisms, soluble in hot water.

Oxalpropylisoamyline is a colourless liquid, boiling at 239—242° (B. = 738 mm., t_B = 23°). It is more sparingly soluble in water than the ethyl compound, and its sp. gr. is 0·9149 at 18°. The *platinochloride* is soluble in alcohol and boiling water, and crystallises in microscopic prisms. Oxaldipropylisoamyline bromide, simultaneously formed, crystallises in colourless prisms, belonging to the rhombic system, soluble in water and alcohol, and melting at 162—163°. With silver nitrate, it gives a precipitate of silver bromide.

Oxalisobutylisoamyline, $C_7H_{11}(\beta Bu)N_2$, boils at 238—242° (B. = 742 mm, t_B = 18°), and has a sp. gr. of 0·9048 at 16·1°. The *platinochloride* crystallises in golden-coloured scales.

Oxalisoamylisoamyline boils at 261—262° (B. = 737 mm., t_B = 19°), is insoluble in water, and has a sp. gr. of 0·9029 at 14·9°. The *platinochloride* forms minute crystals. A double salt with zinc chloride forms very hygroscopic white crystals melting at 86—87°. Oxidised with hydroxyl. oxalisoamylisoamyline yields isoamyloxamide.

The action of these oxalines with tannic, picric, and tungstic acids, &c., is similar to that of those already described. L. T. T.

Oxidation of Oxalines and Glyoxalines by means of Hydroxyl. By B. Radziszewski (*Ber.*, **17**, 1289—1290).—Trommsdorf now supplies a 3 per cent. solution of pure hydroxyl, which the author finds a very convenient oxidising agent.

Wyss found that glyoxaline treated with the ordinary oxidising agents yields only carbonic anhydride and traces of formic acid. The author dissolved glyoxaline in an alkaline solution of hydroxyl; oxygen was liberated, and the mixture was then allowed to remain for several days undisturbed: on examination, it was then found to contain oxamide and apparently traces of oxamic acid. Glyoxalethyline and glyoxalpropyline similarly treated also yielded oxamide, the yield of the latter body increasing with the molecular weight of the original substance.

Glycocine, $C_6H_6N_4$, in sulphuric acid solution, when treated with hydroxyl yields dark violet and black colouring matters, which are insoluble in the ordinary solvents, and are now being investigated. All the oxalines give substituted oxamides with hydroxyl: for instance, oxalethylpropyline and oxalethylethyline both yield ethyloxamide, whilst oxalisoamylamyline yields isoamyloxamide.

L. T. T.

Diazo- and Diazoamido-derivatives of the Paraffin Series. By T. Curtius (*Ber.*, 17, 953—959).—In this preliminary notice, the author confirms his observation (Abstr., 1884, 42) that by the action of sodium nitrite on ethylic glycocine hydrochloride an ethylic diazoacetate is formed—that is, a compound in which two hydrogen atoms of the methyl group in the acetic acid part, are replaced by a double atom of triad nitrogen. This reaction seems to be general in cases in which a hydrochloride of the ethereal salt can be formed, and has been successful with alanine, tyrosine, leucine, amidomalonic acid, and aspartic acid.

Ethylic glycocine nitrite is easily formed by suspending ethylic glycocine hydrochloride in ether, adding finely powdered silver nitrite, and separating the resulting silver chloride with alcohol. When the alcoholic solution of the nitrite is evaporated in a vacuum over sulphuric acid, it yields large colourless crystals of the formula $NOOH.NH_2.CH_2.COOEt$. In time, or more quickly at 50°, or by distillation in steam, water separates out, and the diazo-compound is formed. The comparative stability of this compound is a proof that the nitrogen-atoms are both united to carbon. In small quantities (2—3 grams) it can be distilled, but with larger quantities explosion takes place. The yield is about 80 per cent. of the theoretical quantity.

Ethylic diazoacetate, ($N_2CH.COOEt$) gives on boiling with benzoic, hippuric, or glacial acetic acids respectively benzo-, hippuro-, or acetoethylic glycollate. Chlorine in the cold converts it into ethylic dichloroacetate with separation of nitrogen. The reactions with bromine and iodine are similar. Hydrochloric acid in aqueous solution converts it into ethylic monochloroacetate and ethylic glycollate. Hydrofluoric acid in aqueous solution converts it only into ethylic glycollate or ethylic diglycollate, according to the quantity of water used. With hydrofluoric acid, however, it yields ethylic fluoacetate. This reaction, and also those of nitric, nitrous, and chlorous acids, are under further investigation. On heating it with benzaldehyde, and acting on the oily product with dilute soda, phenylacetic acid is formed with the separation of a carbon-atom. With benzamide no ethylic hippurate was formed as was expected, but a crystalline substance melting at about 95°, and now under investigation. Hydrocarbons such as toluene have no action on it, even on boiling. As it is undecomposed by acetic acid at 60°, it was found possible to reduce it with zinc and acetic acid to ethylic hydrazine acetate, the hydrochloride of which is unstable. This compound reduces Fehling's solution in the cold, and on being evaporated with hydrochloric acid rapidly decomposes into glycocine hydrochloride and ammonium chloride. Potassium and sodium dissolve in ethylic diazoacetate with evolution of hydrogen, and form brown precipitates, which are also under further investigation.

On passing the gases obtained by oxidising arsenic trioxide with nitric acid through a solution of ethylic glycocine in ether, at first no diazoacetate is formed, but a thick orange-coloured oil, insoluble in ether, and seemingly having the properties of a diazoamido-compound. It has not yet, however, been obtained in a pure state. Ethylic diazoacetate, when slowly dissolved in concentrated aqueous ammonia, yields a yellow crystalline mass melting at 97°; this appears to be a diazoacetamide.

The amido-acids of the fatty series do not form diazo-compounds unless the hydrogen of the acid hydroxyl is replaced by an alcohol radical, nor does the acid ether of a dibasic acid. Ethylic aspartic acid gives no diazo-compound, although it forms a stable hydrochloride; ethylic aspartate, on the other hand, yields ethylic diazosuccinate.

A. B.

Derivatives of Formaldehyde. By B. TOLLENS (*Ber.*, 17, 653—659).—A continuation of the author's work on this subject. *Hexamethylenamine* can be conveniently prepared by evaporating a mixture of ammonia and crude formaldehyde. It is stable in the air, readily soluble in water, more sparingly in alcohol. When heated at 230—270° in a vacuum, it sublimes without decomposition. Attempts to determine the vapour density were unsatisfactory, the numbers obtained being 3·809 and 3·889; calculated, 4·86 for $C_6H_{12}N_4$ and 2·43 for $C_3H_4N_2$. The author has further examined the platinochloride. It crystallises in microscopic octohedrons, and has the formula,

$$(C_6H_{12}N_4)_2,H_2PtCl_6 + 4H_2O.$$

Hexamethylenamine is decomposed by acids into formaldehyde or oxymethylene and ammonium salts. Sodium amalgam appears to be without action on it. Heated with methyl iodide, methyl alcohol, and water at 170—200°, a considerable amount of tetramethylammonium iodide is formed.

Anhydroformaldehydaniline, $PhN:CH_2$, is prepared by mixing crude formaldehyde (85 grams) with aniline (5—6 grams), and allowing it to remain at rest for some hours, when the new substance crystallises out. It forms a mass of fine, silky, white needles or plates, which cannot be fused without decomposition. It is readily soluble in chloroform, benzene, and toluene, soluble in ether, very sparingly in alcohol, and almost insoluble in water. It is decomposed by boiling with alcohol or water. Dilute acids scarcely dissolve it, but with concentrated acids it dissolves to a red or brown coloured liquid. Toluidine yields an analogous crystalline compound with formaldehyde; methylaniline gives an oil and carbamide yields a solid sparingly soluble derivative. A. J. G.

Action of Baryta on Acetaldehyde. Aldehyde-gum. By B. TOLLENS (*Ber.*, **17**, 660—661).—By the action of aqueous baryta on acetaldehyde there is obtained, in addition to much aldehyde-resin, a yellow gum-like substance of the formula $C_{10}H_{16}O_4$; it is soluble in alcohol and ether. By treatment with milk of lime, the calcium derivative, $(C_{10}H_{17}O_4)_2Ca$, is obtained as a yellowish-white earthy mass, soluble in absolute alcohol, precipitated in flocks by ether. The gum is decomposed by heat, gives a red coloration with the magenta reagent for aldehydes, yields iodoform on treatment with iodine and soda, and reduces Fehling's solution when boiled with it.

A. J. G.

Potassium and Barium Glyoxal-hydrogen Sulphites. By DE FORCRAND (*Compt. rend.* **98**, 1537—1539).—*Potassium glyoxal-hydrogen sulphite* is obtained by the same method as the sodium salt (*Compt. rend.*, **98**, 824), and forms brilliant prisms containing H_2O. The heat of formation was estimated by the first of the methods employed in the case of the sodium salt (*loc. cit.*), and the following results were obtained:—

$C_2H_2O_2$ solid + $2SO_2$ gas + K_2O solid + H_2O solid = $C_2H_2O_2.2KHSO_3$ solid............ develops + 142·81 cal.
$C_2H_2O_2$ solid + $2SO_2$ gas + K_2O solid + H_2O liquid = $C_2H_2O_2.2KHSO_3$ solid .... „ + 144·24 „
$C_2H_2O_2$ + $K_2O.S_2O_4$ solid + H_2O solid = $C_2H_2O_2.2KHSO_3$ solid .... „ + 14·28 „
$C_2H_2O_2$ + $K_2O.S_2O_4$ solid + H_2O solid = $C_2H_2O_2.2KHSO_3$ diss. .... „ + 0·88 „
$C_2H_2O_2$ + $K_2O.S_2O_4$ solid + H_2O liquid = $C_2H_2O_2.2KHSO_3$ solid .... „ + 15·71 „
$C_2H_2O_2$ + $K_2O.S_2O_4$ solid + H_2O liquid = $C_2H_2O_2.2KHSO_3$ diss. .... „ + 2·31 „

The heat of formation of the potassium salt in the solid state is always greater than that of the sodium compound.

Barium glyoxal-hydrogen sulphite, $2(C_2H_2O_2.BaO.2SO_2) + 7H_2O$, is much less soluble than the sodium and potassium salts.

$C_2H_2O_2$ solid + $2SO_2$ gas + BaO solid + $3\frac{1}{2}H_2O$ solid = $C_2H_2O_2.BaO.S_2O_4.3\frac{1}{2}H_2O$...... develops + 92·73 cal.
$C_2H_2O_2$ solid + $2SO_2$ gas + BaO solid + $3\frac{1}{2}H_2O$ solid = $C_2H_2O_2.BaO.S_2O_4.3\frac{1}{2}H_2O$ diss. .... „ + 84·04 „
$C_2H_2O_2$ solid + $2SO_2$ gas + BaO solid + $3\frac{1}{2}H_2O$ liquid = $C_2H_2O_2.BaOS_2O_4.3\frac{1}{2}H_2O$ solid .... „ + 97·72 „
$C_2H_2O_2$ solid + $2SO_2$ gas + BaO solid + $3\frac{1}{2}H_2O$ liquid = $C_2H_2O_2.BaO.S_2O_4.3\frac{1}{2}H_2O$ diss. .... „ + 89·04 „

These results explain the formation of this salt from barium chloride and sodium glyoxal-hydrogen sulphite, and also the precipitation of a solution of the barium salt by dilute sulphuric acid.

C. H. B.

Action of Carbonic Anhydride on Lead Acetate. By F. Bellamy (*J. Pharm.* [5] 7, 216—220).—It is well known that carbonic anhydride acts on a solution of lead acetate with formation of lead carbonate and free acetic acid. In this paper the extent to which the reaction takes place, under different conditions, is investigated. The results show that the quantity of water present does not affect the decomposition, which is usually complete with a 5 per cent. solution after a rapid current of gas has been passing for about two hours and a half. The whole of the lead acetate is never decomposed, the quantity acted on being inversely as the temperature. It is evident from experiments on this point that the acetic acid reacts with the lead carbonate; this occurs slowly if the solution which has been acted on is allowed to stand. The maximum amount of decomposition effected in a solution of lead acetate by carbonic anhydride at a temperature of 7—8° corresponds with 77·48 per cent. of the salt. W. R. D.

Preparation of Monochloracetic Acid. By W. Hentschel (*Ber.*, **17**, 1286).—Several kilos. of acetic anhydride are heated at 100° in a suitable tubulated vessel, and a stream of dry chlorine gas passed into the liquid, a slow stream of glacial acetic acid being allowed to flow in at the same time. When the absorption of chlorine slackens the mixture is distilled, and the fraction 180—187° which forms the principal product, collected separately. The reactions are the following:—

$$\text{I. } (CH_3CO)_2O + Cl_2 = CH_2Cl.COOH + CH_3.COCl.$$
$$\text{II. } CH_3.COCl + CH_3.COOH = (CH_3.CO)_2O + HCl.$$

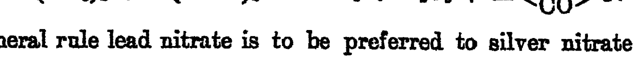
L. T. T.

Melting Point of Monochloracetic Acid. By B. Tollens (*Ber.*, **17**, 664—667).—Monochloracetic acid appears to exist in two modifications distinguished by the difference in their fusing points. On taking the melting point of the distilled acid it is found to be 62·5—63·2°, the acid resolidifies at 62—62·5°. When the melting point of the resolidified acid is again determined, it is generally found to be 52—52·5°. If, however, the solidified acid prior to the second fusion is touched with a trace of the crystallised acid, it rapidly assumes an opaque appearance, and now exhibits the original melting point of about 62°. A. J. G.

Preparation of Acid Anhydrides. By B. Lachowicz (*Ber.*, **17**, 1281—1284).—If silver or lead nitrates be acted on by the chlorides of the monobasic acids, the reaction takes place according to the equation—

$$Pb(NO_3)_2 + 2X.COCl = PbCl_2 + N_2O_5 + (XCO)_2O,$$

If the chlorides of the dibasic acids be employed, the reaction is—



$$Pb(NO_3)_2 + X(COCl)_2 = PbCl_2 + N_2O_5 + X{<}^{CO}_{CO}{>}O.$$

As a general rule lead nitrate is to be preferred to silver nitrate, as the reaction with the latter is generally very violent. As the temperature of reaction lies above the boiling point of some of the lower acid chlorides, and below the melting point of others, the method must be somewhat modified according to circumstances, closed tubes, &c., being used in the one case, and solvents in the other.

The author has prepared acetic, benzoic, and phthalic anhydrides by this method. L. T. T.

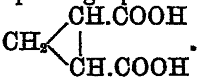
Preparation of Acid Anhydrides. By W. HENTSCHEL (*Ber.*, **17**, 1285—1286).—If anhydrous sodium acetate be heated to a temperature a little above the boiling point of acetic anhydride, and a rapid stream of phosgene gas be passed over it, acetic anhydride distils over. The anhydride thus prepared has a very unpleasant odour. due to a little phosgene gas dissolved in it, but with a little care can be obtained pure enough for many purposes. Propionic, butyric, and benzoic anhydrides have been prepared in a similar manner. Small quantities of the corresponding chlorides are always present in the anhydrides made in this way. L. T. T.

Diacetonylphosphorous Chloride and Diacetonylphosphinous Acid. By A. MICHAELIS (*Ber.*, **17**, 1273—1276).—If aluminium chloride is added to a mixture of 1 vol. phosphorous chloride, and 2—2½ vols. acetone, a brisk reaction takes place, hydrochloric acid is copiously evolved, and the reaction has to be moderated by cooling. From the product a colourless oil is obtained, boiling at 235°, and having the formula $(CH_3.CO.CH_2)_2PCl$. *Diacetonylphosphorous chloride* thus obtained has a peculiar but rather pleasant odour; it is heavier than water, and is decomposed by it, slowly in the cold, violently on heating. This aqueous solution, when evaporated on a water-bath, leaves a thick liquid, which solidifies on standing. *Diacetonylphosphinous acid*, $(CH_3.CO.CH_2)_2PH(OH)_2$, thus obtained crystallises from water in long colourless needles, containing 1 mol. H_2O, which they lose in a vacuum over sulphuric acid, or at 100—110°. Neutralised with ammonia and treated with silver nitrate, this acid yields a white silver salt of the formula $(CH_3.CO.CH_2)_2PH(OAg)_2$, showing that the acid is dibasic. The silver salt is soluble in boiling water, but the solution rapidly decomposes. Diacetonylphosphinous acid is a very stable substance, and may be heated to 120° with fuming nitric acid without decomposition. It melts and gives up water at 63—64°. Its solution slowly decolorises bromine-water and potassic permanganate, and with excess of bromine forms bromacetone. It appears to be closely related to Mulder's acetone phosphorus acid,

$$CH_3.CO.CH_3.HPO_2,$$

which the author considers to be most probably monacetonylphosphinous acid, $CH_3.CO.CH_2.POH.OH$. L. T. T.

Action of $\alpha\beta$-Dibromopropionic Acid on Ethyl Malonate. By M. CONRAD and M. GUTHZEIT (*Ber.*, **17**, 1185—1188).—*Ethyltrimethylenetricarboxylate*,  $CH_2\left\langle\begin{array}{l}C(COOEt)_2\\ |\\ CH.COOEt\end{array}\right.$, is formed when ethyl αβ-dibromopropionate is added to a mixture of ethyl malonate and sodium dissolved in absolute alcohol. After removing the excess of alcohol by evaporation, the addition of water causes the ethereal salt to separate out as an oily liquid (sp. gr. 1·127 at 15°, b. p. 276°); on saponification, *trimethylenetricarboxylic acid* is obtained in prismatic crystals. A neutral solution of the acid gives white crystalline precipitates with lead and silver salts. The acid melts at 184°, splitting up into carbonic anhydride and *trimethylenedicarboxylic acid*,



$CH_2<\begin{array}{l}CH.COOH\\ \mid\\ CH.COOH\end{array}$.

The latter compound crystallises in vitreous prisms, melting at 137°, and soluble in water, alcohol, and ether. The calcium salt is anhydrous. An aqueous solution of the ammonium salt forms white crystalline precipitates with lead acetate and silver nitrate. Trimethylenedicarboxylic anhydride crystallises in glistening needles which melt at 57°. W. C. W.

Ethyl Glycollate. By L. MEYER (*Ber.*, **17**, 669).—A correction to the results given (*Ber.*, **17**, 486). The pressure at which the boiling point of ethyl glycollate was determined was 760 mm., not 730—740 mm. It is very probable that the pressure regulator employed did not act properly. A. J. G.

Solid Carbonic Acid. By H. LANDOLT (*Ber.*, **17**, 309—311).—For the preparation of solid carbonic acid, the author much prefers the cloth bags which have long been supplied by Bianchi, of Paris, to the ordinary tin boxes. These bags are conical in shape, about 40 cm. long, and about 17 cm. across at the wide end. They are of woollen material, and the wide end can be drawn together by a tape. The narrow end is fastened to a wooden tube which fits over the nozzle of the carbonic acid cylinder. The waste of acid is much less with this bag than with the ordinary box. The solid acid keeps much longer if it be compressed. For this purpose the author uses slightly conical moulds of hard wood, fitted with wooden pistons. Specimens obtained by hammering the solid acid into these moulds have the appearance and approximate hardness of chalk, and may be lightly handled without danger. A specimen 53 mm. long and 71 mm. in diameter took five hours to volatilise. The author finds the average density of his specimens to be slightly under 1·2. L. T. T.

Existence of the Trimethylene Ring. By W. H. PERKIN, Jun. (*Ber.*, **17**, 323—325).—The author shows that the trimethylenedicarboxylic (ethylenemalonic) acid described by him (*Ber.*, **17**, 54) is identical with the vinylmalonic acid obtained by Fittig and Roeder (Abstr., 1883, 730). As the experiments of Fittig and Roeder tend to throw doubt on the existence of a trimethylene ring, the author has investigated the action of alkalis on the two substances described by him (this vol., 64) as trimethylenecarboxylic (ethyleneacetic) acid and benzoyltrimethylenecarboxylic (ethylenebenzoylacetic) acid. If these acids were vinyl- and not trimethylene-derivatives they would readily be split up by alkalis into ketones and acids like the homologous allyl derivatives. This is, however, not the case, as they may be boiled for hours with very concentrated potash without undergoing decomposition. The author therefore believes the acid obtained by Fittig and Roeder, and by himself, to be a trimethylene- and not a vinyl-derivative. He believes that in the formation of the hydrobromic acid compound a rupture of the ring takes place. This view is also strengthened by the researches of Freund on free trimethylene, Freund finding that hydriodic acts on trimethylene much more readily than bromine does. L. T. T.

Hydroxymaleïc Acid. By E. Scherks (*Ber.*, **17**, 698—699).—Bourgoin having described a hydroxymaleïc acid prepared by shaking potassium bromomaleate with moist silver oxide (Abstr., 1883, 1021), the author endeavoured to repeat his experiments, but although many modifications of the process were tried, they were invariably unsuccessful. The existence of this acid therefore would seem to be doubtful. A. J. G.

Action of Hydroxylamine on Chelidonic Acid and Meconic Acid. By V. Meyer (*Ber.*, 1061—1062).—Hydroxylamine and its hydrochloride have no reaction on chelidonic acid. It is therefore unlikely that this acid is a ketone acid. Hydroxylamine, however, combines readily with meconic acid, forming an acid containing 1 atom of nitrogen. On this ground meconic acid will probably be found to be a ketone- or aldehyde-acid. The further investigation of this reaction and also of the action of hydroxylamine on comenic acid and hydrocomenic acid will be carried out by Odernheimer. A. B.

Pyrotritartaric Acid. By C. Böttinger (*Ber.*, **17**, 317—318).—When bromine is added to pyrotritartaric (uvic) acid suspended in water, the acid gradually dissolves, hydrobromic acid being formed at the same time. When sufficient bromine has been added, a very unstable yellow oil separates, whilst bromoform is deposited from the aqueous residue on neutralisation with sodium hydroxide. The yellow oil dissolves in cold sodium hydroxide with a yellow, in strong sulphuric acid with a dark cherry-red, coloration. In contact with water this oil decomposes, yielding hydrobromic acid, a dark resinous substance, and an oily brominated ketone, sparingly soluble in water, and volatile with steam. This ketone has a very penetrating odour, and dissolves in a solution of sodium carbonate, but the solution very soon undergoes decomposition. With hydrogen sodium sulphite, it forms an easily soluble crystalline substance. Heated with a solution of silver nitrate reduction takes place, and the smell of acetamide becomes perceptible; the resulting solution yields a reddish-brown silver salt on treatment with nitric acid. The author considers these results as confirmatory of the formula $CMe\colon C.CH(COOH).COMe$, proposed for pyrotritartaric acid by Baeyer and Perkin. L. T. T.

Conversion of Gluconic Acid into Normal Caprolactone. By H. Kiliani and S. Kleemann (*Ber.*, **17**, 1296—1303).—Gluconic acid may be prepared by adding 2 parts of bromine to a cold solution of 1 part of starch in 5 parts of water, and allowing it to remain for 30 to 36 hours. The liquid is then heated to drive off excess of bromine, and the hydrobromic acid is removed by adding the exact quantity of lead carbonate necessary to form lead bromide. The gluconic acid is then purified by means of its calcium salt.

1 part of the dried acid was mixed with 10 parts of concentrated hydriodic acid (b. p. 127°) and $\frac{4}{5}$ parts amorphous phosphorus, and the whole digested for 7 hours, when the solution was found to contain caprolactone. This supports Fittig's formula for gluconic acid, at least as far as the normal character of the carbon-chain is concerned.

L. T. T.

General Reaction for the Amido-fatty Acids. By T. Curtius *Ber.*, **17**, 959—960).—This reaction depends on the formation of a diazo-compound as previously described (this vol., p. 987). The substance to be tested is dissolved in absolute alcohol in a test-tube and treated with hydrochloric acid gas. The excess of hydrochloric acid and alcohol is then boiled off, the remaining liquid dissolved in a very small quantity of water, covered with ether, and a few drops of a concentrated solution of sodium nitrite added. Immediately a small quantity of nitrogen gas is evolved, as it is difficult to drive off all the hydrochloric acid. The liquid is agitated with the ether, and from the latter, on evaporation, the ethereal salt of the diazo-acid if present is obtained in oily drops. On adding hydrochloric acid, these give off quantities of nitrogen gas and become colourless. The altered and intense odour of a chlorinated ethereal salt may also be observed.

A. B.

Sarcosine. By F. Mylius (*Ber.*, **17**, 286—292).—In his original description of sarcosine, Liebig states that it sublimes unchanged if heated for some time at 100°. Strecker, in describing his synthetical sarcosine, says the crystals do not change in appearance at 100°, but melt at a slightly higher temperature and sublime unchanged. Believing the fused body to be no longer sarcosine, the author investigated the subject.

When sarcosine is heated in a retort, it appears to undergo no change below 200°; at 210° it begins to melt, and the fusion is complete at 220°. During fusion, water, carbonic acid, and dimethylamine are given off; the last two, however, in relatively small quantities. The fused mass in the retort forms a pale yellowish oil, which distils at about 350°, with scarcely any decomposition, and on cooling forms a white fibrous crystalline mass which yields colourless prisms when recrystallised from alcohol; these melt at 149—150°, are very easily soluble in water, and have a bitter taste and neutral reaction. Combustion showed its empirical formula to be C_3H_5NO, so that it had been formed according to the equation $C_3H_7NO_2 = C_3H_5NO + H_2O$. It is therefore *sarcosine anhydride*, but as will be seen from its compounds the empirical formula must be doubled, giving as its true formula $C_6H_{10}N_2O_2$. A vapour-density determination made according to Meyer's method, gave numbers approximating tolerably closely to those required by the formula $C_6H_{10}N_2O_2$, considering the decomposition which the substance undergoes above its boiling point. No salt could be obtained by evaporating the anhydride with hydrochloric acid, but with a hydrochloric solution of platinic chloride a platinochloride, $2(C_6H_{10}N_2O_2),H_2PtCl_6 + 4H_2O$, was formed, crystallising in hexagonal plates. Recrystallised from alcohol, it yields cubes or prisms with $2H_2O$. Sarcosine anhydride was obtained by Traube (Abstr., 1883, 192), by passing cyanogen chloride through sarcosine in a melted state, but from analysis of the dehydrated platinochloride, crystallised from alcohol, he assigned to it the formula $C_6H_{12}N_2O_3$. With gold chloride, sarcosine anhydride yields an aurochloride, $(C_6H_{10}N_2O_2)_2,HAuCl_4 + 2H_2O$, crystallising in glistening violet prisms. It also forms a double salt with mercuric chloride, which yields large colourless prisms. Treated in aqueous solution with bromine, transparent red crystals are formed, sparingly soluble in water; these are stable in an atmosphere of bromine, but on exposure to the air lose bromine and leave the unchanged anhydride. The anhydride is reconverted into sarcosine by heating it with aqueous hydrochloric or sulphuric acid, or by fusion with potash.

In aqueous solution, sarcosine anhydride is oxidised by a weak solution of potassium permanganate, with formation of dimethyloxamide and oxalic acid. Sarcosine, on the contrary, yields carbonic, nitrous, and nitric acids, and traces only of oxalic acid.

The author considers it probable that the constitution of sarcosine anhydride is represented by the formula

$$NMe{<}\genfrac{}{}{0pt}{}{CH_2.CO}{CO.CH_2}{>}NMe.$$

The secondary formation of dimethylamine and carbonic acid from sarcosine would be expressed by the equation

$$NHMe.CH_2.COOH = NHMe_2 + CO_2.$$

Kept for some time at a temperature slightly below its melting point, sarcosine yields a sublimate containing small quantities only of the unchanged substance. L. T. T.

Preparation of Carbamide. By W. Hentschel (*Ber.*, **17**, 1286—1287).—A stream of dry ammonia is passed into phenyl carbonate heated on a water-bath, until the odour of ammonia becomes strongly marked. The product is then poured into hot water. On cooling, the liquid separates into a dark-coloured layer of phenol, and an aqueous solution of carbamide. 5 kilos. of the carbonate yield 1 kilo. carbamide, and almost the whole of the phenol is recovered. An almost theoretical yield of phenyl carbonate is obtained by passing dry phosgene gas into a solution of phenol in its equivalent quantity of dilute soda. L. T. T.

Alanine and Ethyl Oxalate: a Correction. By H. Schiff (*Ber.*, **17**, 1033—1034).—The substance which is described in a previous communication (*Ber.*, **17**, 403) as ethylimidodiethyldioxamide has been found to contain a much smaller quantity of nitrogen than that which by a clerical mistake it was supposed to contain and required theoretically. The investigation of this substance, which cannot be the above mentioned, will be continued. A. B.

Uric Acid. By E. FISCHER (*Ber.*, 17, 328—338).—Although phosphoric chloride fails to remove oxygen from uric acid, the author finds that if the uric acid is first methylated, two oxygen- and two hydrogen-atoms can be replaced by two chlorine-atoms, and that on further treatment a third chlorine-atom can be introduced in place of another oxygen- and another hydrogen-atom. These chlorines can then be replaced by hydrogen, ethoxyl, the amido-group, &c., thus giving a large number of derivatives. For convenience of nomenclature, the author looks upon all these as derivatives of a hypothetical non-oxygenised body, $CH_3.C_5N_4H_3$, to which he gives the name *methylpurin*. Methyluric acid then becomes trihydroxymethylpurin, and so on. The methylated uric acid used in this research was prepared by heating neutral lead urate with 2 mols. of methyl iodide for 30 hours at 100°. The product probably consisted of a mixture of mono- and di-methyluric acid, but these were not separated.

Dichlorhydroxymethylpurin, $C_5N_4Me(OH)Cl_2$, was obtained by heating 10 parts of the above described methylated uric acid with 13 parts phosphoric chloride and 50 parts phosphoric oxychloride for 8—9 hours at 130°. The oxychloride was distilled off, the residue decomposed with water, and the whole evaporated to dryness. The residue is extracted with water, when a dark-brown partly crystalline mass is left, which contains all the dichlorhydroxymethylpurin. This mass is then heated with strong nitric acid, when a violent action takes place, all the bye-products (which are to form the subject of another paper) being converted into easily soluble compounds. On the addition of water, dichlorohydroxymethylpurin is precipitated in an almost pure state. When recrystallised from alcohol, it forms thin white needles melting at 274°. It is more stable than uric acid, volatilises undecomposed, and is not attacked by boiling with fuming nitric acid or hydrochloric acid and potassium chlorate. It dissolves easily in alkalis, and can be boiled with them without decomposition. The chlorine-atoms are replaced by hydrogen by treatment with fuming hydriodic acid.

Trichloromethylpurin, $C_5N_4MeCl_3$, is obtained by heating 1 part of the dichloro-derivative with 1½ parts phosphoric chloride and 5 parts phosphoric oxychloride in closed tubes at 160° for 8 hours. It crystallises in small colourless needles which melt at 174°. It is insoluble in alkalis, and, unlike the dichloride, is easily reconverted into methyluric acid. When heated on the water-bath with alcoholic soda, it yields diethoxychloromethylpurin, which crystallises in needles; but if the action of the alkali be continued, a substance is produced which is free from chlorine, melts under boiling water, and is probably triethoxymethylpurin. If diethoxychloromethylpurin is heated with fuming hydrochloric acid at 130°, it is converted into $C_5N_4MeH_4O_3$, which, from its reactions, &c., is undoubtedly a monomethyluric acid. This body is almost as sparingly soluble as uric acid, requiring for solution more than 2000 parts of boiling water, and therefore appears to be different from the methyluric acid described by Hill (this Journal, **30**, 75).

Hydroxymethylpurin, $C_5N_4MeH_3O$, obtained by the reduction of dichloroxymethylpurin by fuming hydriodic acid, crystallises in colourless prisms, melting at 233°, and easily soluble in water to an alkaline solution. Its hydriodide crystallises in colourless scales, soluble in alcohol and water; the hydrochloride is easily soluble in water, sparingly so in alcohol. The aurochloride crystallises in thin yellow plates; the platinochloride in orange prisms. In slightly acid solutions, silver nitrate precipitates silver hydroxymethylpurin as a white crystalline powder. As hydroxymethylpurin has the composition of a methylsarcine, the author endeavoured to methylate sarcine by acting on its di-silver derivative with methyl iodide. He obtained a dimethylsarcine, which, however, differed from hydroxymethylpurin and also from hydroxydimethylpurin.

Dichloroxydimethylpurin, $C_5N_4Me_2OCl_2$, is obtained by acting on the lead salt of the monomethyl-derivative with methyl iodide. It crystallises in thin, slightly coloured needles, which melt at 183°. It is insoluble in alkalis, but is decomposed by boiling alkalis. Alcoholic potash removes one chlorine-atom at ordinary temperatures, the second on heating, ethoxyl being introduced in their place.

Hydroxydimethylpurin, $C_5N_4Me_2H_2O$, is easily obtained from the dichloro-derivative by reduction with hydriodic acid. It crystallises in needles melting at 112°. It is easily soluble in alcohol and water to a strongly alkaline solution; sparingly soluble in ether, almost insoluble in alkalis. Its aurochloride gives characteristic yellow needles. It has the composition of dimethylsaricne, but is not identical with that above described; and the author is at present in doubt whether it should be regarded as a dimethylsarcine or not.

Ethoxychloroxydimethylpurin, $C_5N_4Me_2OCl.OEt$, is obtained by acting on dichloroxydimethylpurin with 50 per cent. alcoholic potash, the temperature not being allowed to rise above 40°. It often crystallises in a mass of slender needles, but gradually changes into heavier crystalline agglomerations which fuse at 160°. When heated with fuming hydriodic acid, it loses chlorine and ethoxyl and yields trihydroxydimethylpurin.

Dihydroxydimethylpurin, $C_5N_4Me_2H_2O_2$, is formed by heating ethoxychloroxydimethylpurin with ten times its weight of fuming hydriodic acid. This substance is crystalline and distils unchanged. Although identical with theobromine in composition, it differs from it in properties, but shows its relation to uric acid by giving the murexide reaction.

Diethoxyoxydimethylpurin, $C_5N_4Me_2O(OEt)_2$, prepared from the dichloro-derivative by boiling it with excess of alcoholic soda, crystallises from water in minute scales melting at 126—127°. It is easily soluble in alcohol, sparingly so in water. It is insoluble in alkalis, but easily soluble in concentrated hydrochloric acid. If heated with strong hydrochloric acid, in sealed tubes at 130°, it loses both ethyl-groups, and is converted into *trihydroxydimethylpurin*. The reaction is more rapid with concentrated sulphuric acid at a temperature of 140°.

Trihydroxydimethylpurin, $C_5N_4Me_2H_3O_3$, forms almost colourless crystals which melt at a very high temperature, undergoing decomposition at the same time. It is sparingly soluble in boiling water. This body is not decomposed by boiling with ammoniacal silver nitrate, but yields a gelatinous silver salt on evaporation of the excess of ammonia, thus differing entirely from the dimethyluric acid described by Hill. Chlorine or potassium chlorate and hydrochloric acid decompose it quickly into easily soluble products, but only very slight traces of any compound resembling alloxan. The principal product is an easily soluble crystalline substance which the author is now investigating. The author postpones any discussion of the uric acid formula until his researches are further advanced. L. T. T.

Chemical Nomenclature. By A. BAEYER (*Ber.*, 17, 960—963). —In this paper, the author describes a method of naming complicated organic substances by which from the name alone the exact position of the atoms and groups of atoms may at once be understood. Organic bodies may be divided into three classes; 1st, those in which there is an open chain of carbon-atoms; 2nd, those in which the chain is closed; and, 3rd, those in which there are both open and closed chains. The position of the atoms in the first is usually shown by means of Greek letters, and in the second by the use of Arabic numbers. In cases such as naphthalene and quinoline when there are two rings of atoms, one ring is represented by numbers and the other by letters. The author proposes to use letters for these rings. Thus using for the benzene-ring the letter B, and for the pyridine-ring the letters Py; the constitutional formula corresponding to the name B 1·4-dichloro-, Py 1·3-dihydroxy-quinoline, is readily understood to be that of a quinoline in which two particular hydrogen-atoms in the benzene-ring have been replaced by chlorine-atoms, and two particular hydrogen-atoms in the pyridine-ring by hydroxyls, provided the order in which the atoms are to be counted is fixed. In naphthalene the letters B and BB′, and in anthracene -B, -BB′, and perhaps A for the middle ring, may be used; thus, for example, phenylanthracene is a name which may have a treble meaning, and distinction has to be drawn between A phenylanthracene, B phenylanthracene, and BB′ phenylanthracene.

In the case of open chains, the present system of naming by means of Greek letters may be used with a slight alteration. There is an inconvenience in the present system that in substituted acids the first carbon-atom, that of the carboxyl-group, is not named α but the one next to it, whilst in substituted hydrocarbons the first carbon-atom is named α. The author now proposes in all cases to call the first carbon-atom by the last letter of the Greek alphabet, ω, and the carbon-atoms next to it in order α, β, γ, &c. The nomenclature of acids remains unaltered, but it is altered in substituted hydrocarbons; α-chlorostyrolene, $Ph.CH \vdots CHCl$, becomes ω-chlorostyrolene, and β-chlorostyrolene, $Ph.CCl \vdots CH_3$, becomes α-chlorostyrolene. There are scarcely any other similar changes, and the drawback in this case might be diminished by styling the present β-chlorostyrolene, α-* chlorostyrolene.

The following are examples of this change in nomenclature :—

Benzyl chloride .... = ω-chlorotoluene,
Benzylene dichloride .... = ω-dichlorotoluene,
Benzenyl trichloride .... = ω-trichlorotoluene,
o-Xylylene bromide .... = ω_2-dibromo-o-xylene,
Mesitylene with 3 Cl in 3 methyls = ω_3-trichloromesitylene,
Mesitylene with 3 Cl in 1 methyl = ω-trichloromesitylene,
Ph.CH_2.CH_2Br .... = ω-bromethylbenzene,
Ph.CHBr.CH_3 .... = α-bromethylbenzene,
α-Chlorostyrolene. .... = ω-chlorostyrolene,
β-Chlorostyrolene.............. = α-chlorostyrolene,
Acetophenone bromide.......... = ω-bromacetophenone,
Ph.CH_2.CH_2.CH_2Br .... = ω-bromopropylbenzene,
Ph.CH_2.CHBr.CH_3 .... = α-bromopropylbenzene,
Ph.CHBr.CH_2.CH_3 .... = β-bromopropylbenzene.

For a compound in which substitution takes place both in the closed ring and in the side chain, the above signs require to be combined. Thus an acetophenone bromide in which the benzene-ring is also brominated in the para-position, is ω-bromo-4-brom-acetophenone, or more shortly ω-4-dibromacetophenone. A substituted cinnamic acid in which one hydrogen-atom is replaced in the ring, or one in the side chain by bromine, may be called α-4-dibromo-cinnamic acid. A quinaldine, in which hydrogen in the methyl-group, in the pyridine-ring, and in the benzene-ring, has been replaced by hydroxyl groups, may be named ω-Py2-B1-trihydroxyquinaldine.

The author also proposes to use the prefixes eso- or es-, and exo- or ex- to express compounds in which hydrogen-atoms are substituted, either in the closed ring or open chain, but the more exact position of which is not known or expressed. For example, three dichlorethylbenzenes are possible in which the hydrogen-atoms in each case are substituted in the side chain. When the exact position is unknown they may be called exodichlorethylbenzene. If three hydrogen-atoms are also substituted in the benzene-ring, it may be esotrichloro-exodichlorethylbenzene. Again, if the total number of chlorine-atoms are known, but the exact positions are unknown, it may be called eso-exo-pentachlorethylbenzene. Lastly, in a similar way, if the position of the substituted atoms is only known in part of the compound, this method is of use. For example, in the case of a quinoline-cinnamic acid in which in the benzene-ring, in the pyridine-ring, and in the side chain, hydrogen-atoms have been replaced by hydroxyl-groups, but the exact position of these is unknown, the name and constitution of the acid may be expressed as B-hydroxy-Py-hydroxy-ex-hydrcxyquinolinecinnamic acid, or more shortly as B-Py-exotrihydroxyquinolinecinnamic acid; and if it is uncertain in which part of the quinoline the substitution has taken place, as es-dihydroxy-ex-hydroxyquinolinecinnamic acid.

N.B.—This system of nomenclature is used by Baeyer and his collaborators in their recently published communications.

A. B.

Xylenes. By A. Colson (*Compt. rend.*, **98**, 1543—1545).—*Orthoxylene glycol* (*phthalic glycol*), $C_6H_4(CH_2.OH)_2$, is obtained by boiling orthodibromo-xylene with the requisite quantity of potassium carbonate, and 20 or 30 times its weight of water, filtering, evaporating to dryness in a vacuum, and extracting the residue with ether. It forms rhomboidal plates, which melt at 64·5°, and readily remain in superfusion: sp. gr. of the liquid at 75° = 1·141. The glycol has a bitter taste, and dissolves in five times its weight of ether and six times its weight of water, but is more soluble in alcohol. When boiled with concentrated hydrochloric or hydrobromic acid, it yields the corresponding chloride or bromide.

Orthodibromo-xylene is obtained by adding bromine drop by drop to orthoxylene heated at 140—190°. The liquid is filtered and the solid product washed with ether and purified by repeated crystallisation from alcohol. It melts at 94·6°, and is more soluble in hot ether, alcohol, and light petroleum than in these liquids when cold. On oxidation, it yields phthalic acid, and it is partially saponified by alcohol.

Orthodichloro-xylene, obtained by the action of concentrated hydrochloric acid on the glycol, is a crystalline substance which melts at 54·8°, and sublimes easily; sp. gr. at 20° = 1·33. It is very soluble in ether and light petroleum. The dichloro-xylene obtained by Rayman (*Bull. Soc. Chim.*, **26**, 532), melting at 103°, was doubtless 1 : 4 dichloro-xylene. C. H. B.

Tribenzoylmesitylene. By E. Louise (*Compt. rend.*, **98**, 1440—1442).—Monobenzoyl- or dibenzoyl-mesitylene is dissolved in an excess of benzoic chloride, and heated with aluminium chloride at 198°, the product washed with water, and the black residue extracted with boiling alcohol. As the alcoholic solution cools, it deposits amber-coloured crystals of symmetrical tribenzoyl-mesitylene, $C_{30}H_{24}O_3$. This compound melts at 215—216°, is almost insoluble in cold alcohol, more soluble in boiling alcohol, ether, benzene, &c., but most readily dissolved by a mixture of chloroform and acetone. From this latter solvent it is deposited in large oblique rhombic prisms, the acute angle of which = 76° 46′, and the angle of the principal face on the lateral face, $P : m = 94° 10′$.

The formation of the benzoyl-derivatives of mesitylene is a function of the temperature. Below 118° the mono-derivative is formed alone, the di-derivative at 150°, and the tri-derivative at 198°.

C. H. B.

Phenethyl Compounds. By K. Mainzer (*Ber.*, **17**, 1160).—A question of priority.

Condensation Products of Thiophene with Aldehydes, Methylal, and Benzyl Alcohol. By A. Peter (*Ber.*, **17**, 1341—1347).—Comey (*Ber.*, **17**, 790) has shown that the Friedel-Crafts reaction is applicable to thiophene, and Nahnsen (*Ber.*, **17**, 789) that dithienyl, analogous to diphenyl, is formed by passing thiophene through tubes heated to dull redness. The author has further investigated the analogy between benzene and thiophene.

Dithienyltrichlorethane, $CCl_3.CH(C_4H_3S)_2$, analogous to the diphenyltrichlorethane obtained by Baeyer, is prepared as follows:—10 grams of chloral and 23 grams of crude thiophene (about half thiophene, half benzene) is dissolved in 200 glacial acetic acid; to this solution an equal volume of a mixture of equal parts of glacial acetic and strong sulphuric acids is gradually added, and finally concentrated sulphuric acid until the mixture no longer gives the thiophene reaction. The product is then poured into cold water, and purified in the usual way. Dithienyltrichlorethane is easily soluble in ether, carbon bisulphide, and boiling alcohol, sparingly in cold alcohol. It melts at 76°, and gives a very intense violet-red coloration when *heated* with sulphuric acid and isatin; so that mere traces can be detected by this reaction. The yield of dithienyltrichlorethane is about 30 per cent., but the aqueous filtrate contains a considerable quantity of its sulphonic acid.

Dithienyldichlorethylene, $CCl_2 : C(C_4H_3S)_2$, was obtained from the trichloro-compound by treatment with $1\frac{1}{4}$ mols. potassium hydroxide, but a better yield was obtained when the latter was replaced by potassium cyanide. It forms a colourless oil, which distils in a current of steam, and gives a violet-blue colour with sulphuric acid and isatin in the *cold*. Unlike the trichloro-derivative, it is decomposed by sulphuric acid.

Hexabromodithienyltrichlorethane, $CCl_3.CH(C_4Br_3S)_2$, was obtained by brominating the trichloro-derivative. It forms a white crystalline powder, soluble in boiling alcohol. It gives no colour reaction with sulphuric acid and isatin.

Dithienyltribromethane, $CBr_3.CH(C_4H_3S)_2$, obtained from bromal and thiophene, crystallises in small well-formed pyramids, which melt at 101—102°; and is analogous in its properties to the dithienyltrichlorethane.

Dithienyldibromethylene is obtained by the action of potassium hydroxide or cyanide on the tribromo-compound. It is a colourless oil, which can be distilled with steam; and resembles the dichloro-derivative in properties.

Dithienylmethane, $CH_2(C_4H_3S)_2$, was obtained by Baeyer's reaction for obtaining diphenylmethane. The yield, however, never exceeded 10 per cent., as a great deal of decomposition and formation of the sulphonic acid took place. It is a colourless oil, having an odour of oranges, and boiling at 267°. With isatin and sulphuric acid it gives a red coloration in the cold, but the colour becomes more intense on gently warming the mixture. Sulphuric acid alone causes decomposition. In one preparation of dithienylmethane, the oil solidified to lanceolate crystals; these melted at 43°, and showed the characteristic reaction of dithienylmethane with isatin and sulphuric acid, but they only weighed 0·03 gram, and the author has not been able to obtain the oil again in a crystalline state.

Phenylthienylmethane, $CH_2Ph(C_4H_3S)$, was obtained by digesting benzyl alcohol and thiophene with stannic chloride. A better yield was obtained, however, by dissolving 5 grams of benzyl alcohol, and 6 grams of pure thiophene which was diluted with its own volume of light petroleum, in 100 grams glacial acetic acid; then adding an equal volume of a mixture of equal parts of sulphuric and glacial acetic acids, and then sulphuric acid until the thiophene reaction could no longer be obtained. Phenylthienylmethane is an oil of fruity odour, and boils at 265° (uncorr.). With sulphuric acid and isatin in the cold, it gives a red coloration, which turns to a magenta-red on warming. It does not decompose so readily with sulphuric acid as most of the foregoing compounds. L. T. T.

Preparation of Phenyl Cyanate. By W. HENTSCHEL (*Ber.*, **17**, 1284—1285).—If a stream of phosgene gas be passed over fused carbanilide, phenyl cyanate distils over as a colourless oil. A still easier method of obtaining it consists in melting dry aniline hydrochloride in a retort, and passing over it a current of phosgene gas: hydrochloric acid is given off, and phenyl cyanate distils over. The phenyl cyanate absorbs a good deal of hydrochloric acid, and becomes solid, but on redistillation gives up the acid, and then remains liquid. It would seem, therefore, to possess slightly basic properties, and to form a compound with hydrochloric acid, similar to that formed by cyanic acid. These methods render it very easy to prepare phenyl cyanate in quantity. L. T. T.

Ethylphenol. By H. AUER (*Ber.*, **17**, 669—673).—Propyl-, butyl-, and amyl-phenols have been prepared by Liebmann (Abstr., 1882, 171, 727) by condensation from the respective fatty alcohols and phenol by aid of zinc chloride; and methylpropylphenol has been prepared by Mazzara (Abstr., 1883, 463), using, however, magnesium chloride as the dehydrating agent. The author has applied this reaction to the preparation of ethylphenol.

Equivalent quantities of phenol and absolute alcohol, with about twice the weight of zinc chloride, were heated in a vessel provided with a reflux condenser. The temperature remained for a long time constant at 173°, then slowly rose to 181°, when the reaction was stopped. The main products of the reaction were ethylphenol and ethylphenetoïl; they can be separated by treatment with dilute aqueous potash, in which the former alone is soluble. *Ethylphenol*, $C_6H_4Et.OH$, so obtained forms an oily colourless liquid, boils between 191—215°, has sp. gr. 1·049 at 14°, is sparingly soluble in water, readily soluble in ether and alcohol. With ferric chloride, it gives a dirty green coloration. It is probably identical with the β-ethylphenol obtained by Beilstein and Kuhlberg by the action of potash on β-ethylbenzenesulphonic acid. *Ethylphenetoïl*, $C_6H_4Et.OEt$, is a mobile colourless liquid of strong, persistent, aromatic odour. It turns yellow on exposure to light. It is insoluble in water, soluble in alcohol and ether. Sp. gr. = 0·986 at 14°. *Ethylphenolphthaleïn*, $C_{22}H_{16}O_4 + H_2O$, prepared by heating ethylphenol with phthalic acid and zinc chloride, forms a pale reddish-grey crystalline powder, insoluble in water, readily soluble in ether and alcohol. It closely resembles phenolphthaleïn, but is distinguished from it by its alkaline solution having a violet-red colour, by not being decomposed below 139°, and by the greater instability of its compound with ammonia.

Methyl alcohol, when heated with phenol and zinc chloride, yields only anisoïl, and that in very small quantity. A. J. G.

High-boiling Phenols contained in Coal-tar. By E. Nölting (*Ber.*, **17**, 386—387).—The coal-tar oils boiling above 300° probably contain the phenols of anthracene and phenanthrene.
W. C. W.

Ethereal Salts of Nitrosophenol. By J. F. Walker (*Ber.*, **17**, 399—401).—Sodium nitrosophenol is best prepared by adding phenol (1 mol.) to a concentrated alcoholic solution of sodium ethylate (1 mol.), and stirring the mixture thoroughly with amyl nitrite (1 mol.). The solution is then evaporated over sulphuric acid, and the residue is washed with ether and dried on porous tiles. *Benzoylnitrosophenol*, $C_6H_4(NO).O\overline{Bz}$, obtained by adding benzoic chloride to sodium nitrosophenol covered with a layer of anhydrous chloroform or ether, is a yellow crystalline substance which melts at 168° with decomposition. It dissolves freely in chloroform and in hot alcohol. It is decomposed by boiling with alkalis. *Ethyl nitrosophenolcarboxylate*, $C_6H_4(NO)O.COOEt$, crystallises in golden needles, which melt at 109°. It is soluble in chloroform and in hot alcohol. The corresponding methyl compound forms yellow prisms which melt at 137°. Mononitrosoresorcinol yields analogous compounds.
W. C. W.

Nitroso-orthocresol. By E. Nölting and O. Kohn (*Ber.*, **17**, 370—371).—Nitroso-orthocresol is prepared by slowly adding nitrosyl sulphate to orthocresol dissolved in 30 times its weight of water. After purifying the product by Ter Meer's process (*Ber.*, **8**, 623), the nitrocresol is obtained in white needles, soluble in alcohol, ether, chloroform, or hot water. The crystals melt at 135°, with decomposition. The sodium salt is deposited from acetone in brown needles containing 3 mols. H_2O. The potassium salt is anhydrous. Both salts dissolve freely in alcohol and in water. The aqueous solution yields precipitates with the salts of the heavy metals.

On oxidation by potassium ferricyanide, nitrosocresol is converted into the nitrorthocresol, melting at 95°, described by Neville and Winther (*Ber.*, **15**, 2978). Nitric acid (sp. gr. 1·33) converts it into dinitrorthocresol, melting at 86°. On reduction, the nitroso-compound yields the amidocresol, melting at 175°, which is also obtained by the reduction of the azo-compounds of orthocresol (see this vol., p. 902). The nitroso-group in this compound stands in the para-position as regards the hydroxyl. W. C. W.

Two Isomeric Phenyl Methyl Glycols. By T. Zincke (*Ber.*, **17**, 708—713).—Some time back the author showed that two alcohols might be obtained from stilbene bromide or chloride—hydrobenzoïn and isohydrobenzoïn—both of which can only be expressed by the same formula, CHPh.(OH).CHPh.OH (Abstr., 1877 [i], 460). Later, in conjunction with Wachendorff and Breuer (Abstr., 1878, 885), he found that styrolene bromide, $CHPhBr.CH_2Br$, yields only a single dihydric alcohol. In his present communication, he extends his researches to the dibromide CHPhBr.CHMeBr, obtained by the bromination of propylbenzene, and finds that this also yields two isomeric phenyl methyl glycols, CHPh(OH)CHMe.OH.

α-Phenyl methyl glycol is prepared by boiling the dibromide in acetic acid solution with potassium acetate, diluting with water, extracting the acetate formed with ether, and saponifying with alcoholic potash. It forms large tabular crystals which melt at 52—53°. It is readily soluble in water, alcohol, ether, acetone, benzene, and chloroform, sparingly soluble in light petroleum.

β-Phenyl methyl glycol is prepared by converting the dibromide into the benzoate and saponifying, or by boiling the dibromide for three to four days with a solution of potassium carbonate (1: 6). It is crystalline, melts at 92—93°, and is markedly less soluble than the α-alcohol in the solvents mentioned above. The investigation of these bodies and some related compounds is in progress.

A. J. G.

Trinitro-resorcinol. By E. Nölting and A. Collin (*Ber.*, **17**, 259—261).—When styphnic ether is heated with a solution of sodium hydroxide or carbonate, sodium styphnate is formed. If a cold alcoholic solution of the ether is mixed with excess of alcoholic ammonia, and the whole allowed to stand, the liquid becomes red, then yellow, and deposits the trinitrometaphenylenediamine, $C_6H(NH_2)_2(NO_2)_3$ [$NH_2 : NO_2 : NH_2 : NO_2 : NO_2 = 1 : 2 : 3 : 4 : 6$] in the form of yellow miscroscopic needles. This substance is very sparingly soluble in the ordinary solvents, and melts at a very high temperature. Ammonia is evolved on heating it with dilute soda, and sodium styphnate is re-formed. No trace of nitrous acid could be detected by Griess' reaction in the mother-liquors from which the trinitrophenylenediamine had crystallised. Styphnic acid (trinitroresorcinol), when heated with aniline, yields an aniline salt, but no trace of diazoamidobenzene. Styphnic ether and aniline yield a crystalline body, probably $C_6H(NO_2)_3(NHPh)_2$, but not further investigated; no trace of diazoamidobenzene was found. From these reactions, the authors consider that the positions of the side groups in styphnic acid must be [$OH : NO_2 : OH : NO_2 : NO_2 = 1 : 2 : 3 : 4 : 6$]. If either of the other two possible formulæ [1 : 2 : 3 : 4 : 5, or 1 : 3 : 4 : 5 : 6] were correct, nitrous acid should be eliminated when styphnic acid is treated with alkalis or ammonia. (Compare also Henriqués, Abstr., 1883, 327.)

L. T. T.

Nitrobenzyl Chlorides and Iodides. By G. Kumpf (*Ber.*, **17**, 1073—1074).—On nitrating benzyl chloride, besides solid paranitrobenzyl chloride, an oily mother-liquor is left from which, after a time, two kinds of crystals are deposited. Some of these are needles having the form of paranitrobenzyl chloride, but others have quite a different form, being thick and rhombic. The author carefully picked out the latter, and found them to be a nitrobenzyl chloride giving, on oxidation, orthonitrobenzoic acid of melting point 147°; they are therefore crystals of orthonitrobenzyl chloride.

On boiling orthonitrobenzyl chloride with potassium iodide and alcohol, orthonitrobenzyl iodide is formed. It crystallises in rhombic plates, and melts at 75°. Paranitrobenzyl iodide prepared in the same way from paranitrobenzyl chloride crystallises in colourless needles, and melts at 127°. A. B.

Orthonitrobenzyl Chloride. By E. NÖLTING (*Ber.*, **17**, 385—386).—The oil which is obtained as a bye-product in the preparation of paranitrobenzyl chloride (which is crystalline) is oxidised by potassium permanganate, yielding orthonitrobenzoic acid. It consists chiefly of orthonitrobenzyl chloride. W. C. W.

Paranitrophenyl-benzyl Ethers and Phenyl Paranitrobenzyl Ethers. By G. KUMPF (*Ber.*, **17**, 1075—1078).—A number of nitro-derivatives of phenyl benzyl ether have been prepared. The general method has been to act on benzyl chloride or paranitrobenzyl chloride with the potassium salt of nitrophenol. As the potassium salts of dinitrophenol and picric acid have no action on benzyl chloride, the silver salts and benzyl iodide were used. The ethers obtained are as a rule crystalline, and soluble in benzene or glacial acetic acid. The following were prepared:—Paranitrophenyl benzyl ether, $NO_2.C_6H_4.O.CH_2Ph$, melting at 106°; orthonitrophenyl benzyl ether, melting at 29°; *α*-dinitrophenyl benzyl ether $(NO_2)_2C_6H_3.O.CH_2Ph$, melting at 149°; *β*-dinitrophenyl benzyl ether, melting at 76°; benzyl picrate, $(NO_2)_3CH_2\ O.CH_2Ph$, melting at 149°; phenyl paranitrobenzyl ether, $PhO.CH_2.C_6H_4.NO_2$, melting at 91°; paranitrophenyl paranitrobenzyl ether, $NO_2\ C_6H_4.O.CH_2.C_6H_4.NO_2$, melting at 183°; orthonitrophenyl paranitrobenzyl ether, melting at 129°; *α*-dinitrophenyl paranitrobenzyl ether, $(NO_2)_2C_6H_3.O.CH_2.C_6H_4.NO_2$, melting at 201°; *β*-dinitrophenyl paranitrobenzyl ether, melting at 137°; paranitrobenzyl picrate, $(NO_2)_3C_6H_2.O.CH_2.C_6H_4.NO_2$, melting at 108°.

A. B.

Ethyl Phenylcarbonate. By B. PAWLEWSKI (*Ber.*, **17**, 1205).—When aluminium chloride is added in successive portions to a mixture of phenol and ethyl chlorocarbonate, ethyl phenylcarbonate is formed. This compound has been described by Fatianow (*Jahresb.*, 1864, 447).

W. C. W.

Aniline Derivatives. By A. CLAUS and H. HOWITZ (*Ber.*, **17**, 1324—1328).—With the idea of throwing light on the valency relationships of atoms, the authors have examined the di-substituted anilines and tetra-substituted ammonium iodides.

Methylethylaniline, NPhMeEt, was prepared by methylating ethylaniline, by ethylating methylaniline, and finally by decomposing the methiodide of diethylaniline with alcoholic potash. The substance obtained was in all cases identical. It is a colourless oil, which boils at 201° (uncorr.) It combines very readily, even in the cold, with methyl iodide to form *dimethylethylphenylammonium iodide*, which melts at 126°, is identical with dimethylaniline ethiodide, previously described by Claus and Rautenberg, and to which the erroneous melting point 124·5° was then ascribed. Treated with alcoholic potash, this quaternary iodide yields dimethylaniline, boiling at 192°, the identity of which was further proved by bromination, when dimethylparabromophenylamine, melting at 55°, was formed. *Diethylaniline methiodide*, mentioned above, was obtained by digesting molecular proportions of diethylaniline and methyl iodide for some time on the water-bath. It melts at 102°, and is identical with the ethiodide of methylethylaniline. These results prove that, at least as far as ethyl and methyl are concerned, the *order* of the introduction of the single radicals in ammonium compounds has no influence on the final compound obtained, and that by the decomposition of the tetra-substituted ammonium iodides by alcoholic potash, that alcohol radical is split off which contains most carbon-atoms. The authors now intend to carry on their investigations with analogous compounds containing propyl, butyl, &c.

Diethylbromophenylamine, $NEt_2.C_6H_4Br$, crystallises in colourless needles or prisms, which melt at 33°, and boil at 270°.

Methylethylbromophenylamine is a colourless oil, which boils at 265°, and solidifies below 0° to easily fusible needles.

Dimethylpropylphenylamine, $NMe_2.C_6H_4Pr$, was prepared by treating an ethereal solution of dimethylparabromophenylamine with propyl bromide and sodium. It is a colourless oil, boiling at 230° (uncorr.). It combines readily with methyl iodide, even in the cold, forming trimethylpropylphenylammonium iodide, which crystallises in colourless needles, melting at 168°. Treatment with alcoholic potash reproduces dimethylpropylphenylamine. L. T. T.

Action of Aniline on Pyrotartaric Acid. By C. BÖTTINGER (*Ber.*, 17, 996—999).—On heating a mixture of aniline and pyrotartaric acid, a violent reaction takes place, and carbonic acid and water are given off. From the liquid thus obtained, a yellowish-white precipitate is thrown down by hydrochloric acid, which, after being washed with water, may be crystallised in fine needles from alcohol. Only a very small quantity, however, crystallises, and on evaporating the mother-liquor a thick mass is obtained, from which only a very little of the crystalline substance can be extracted. The crystalline substance melts at 194·5°, and distils undecomposed when heated in small quantities at a time. It is soluble in alcohol, ether, chloroform, and benzene. It dissolves in concentrated hydrochloric acid, and from this solution double salts of mercuric chloride and platinic chloride are obtained. When heated with alcohol and concentrated hydrochloric acid at 150° in a closed tube, some aniline or ethylaniline is formed. Analysis leads to the formula $C_{14}H_{16}N_2O$, and it is possibly a hydroxy-derivative of ethylidenediphenylamine. Lazarus, who has prepared this substance, has also obtained a compound of the formula $C_{16}H_{20}N_2O$ by the action of paratoluidine on pyrotartaric acid.

A. B.

Nitro-orthotoluidine of Melting Point 107° and its Derivatives. By E. NÖLTING and A. COLLIN (*Ber.*, 17, 268—272).—When the *nitro-orthotoluidine* obtained by the authors (see p. 1012) by nitrating orthotoluidine dissolved in 10 parts of concentrated sulphuric acid, is reduced with tin and hydrochloric acid, it yields metatoluylenediamine, $C_6H_3Me(NH_2)_2$ [$NH_2 : Me : NH_2 = 1 : 2 : 5$], and therefore has the constitution $C_6H_3Me(NH_2)(NO_2)$ [$NH_2 : Me : NO_2 = 1 : 2 : 5$]. It crystallises in well-formed bright yellow monosymmetric prisms, melting at 107°, and is soluble in ether, alcohol, and acetone, sparingly so in water. The *sulphate* crystallises in yellow scales, which are slowly decomposed by water; the *nitrate* also forms yellow scales. By boiling it with 1½ times its weight of acetic anhydride an *acetonitrotoluide* is obtained, crystallising in yellowish-white needles, melting at 150—151°.

Nitro-orthocresol, $C_6H_3(OH)Me(NO_2)$ [$OH : Me : NO_2 = 1 : 2 : 5$], obtained from the nitrotoluide by means of the diazo-reaction, crystallises from boiling light petroleum in long pliant yellow needles, melting at 106—108°. It is sparingly soluble in cold water, light petroleum, and carbon bisulphide, easily in alcohol, ether, benzene, and boiling water. It is dissolved by alkalis to a yellowish-red solution, and reprecipitated by acids. The *potassium salt* crystallises in yellow needles, the *ammonium salt* in yellowish-white needles, and the *silver salt* in greenish-yellow scales. By treating an aqueous solution of nitrocresol with bromine, *dibromonitrocresol* is obtained, crystallising in yellowish needles, melting at 91—92°. It is sparingly soluble in water and light petroleum, easily so in alcohol. *Amidocresol*, $C_6H_3(OH)Me(NH_2)$ [$OH : Me : NH_2 = 1 : 2 : 5$], is obtained by the reduction of the nitro-body with tin and hydrochloric acid. It melts at 159—161°, and is identical with that described by Wallach (Abstr., 1883, 329). *Trinitro-orthocresol* was obtained by dissolving nitrotoluidine in two molecular proportions of nitric acid, diazotising, pouring the liquid product into moderately concentrated hot nitric acid, and boiling the whole. It crystallises in thick orange-yellow prisms, melting at 102°. It is sparingly soluble in cold water, easily so in alcohol, ether, acetone, acetic ether, and chloroform. Its constitution must be either [$OH : Me : NO_2 : NO_2 : NO_2 = 1 : 2 : 4 : 5 : 6$, $1 : 2 : 3 : 4 : 5$, or $1 : 2 : 3 : 5 : 6$] the authors think the first most probable. Alkalis decompose it with formation of a nitrite; with aniline it yields diazoamidobenzene. It forms molecular compounds with hydrocarbons like benzene and naphthalene; the compound with naphthalene crystallises in yellowish needles, which soften at 102°, and melt at 106°.

The authors are now investigating the reactions of metamidocresol, from which they have obtained a number of colouring matters.

L. T. T.

Derivatives of Propylphenylamine. By A. FRANCKSEN (*Ber.*, **17**, 1220—1231).—Propylphenylamine, $C_6H_4Pr.NH_2$, was prepared according to the directions given by Louis (*Ber.*, **16**, 105). Contrary to Louis' statements, the author has obtained the *hydrochloride* of this base in the form of white crystalline scales, soluble in water and alcohol, sparingly so in ether, and melting at 203—204°. The *platinochloride* crystallises in small bright yellow scales. The *hydrobromide* crystallises in glittering white scales, easily soluble in water and alcohol, and melting at 213°. The *hydriodide*, $C_3H_7.C_6H_4.NH_3I$, forms small white scales, soluble in water, alcohol, and ether, but becoming rapidly discoloured on exposure to the air.

Dipropylphenlythiocarbamide, $CS(NH.C_6H_4Pr)_2$, is obtained by digesting an alcoholic solution of the free base with carbon bisulphide. It crystallises in glittering white scales, sparingly soluble in cold alcohol, easily so in boiling alcohol, ether, and carbon bisulphide, and melting at 138°. *Propylphenylthiocarbamide*, $NH_2.CS(NH.C_6H_4Pr)$, was prepared by evaporating an aqueous mixture of propylphenylamine hydrochloride and ammonium thiocyanate. It crystallises in minute glittering white needles, easily soluble in ether and boiling alcohol, and melting at 159°.

Propylphenylthiocarbimide, $C_6H_4Pr.NCS$, was obtained by Hofmann's reaction, by heating dipropylphenylthiocarbamide with a very concentrated solution of phosphoric acid (containing about 60 per cent. anhydride). It is a colourless oil which turns yellowish on exposure to the air. It boils at 263°, but is volatile in a current of steam. It is easily soluble in alcohol and ether.

Dipropylphenylcarbamide, $CO(NH.C_6H_4Pr)_2$, is obtained in almost theoretical quantity when propylphenylamine is heated with carbamide at 150—170°. It forms a pure white crystalline mass, consisting of groups of needles. It is sparingly soluble in cold alcohol, easily so in boiling alcohol and in ether. It melts at 205°. It may also be prepared by treating a solution of propylphenylamine in benzene with phosgene gas, and in small quantity by the action of potassium thiocyanate on propylphenylamine sulphate. *Monopropylphenylcarbamide*, $NH_2.CO.NH.C_6H_4Pr$, was prepared by mixing an aqueous solution of propylphenylamine hydrochloride with potassium isocyanate in the cold, and then warming the mixture gently. A small quantity of an oily base is formed and must be skimmed off the surface, and the aqueous solution evaporated. The di-substituted carbamide is always formed in this reaction, especially if the two solutions are not kept cool during the mixing. Monopropylphenylcarbamide forms colourless crystalline scales, which are easily soluble in boiling alcohol, very sparingly in cold alcohol, ether, and water. It melts at 143°.

Dipropylphenylguanidine, $NH : C(NH.C_6H_4Pr)_2$, is obtained by heating an alcoholic solution of dipropylphenylthiocarbamide with excess of ammonia and lead oxide; the filtrate from the lead sulphide is mixed with water whilst still warm, and on cooling the guanidine crystallises out in small white needles. It is easily soluble in ether and boiling alcohol, and melts at 113°. The *platinochloride* forms a yellowish-brown amorphous powder. *Phenyldipropylphenylguanidine*, $NPh : C(NH.C_6H_4Pr)_2$, is prepared by heating an alcoholic solution of dipropylphenylthiocarbamide with excess of aniline and lead oxide. It forms a yellowish resinous mass, easily soluble in ether, benzene, and boiling alcohol. *Tripropylphenylguanidine*, $NC_6H_4Pr : C(NH.C_6H_4Pr)_2$, is prepared in a similar manner, propylphenylamine being substituted for aniline. It was not obtained in a crystalline form. Its *platinochloride* forms a brown amorphous powder, sparingly soluble in alcohol. In analogy with tri-substituted guanidines, tripropylphenylguanidine, when heated with carbon bisulphide at 190—200°, splits up into dipropylphenylthiocarbamide and propylphenylthiocarbimide.

Carbodipropylphenylimide, $C(N.C_6H_4Pr)_2$, is obtained by heating a solution of dipropylphenylthiocarbamide in benzene with excess of lead oxide. It crystallises in clusters of needles, having an odour somewhat resembling that of oil of mustard. It melts at 168°. The *hydrochloride* forms white crystalline flakes. The imide is converted into the corresponding carbamide, $CO(NH.C_6H_4Pr)_2$, if its solution in dilute alcohol be heated for a short time on the water-bath. Heated with carbon bisulphide at 190° it yields propylphenylthiocarbimide. Heated with propylphenylamine in benzene solution, it gives tripropylphenylguanidine. Attempts to obtain dipropylphenylcarbamide by treatment of the imide with sulphuretted hydrogen were unsuccessful.

Propylphenyl cyanide, $C_6H_4Pr.CN$, was prepared by heating propylphenylthiocarbimide with freshly reduced copper powder at 220°. The copper rapidly blackens, and the odour of an isocyanide becomes perceptible, but after a time gives place to that of the nitrile. Propylphenyl cyanide is a colourless oil of aromatic odour, and boils at 227°. It is converted into the corresponding benzoic acid by heating it with excess of hydrochloric acid at 200°. The propylbenzoic acid thus obtained melts at 137°, and resembles in all its properties Paterno and Spica's para-propylbenzoic acid (*Ber.*, 10, 1746), obtained by the oxidation of para-propylisopropylbenzene, and for which they found the melting point 138—139. It is thus clear that the cyanide, and consequently the propylphenylamine investigated, are para-compounds. L. T. T.

Constitution of Amidoisobutylbenzene. By A. Pahl (*Ber.*, 17, 1232—1245).—The author has employed two methods for determining the relative position of the two side groups in this compound: A,—its conversion into a diazo-salt, thence into iodoisobutylbenzene, and the oxidation of this compound to an iodobenzoic acid. B,—by the successive conversion of the amine into di-isobutylphenylthiocarbamide, isobutylphenylthiocarbimide, isobutylphenyl cyanide, isobutylbenzoic acid, and finally the oxidation of this last-named body into one of the three well-characterised phthalic acids.

The isobutylphenylamine employed was prepared by acting on a mixture of isobutyl alcohol and aniline with zinc chloride, and was identical with that obtained by Studer by simply heating a mixture of isobutyl alcohol and aniline at 230°.

A. *Iodoisobutylbenzene*, $C_6H_4I.C_4H_9$, was obtained by the conversion of the hydrochloride of the amine into the diazo-salt, treating the solution of this salt with excess of hydriodic acid, and heating to boiling. It forms an easily fusible colourless crystalline mass, which boils at 255—256° (corr.), and volatilises in a current of steam. An attempt was made to oxidise this substance with chromic acid in acetic solution, but the results were not satisfactory; by heating the iodoisobutylbenzene with excess of nitric acid of sp. gr. 1·12 at 200°, however, it is converted into *iodobenzoic acid*. This sublimes easily in white nacreous scales, melting at 262°. Its methyl salt crystallises in needles which melt at 115°. It is thus clear that the iodobenzoic acid in question is identical with the paraiodobenzoic acid of Schmidt and Schultz.

B. *Di-isobutylphenylthiocarbamide*, $CS(NH.C_6H_4.C_4H_9)_2$, was obtained by digesting an alcoholic solution of isobutylphenylamine with carbon bisulphide. It crystallises in beautiful white groups of needles, insoluble in water, sparingly soluble in boiling alcohol, easily so in boiling ether and benzene. It melts at 192·5°, and is converted into *isobutylphenylthiocarbimide*, $C_4H_9.C_6H_4.NCS$, by the action of syrupy phosphoric acid; this crystallises in needles melting at 42°, and boils at 272°. It is very soluble in alcohol and ether.

Isobutylphenyl cyanide, $C_4H_9.C_6H_4.CN$, obtained by Weith's method by heating the thiocyanate with powdered copper at 200°, forms a thick colourless liquid which boils at 238°, and does not solidify at −15°. A vapour-density made in V. Meyer's apparatus gave 5·35 instead of 5·51 required by theory.

Isobutylbenzoic acid, $C_4H_9.C_6H_4.COOH$, was obtained by the saponification of the cyanide with alcoholic potash. It forms a white crystalline mass, which sublimes in long flat needles. It melts at 161°, and is easily soluble in alcohol and ether, very sparingly so even in boiling water. It forms characteristic salts which, with the exception of those of the alkalis, are insoluble, or nearly so, in water. The *silver salt* forms a white flocculent precipitate; the *barium salt* is easily soluble in boiling water, sparingly so in cold; the *calcium salt* forms a crystalline precipitate, which dissolves in boiling water and crystallises out again on cooling; the *methyl salt* is colourless and boils at 247°. Subjected to oxidation by an alkaline permanganate solution, isobutylbenzoic acid yielded *terephthalic acid*. From this result, and the iodobenzoic acid obtained by method A, it is clear that the isobutylphenylamine employed, and consequently that obtained by Studer, is the para-compound.

The author has also prepared the following derivatives:—*Di-isobutylphenylcarbamide*, $CO(NH.C_6H_4.C_4H_9)_2$, was obtained by passing carbon oxychloride into a solution of the original amine in benzene and also from the corresponding thiocarbamide already described. It crystallises in colourless needles, which melt at 283—284°, and are easily soluble in boiling alcohol, very sparingly so in water.

Di-isobutylphenylguanidine, $NH : C(NH.C_6H_4.C_4H_9)_2$, was obtained by treatment of the thiocarbamide with ammonia and lead oxide. It crystallises in colourless flakes, melting at 173°, and is easily soluble in hot alcohol and benzene. The platinochloride forms a yellow crystalline precipitate.

Tri-isobutylphenylguanidine, $C_4H_9.C_6H_4N : C(NH.C_6H_4.C_4H_9)_2$, was prepared in a manner similar to the substance last described, except that isobutylphenylamine took the place of ammonia. It crystallises in small white needles, which melt at 163—164°, and are easily soluble in boiling alcohol and benzene. The *platinochloride* is a bright yellow crystalline precipitate. Heated with carbon bisulphide, this guanidine forms di-isobutylphenylcarbamide and isobutylphenylthiocarbimide.

Carbodi-isobutylphenylimide, $C(N.C_6H_4.C_4H_9)_2$, was prepared from the di-substituted thiocarbamide by the action of lead oxide. The crystals melt at 189°, and are easily soluble in boiling benzene or toluene, sparingly so in boiling alcohol. Its solution in dilute alcohol easily yields the di-substituted carbamide when heated, and with ammonia gives di-isobutylphenylguanidine. When heated with carbon bisulphide at 170°, it yields isobutylphenylthiocarbimide.

L. T. T.

Aromatic Alkines. By W. LAUN (*Ber.*, **14**, 675—679).—*Methylphenylethylalkine*, $NPhMe.C_2H_4OH$, is obtained as hydrochloride, by heating equal molecular weights of methylaniline and ethylene chlorhydrin in sealed tubes at 100° for 35 hours. The free base is a colourless liquid of aniline-like odour; it boils at 218—219° under 110 mm. pressure, but cannot be distilled unchanged at the ordinary pressure, has sp. gr. 1·08065 at 0°, and is nearly insoluble in water. By long exposure to air, it is converted into a viscid blue syrup, soluble in water or alcohol with blue colour. The sulphate and nitrate could only be crystallised with great difficulty; neither platinochloride nor aurochloride could be prepared, the base precipitating both gold and platinum from their solutions. By heating the base with methyl iodide, the additive-compound, $NPhMe(C_2H_4.OH),MeI$, is obtained, crystallising in colourless tables and plates; treated with alcoholic solution of iodine, it yields a periodide,

$$NPhMe(C_2H_4.OH)MeI,I_4,$$

crystallising in lustrous plates, and melting with decomposition at 87°.

Phenyldiethylalkine, $NPhEt.C_2H_4.OH$, prepared from ethylaniline and ethylene chlorhydrin, closely resembles the foregoing compound, but distils unaltered at 267—268·5° under the ordinary pressure.

Methylphenylpropylalkine, $NMePh.C_3H_6.OH$. prepared from methylaniline and propylene chlorhydrin, boils at 262°.

Ethylphenylpropylalkine, $NEtPh.C_3H_6.OH$, prepared from ethylaniline and propylene chlorhydrin, is a colourless substance of very weak basic properties; it boils at 261—263°.

Benzaldipiperyl, $CHPh(C_5H_{10}N)_2$, is obtained by long-continued heating of a mixture of benzaldehyde and piperidine in sealed tubes. It forms lustrous transparent prisms, of faint odour, recalling both its components, melts at 80—81°, and is destitute of basic properties. It is readily reconverted into benzaldehyde and piperidine by dilute acids, or by a few minutes' boiling with water. A. J. G.

Nitration of Benzene Derivatives. By E. NÖLTING and A. COLLIN (*Ber.*, **14**, 261—268).—It is well known that, in the nitration of mono-substitution products of benzene, the para-disubstitution product is principally formed, together with small quantities of the ortho- and, quite exceptionally, traces of the meta-compounds, when the primary side group is of a basic (NH_2), neutral (CH_3 or a halogen), or only slightly acid (OH) character; but that when this primary group is of a distinctly acid character, the meta-compound is that chiefly obtained. Hübner and Frerichs (*Ber.*, **10**, 1716), and Mears (*Ber.*, **9**, 744), have shown that if the basicity of the NH_2-group is neutralised by combination with a strong acid, or by substitution of one of its hydrogen-atoms by an acid radical, the formation of metabisubstitution products takes place simultaneously with that of para- and ortho-derivatives. In the present communication, the authors show that by the use of strong acid solvents in large excess, when nitrating amido-derivatives, the formation of meta-derivatives can be determined, in some cases even to the exclusion of that of para- and ortho-derivatives.

Aniline.—Hübner and Frerichs have shown that aniline dissolved in 100 per cent. sulphuric acid (66° Baumé), and nitrated with a mixture of strong nitric and sulphuric acids, yields a mixture of the three isomeric nitranilines. The authors, by using a very large excess of sulphuric acid (50 parts) have succeeded in increasing the proportion of metanitraniline, but the para-body was always present.

Acetanilide.—The nitration of this body may be conveniently carried out on a considerable scale as follows:—590 grams (1 mol.) of nitric acid of sp. gr. 1·478 (or the corresponding quantity of acid of sp. gr. 1·400), mixed with 1200 grams of sulphuric acid, is allowed to flow slowly into a solution of 1 kilo. acetanilide in 4 kilos. sulphuric acid, cooled by ice and salt. The whole is allowed to stand for some time and then poured into iced water, when paranitracetanilide separates out in pale yellow flakes, which, after one recrystallisation, have the correct melting point, 207°. The yield is over 95 per cent., and the authors have worked with quantities up to 2 kilos. of acetanilide. Paranitraniline is obtained from the aceto-compound by saponification with concentrated sulphuric acid: a trace of orthonitraniline is always present in the mother-liquors. By largely increasing the proportion of sulphuric acid used as a solvent, small quantities of metanitracetanilide are produced, but the para-body is always the principal product.

Paratoluidine, dissolved in 10 parts of sulphuric acid, and nitrated in a similar manner, yields a mixture of the two isomeric nitrotoluidines of melting points 114° [$NH_2 : NO_2 : Me = 1 : 2 : 4$] and 78° [$1 : 3 : 4$], the latter always being in excess. If the sulphuric acid be increased to 15—20 parts, the [$1 : 3 : 4$] derivative alone is produced.

Paracetotoluide, dissolved in 4 parts sulphuric acid, yields the same nitroacetotoluide—of m. p. 92°, and yielding nitrotoluidine of m. p. 114° and constitution [$NH_2 : NO_2 : CH_3 = 1 : 2 : 4$]—obtained by Beilstein and Kuhlberg by adding paracetotoluide to fuming nitric acid. The yield is good. If 10 parts of sulphuric acid be used, a mixture of the two isomerides [$1 : 2 : 4$] and [$1 : 3 : 4$] is obtained; and if the acid be increased to 20 parts, the proportion of the latter is increased, but this could not be obtained as the sole product even by still further increasing the proportion of sulphuric acid used.

Orthotoluidine in 10 parts sulphuric acid yields a nitro-derivative, melting at 107°, and which the authors show (p. 1007) to be $C_6H_3(NH_2)Me(NO_2)[NH_2 : Me : NO_2 = 1 : 2 : 5]$. With more than 10 parts sulphuric acid, the reaction takes place less regularly.

Orthacetotoluide in 4 parts sulphuric acid gives a mixture of the two isomeric nitro-orthacetotoluides [$NHAc : Me : NO_2 = 1 : 2 : 5$ and $1 : 2 : 4$]; with 20 parts, exclusively the former.

Metaxylidine in 10 parts sulphuric acid gives the nitroxylidine [NH_2 : Me : Me : NO_2 = 1 : 2 : 4 : 5], melting at 123°, and already described by Fittig, Ahrens, and Matheides (*Annalen*, **147**, 18).

Metaceto-xylide in 10 parts sulphuric acid yields the aceto-derivative corresponding with the above-named nitro-xylidine; with 4 parts sulphuric acid, this is mixed with the [1 : 2 : 4 : 6] derivative obtained when fuming nitric acid alone is used.

Parabromaniline in 10 parts sulphuric acid yields a new *parabromonitraniline*, melting at 131—132°, and having the constitution [NH_2 : NO_2 : Br = 1 : 3 : 4]. It crystallises from alcohol in flat needles, is easily soluble in alcohol, ether, acetic acid, ethyl acetate, and chloroform, sparingly so in water. Treated in acetic solution with excess of bromine, it yields the tribromonitraniline, melting at 102·5°, already obtained by brominating metanitraniline, thus establishing the correctness of the above formula.

Ethylacetanilide in 5 parts of sulphuric acid yields *paranitroethylacetanilide*, melting at 118°. When saponified with hydrochloric acid, this yields paranitroethylaniline; it crystallises from alcohol in pale yellow prisms, showing a bluish-violet fluorescence, and melting at 96°. By reduction with tin and hydrochloric acid, a monethylphenylenediamine is obtained, which yields a hydrochloride, crystallising in white scales, soluble in water and alcohol. This diamine has all the characteristics of a para-diamine, and yields safranine, indophenol, and quinone; thus proving the para-position of the nitro-group.

Dimethylaniline in 20 parts of nitric acid yields *paranitrodimethylaniline*. No isomerides could be detected.

These researches show the great influence which the solvent has in determining the position of the hydrogen-atom substituted during the process of nitration. L. T. T.

Introduction of the Diazo-group into so-called Aromatic Para-compounds. By P. Griess (*Ber.*, **17**, 338—341).—In reference to the statements of Liebermann and v. Kostanecki (this vol., p. 736), the author points out that he some time ago (Abstr., 1882, 182) proved the incorrectness of the generally received idea that the diazo-group always enters phenols in the para-position relatively to the hydroxyl-group. After the author had found that of the three diamidobenzenes and their homologues only the meta-compounds are capable of uniting with the diazo-compounds to form dyes, he investigated the action of the phenols in this respect, but found that although the same is the case with the three dihydroxybenzenes, no such regularity exists with regard to other di-substituted derivatives containing a hydroxyl-group. As regards the statement of Nölting and Witt (*Ber.*, **17**, 77, this vol., p. 742) "that it has hitherto always been accepted as a fact that amido- and oxyazo-derivatives can only be formed by the action of diazo-compounds on phenols and amines when the para-position in these is still unoccupied," the author draws attention to the fact that he has always contested this, and long ago proved its incorrectness.

Paranitrophenol is capable of entering into combination with certain diazo-derivatives, but the compounds so obtained approach the diazo-compounds in character much more nearly than they do to the azo-compounds. When a cold concentrated and slightly alkaline solution of paranitrophenol is treated with the nitrate of orthodiazobenzoic acid, it yields a substance crystallising in minute white scales; this is easily soluble in alcohol, but insoluble in ether, and is at once decomposed by boiling water according to the equation—

$$\underset{\text{New compound.}}{C_6H_4(COOH).N_2.O.C_6H_4(NO_2)} + H_2O = \underset{\text{Salicylic acid.}}{C_6H_4(OH).COOH} + \underset{p\text{-Nitrophenol.}}{C_6H_4(NO_2).OH} + N_2.$$

An analogous but less stable compound is obtained when orthonitrophenol is substituted for the para-compound, and is now under investigation. L. T. T.

Action of Hydrochloric Acid on Amidoazo-compounds. By O. WALLACH and A. KÖLLIKER (*Ber.*, 17, 395—399).—Amidoazobenzene is rapidly decomposed by hydrochloric acid at 100°, the chief products of the decomposition being aniline, paraphenylenediamine, and di-, tri-, and tetra-chloroquinol. This decomposition can only be accounted for on the assumption that the hydrochloric acid acts like a mixture of free hydrogen and free chlorine. The formation of induline by the action of strong hydrochloric acid on amidoazobenzene is due to a secondary reaction. W. C. W.

Diazoamidobenzene. By B. FISCHER (*Ber.*, 17, 641—642).—In the preparation of amidoazobenzene, sodium acetate was added to the mixture of aniline, hydrochloric acid, and sodium nitrite in the expectation that the reaction would be facilitated. It was found, however, that under these circumstances diazoamidobenzene was obtained, and not amidoazobenzene. When sodium hydroxide is added, however, instead of the acetate, amidoazobenzene is produced.

A. J. G.

Azophenols. By R. BOHN and K. HEUMANN (*Ber.*, 17, 272—276).—The authors have already shown (Abstr., 1883, 583) that on nitrating parazophenol the azo-group is eliminated and dinitrophenol formed. They have now further investigated the behaviour of azophenols towards various reagents. Parazophenolmonosulphonic acid was introduced into warm nitric acid, and the product precipitated with water: [1 : 2 : 4] *dinitrophenol* was obtained, melting at 113—114°, showing that both the azo- and sulphonic-groups had been removed. Orthazophenol, melting at 171°, prepared by fusing orthonitrophenol with potash, was nitrated in acetic solution: picric acid was obtained, showing that here also the azo-group had been destroyed. The author believes that the formation of a tri- instead of a di-nitro-derivative was probably due to the reaction having accidentally become more violent. By chlorinating parazophenol in acetic solution, *trichlorophenol*, $C_6H_2Cl_3.OH$, was obtained. On first passing the stream of chlorine, a slight precipitate, consisting of dark violet needles, was produced; this proved to be a modified crystalline form of parazophenol. Chlorine passed into an acetic solution of orthazophenol yielded *trichlororthazophenol*, the behaviour of the ortho- and para-derivatives to chlorine being thus quite different. Trichlororthazophenol crystallises in long, reddish-yellow needles, which melt at 235°, and sublime unchanged. It is soluble in benzene, sparingly so in alcohol and light petroleum, and crystallises from the latter in yellow silky needles. It dissolves in alkalis with red coloration, and gives a deep red colour with ferric chloride or other oxidising agents.

L. T. T.

Hydrazobenzene and Benzidine. By D. STERN (*Ber.*, **17**, 379—381).—The product of the action of hydrazobenzene on benzoic chloride is partly soluble in alcohol. The crystalline residue, consisting of *dibenzoylbenzidine*, $NPh\overline{Bz}.NPh\overline{Bz}$, is insoluble in the usual solvents, but dissolves in hot nitrobenzene. The colourless crystals sublime without decomposition. This compound is also formed by the action of benzoic chloride on benzidine.

Diformylbenzidine, $CHO\ NH.C_6H_4.NH.CHO$, prepared by the action of formic acid on hydrazobenzene, resembles the preceding compound. *Monacetohydrazobenzene* is formed by bringing together acetic anhydride and hydrazobenzene at the ordinary temperature. It is deposited from alcohol in needle-shaped crystals melting at 159°, soluble in water. It is decomposed by heat into azobenzene and acetanilide.

W. C. W.

Action of Bibasic Organic Acids on Hydrazobenzene. By E. BANDROWSKI (*Ber.*, 17, 1181—1185).—Beilstein's statement that organic acids have no actionon hydrazobenzene is incorrect. On heating a mixture of hydrazobenzene (1 mol.) with phthalic anhydride (2 mols.) at 130° for three hours, a reaction takes place. The product is partly soluble in benzene and alcohol. The insoluble residue consists of diphthalyl-diparabenzidine, $C_{28}H_{16}N_2O_4$, and the solution contains azobenzene, phthalanile, and a substance melting at 194°, probably the diphthalyl of parorthobenzidine.

Diphthalyl-diparabenzidine is deposited from its solution in hot nitrobenzene in yellow crystals which melt above 360°. It dissolves in strong sulphuric acid; if the solution is heated to 140°, it splits up into diparabenzidine and phthalic anhydride. The compound may be easily prepared by heating a mixture of these two bodies. Diphthalyl-diparabenzidine dissolves in fuming nitric acid; and on diluting the solution with water, a dinitro-product, $C_{28}H_{14}(NO_2)_2N_2O_4$, is precipitated. Alcohol precipitates it from its solution in nitrobenzene as a crystalline powder.

An energetic reaction takes place on heating a mixture of hydrazobenzene and anhydrous oxalic acid. On extracting the crude product with alcohol, a crystalline compound goes into solution, and a violet-grey residue remains having the composition $C_{16}H_{12}N_2O_4$; it is insoluble in the usual solvents, but dissolves in strong sulphuric acid.

The addition of water to the solution produces an amorphous precipitate, which dissolves in alkalis, forming a deep red liquid. The colour is destroyed by zinc-dust, but reappears on exposure to the air.

W. C. W.

Paramidoacetanilide, and some New Azo-derivatives. By R. Nietzki (*Ber.*, **17**, 343—346).—By the reduction of paranitracetanilide with iron and a little acetic acid, the author has obtained *paramidoacetanilide*. Hitherto when dealing with nitrated anilides, the action has gone further, acetic acid being always eliminated. The author believes this to be due to the use of too energetic reducing agents. *Paramidoacetanilide* crystallises in long colourless concentrically-grouped needles, very sparingly soluble in cold water, easily so in boiling water, alcohol, and ether: it melts at 161°. It acts as a monacid base forming crystalline salts; its platinochloride crystallises in yellow, sparingly soluble needles. When boiled with dilute acids, it is readily decomposed into acetic acid and paraphenylenediamine.

If the diazo-compound is added to an alkaline solution of β-naphtholdisulphonic acid, a body crystallising in glistening golden scales, and having the probable constitution $NH\overline{Ac}.C_6H_4.N_3.C_{10}H_4(HSO_3)_2.OH$, is formed. On boiling this with dilute sulphuric acid, the acetyl-group is removed and a purplish-red colouring matter is obtained which can again be further diazotised. If this is treated with β-naphtholdisulphonic acid, it yields a colouring matter crystallising in green iridescent needles, and dyeing wool and silk a deep indigo-blue: the colour is however unstable if exposed to the light, soon changing into a brownish-violet.

Paradiazoacetanilide and aniline yield *acetyldiamidoazobenzene*, $NH.\overline{Ac}C_6H_4.N_2.C_6H_4.NH_2$, crystallising in golden-yellow scales which melt at 212°. Acids turn it red. The hydrochloride forms silver-grey scales. Boiling with dilute sulphuric acid converts the acetyl compound into symmetric paradiamidoazobenzene. This substance has also been described by Mixter (this vol., 665) under the name of parazoaniline. It crystallises from alcohol in long, golden-yellow needles, easily soluble in alcohol, sparingly so in benzene and light petroleum. It forms two series of salts, those with two proportions of the acid being red in colour, those with one equivalent of acid green. The dihydrochloride is precipitated from an alcoholic solution of the base by excess of hydrochloric acid in the form of very dark green iridescent needles.

L. T. T.

Action of Sulphuric Acid on Carbanilide. By W. Hentschel (*Ber.*, **17**, 1287—1289).—Pure carbanilide dissolves in cold concentrated sulphuric acid without discoloration, and the solution may be kept for days without change. But if carbanilide be digested on the water-bath for about half an hour with about five times its weight of acid, although there is no apparent reaction, a change has taken place. The product, poured into water and treated with barium carbonate, yields barium sulphanilate and the barium salt of an acid having the formula $C_7H_7NSO_5$. The free acid is easily soluble in water, and the author believes it to be an amidosulphobenzoic acid, the reaction being as follows:—

$$CO(NHPh)_2 + 2H_2SO_4 = NH_2.C_6H_4.SO_3H + NH_2.C_6H_3(SO_3H).COOH + H_2O.$$

L. T. T.

Derivatives of Thiocarbamide. By B. RATHKE (*Ber.*, **17**, 297—309).—The author has carefully investigated some of the compounds which thiocarbamide forms with metallic salts, as they seem to prove that many of the so-called molecular compounds are really true chemical compounds.

The author has already (Abstr., 1883, 166) described a copper compound of thiocarbamide obtained by adding cupric chloride to a solution of thiocarbamide. Prätorius and Seidler have since described a similar compound to which they have ascribed the formula

$$2CSN_2H_2,CuSO_4.$$

This is incorrect, as the copper contained in the compound must be monovalent, since sulphuretted hydrogen precipitates Cu_2S and not CuS. If cupric chloride is added to a solution of thiocarbamide as long as a precipitate is formed, the latter is found to consist of minute white needles of the formula $CSN_2H_4,CuCl$: the colourless and strongly acid filtrate contains the compound of 1 mol. thiocarbamide and 1 atom of chloride described by Claus (*J. pr. Chem.*, **21**, 146). Cupric sulphate yields similar compounds. Cuprous chloride yields three compounds containing respectively 1, 2, and 3 mols. of thiocarbamide to the group CuCl. The first of these is insoluble in water, the third soluble, whilst excess of water splits up the second into equal proportions of the first and third. The body $3CSN_2H_4,CuCl$ is obtained by adding a dilute solution of cupric chloride to a boiling solution of thiocarbamide as long as the precipitate formed is quickly redissolved; also, by digesting together the calculated quantities of these two substances; or by covering pieces of copper-foil with a solution of thiocarbamide and adding small quantities of hydrochloric acid from time to time, when a copious evolution of hydrogen takes place, and the solution contains the substance in question. It forms large colourless and strongly refractive crystals belonging to the quadratic system. Its solution has an alkaline reaction. It is reprecipitated unchanged from its solution by soluble chlorides. Zinc precipitates copper from its solutions; ammonia and sodium hydroxide and carbonate give white precipitates which gradually blacken, becoming converted into cuprous sulphide: sulphuretted hydrogen causes a precipitation of cuprous sulphide, but only *very* slowly. The body $CSN_2H_4,CuCl + \frac{1}{2}H_2O$ is obtained if excess of cupric chloride is used, and forms a voluminous white precipitate consisting of minute needles. It is also obtained by digesting together the calculated quantities of thiocarbamide and cuprous chloride. It loses its water in the desiccator, becoming at the same time very slightly greyish-blue. $2CSN_2H_4,CuCl$ is obtained by uniting the two previously-described compounds, and is again decomposed into these two by excess of water. It crystallises in needles. Cupric sulphate added in excess to a solution of thiocarbamide precipitates a yellow oil which solidifies on exposure to the air. If this substance is dissolved in a boiling solution of thiocarbamide a body crystallises out on cooling in long needles having the formula $5CSN_2H_4,Cu_2SO_4 + 2H_2O$. Analogous compounds may be obtained containing cuprous nitrate or carbonate. In all these compounds half the sulphur is precipitated as cuprous sulphate on boiling the substance with dilute ammonia: the remainder of the sulphur can then be precipitated from the filtrate by ammoniacal silver nitrate.

The author believes all these compounds to be true *chemical* and not merely *molecular* compounds, for the following reasons:—(1.) Neither cuprous carbonate nor nitrate can exist in the free state. (2.) The soluble among these compounds (even that with mercuric chloride) have an alkaline reaction. (3.) Copper, when heated with thiocarbamide and hydrochloric acid, dissolves readily with evolution of hydrogen. (4.) Cuprous chloride, both in hydrochloric and ammoniacal solution, absorbs carbonic acid readily, but in these compounds it does not do so.

The author has also obtained analogous compounds with phenylthiocarbamide. If a little copper chloride be added to a solution of monophenylthiocarbamide in boiling water, the smell of phenylthiocarbimide becomes perceptible, and a yellow oil is precipitated. This oil solidifies on cooling, and, when recrystallised from alcohol, yields colourless crystals. The same substance is obtained by boiling cuprous chloride in a solution of monophenylthiocarbamide, and also by boiling the compound $CSN_2H_4,CuCl$ with phenylthiocarbamide and water. Analysis showed the composition of this substance to be

$$3CSN_2H_3Ph,CuCl + 3H_2O.$$

It appears to lose its water of crystallisation at 100°, but also undergoes partial decomposition: it melts at 144—145°. Another compound of phenylthiocarbamide containing a larger proportion of cuprous chloride was also obtained. Diphenylthiocarbamide yields analogous compounds when treated with cuprous chloride.

The compounds of thiocarbamide which Reynolds has obtained with gold and platinum chlorides also belong to this class of bodies. The author has examined the gold chloride compounds and finds the gold to be present in the aurous state.

Salts of barium, magnesium, cobalt, nickel, manganese, zinc, iron as ferrous salt, and chromium, do not show any change in reaction of their neutral or acid solutions when mixed with thiocarbamide, but solutions of mercuric chloride and cyanide, silver chloride and nitrate, cadmium and thallium sulphates, and lead chloride become strongly alkaline when so treated, pointing to the formation of double compounds.

The author has replaced the metals in these compounds by ethyl (by treatment with ethyl iodide), and obtained the compound $HI,NH : C(NH_2).SEt$, which seems clearly to point to the metal being attached to the sulphur-atom. The proof is however not absolute, as the same compound is obtained when free thiocarbamide is treated with ethyl iodide.

L. T. T.

Methylphthalimide. By C. GRAEBE and A. PICTET (*Ber.*, 17, 1173—1175).—*Methylphthalimide*, NMe :  $\mathrm{C}{<}\overset{\mathrm{C_6H_4}}{\underset{-\mathrm{O}-}{\quad}}{>}\mathrm{CO}$, formed by the action of potassium phthalimide on methyl iodide at 150°, crystallises in silky needles which are soluble in alcohol and in hot water. Methylphthalimide melts at 132° and boils about 277°. On reduction with tin and hydrochloric acid it yields a base, C_9H_9ON, which melts at 120° and boils at 300°. It is deposited from an ethereal solution in large plates which dissolve freely in water, alcohol, ether, and chloroform. The *hydrochloride* is insoluble in ether and chloroform. The *aurochloride*, $(C_9H_9ON)_2,HAuCl_4$, forms beautiful crystals which melt under boiling water. In the dry state they melt at 195° with gradual decomposition. W. C. W.

Pyrotartrylfluoresceïn. By E. HJELT (*Ber.*, 17, 1280—1281).—The fluoresceïn of pyrotartaric acid was obtained by heating together 5 parts of tartaric acid, 9 parts resorcinol, and 18 parts sulphuric acid at 150°. This colouring matter forms a brownish-red crystalline powder, $C_{17}H_{14}O_5 + H_2O$, sparingly soluble in water, easily in dilute acids and alcohol. A concentrated alkaline solution is red, but when diluted shows beautiful yellow-green fluorescence. Its alkaline solution forms a basic salt with copper sulphate. The hydrochloric solution, if treated with bromine, yields pyrotartryleosin,

$$C_{17}H_{10}Br_4O_5 + H_2O.$$

This forms a red flocculent precipitate. In dilute alkaline solution this substance shows no red colour, and has only a very slight fluorescence. L. T. T.

Use of Dry Oxalic Acid in the Formation of Condensation-products. By R. ANSCHÜTZ (*Ber.*, 17, 1078—1079).—Owing to the great affinity which anhydrous oxalic acid, obtained by heating oxalic acid at 110° until all its water of crystallisation is given off, has for water, the author has found it useful in the elimination of water from mixtures of substances which are capable of forming condensation-products. On heating 5 grams benzaldehyde and 11·5 of dimethylaniline together for two hours at 110°, no change takes place, but if 7·5 grams anhydrous oxalic acid are added, and the mixture heated for the same time at 110°, the product of condensation, leucomalachite-green, is formed in large quantities. In a similar way benzaldehyde, when heated with diphenylamine or benzyldiphenylamine, in presence of dry oxalic acid, yields condensation-products and phthalic anhydride, whilst resorcinol gives fluoresceïn. The water eliminated in this way does not, owing to the high temperature, combine to form water of crystallisation with the oxalic acid, but the oxalic acid remains unchanged. This property of dry oxalic acid is under further investigation. A. B.

Orthamidobenzaldehyde. By P. FRIEDLÄNDER and C. F. GÖHRING (*Ber.*, 17, 456—461).—Orthamidobenzaldehyde is prepared by warming pure orthonitrobenzaldehyde (3 grams) with ferrous sulphate (50 grams) and ammonia. The mixture is distilled in a current of steam. About 30 per cent. of the aldehyde is deposited from the distillate on cooling to 0°, and the remainder is obtained by adding common salt to the mother-liquor, and extracting with ether. The properties of the compound have been previously described (*Ber.*, **15**, 2004, 2572).

Acetylorthamidobenzaldehyde, prepared by warming the amidoaldehyde with pure acetic anhydride, is deposited from hot aqueous solutions in white needles, which melt at 70°.

Orthamidobenzaldehyde dissolves in strong hydrochloric acid, forming a red solution which, on the addition of platinum chloride, deposits yellow prisms of the platinochloride $(C_7H_7NO)_2,H_2PtCl_6$.

Amidobenzaldehyde is easily converted into a condensation-product, $C_{14}H_{12}N_2O$, by the action of dilute mineral acids. This compound forms tabular crystals, which melt at 189° when rapidly heated. It dissolves in strong acids, with regeneration of the amidoaldehyde.

β-Carbostyrilcarboxylic acid, $C_{10}H_7NO_3$ is formed when orthamidobenzaldehyde is heated with a slight excess of malonic acid at 120°. It crystallises in needles, which melt above 320°, and are sparingly soluble in alcohol and acetic acid. Phosphorous pentachloride converts it into α-chloro-β-quinolinecarboxylic acid, which crystallises in needle-shaped crystals, melting at 200° with partial decomposition into chloroquinoline and carbonic anhydride. Boiling with alcoholic potash converts the chloroquinoline into α-ethoxy-β-quinolinecarboxylic acid, which melts at 130° and is rapidly decomposed by heat into ethylcarbostyril and carbonic anhydride. W. C. W.

Derivatives of Phenylacetaldehyde. By C. Forrer (*Ber.*, **17**, 982—985).—*Action of Phosphorous Pentachloride on Phenylacetaldehyde.* —The reaction takes place in the usual way, the oxygen of the aldehyde being replaced by two atoms of chlorine, with formation of *dichlorethylbenzene*, $CH_2Ph.CHCl_2$. It is a heavy liquid, smelling like turpentine, and rapidly decomposes with evolution of hydrochloric acid; by distillation it is completely decomposed. Heated at 120°, it is completely converted into α-chlorostyrolene, $CHPh\colon CHCl$. When this is heated in a closed tube with alcoholic potash, an oil is obtained free from chlorine, and which on distillation gives phenylacetaldehyde again. This is the third dichlorethylbenzene:—

$C_6H_5.CCl_2.CH_3$ α-dichlorethylbenzene from acetophenone.
$C_6H_5.CCl.CH_2Cl$ αω-dichlorethylbenzene from styrolene.
$C_6H_5.CH_2.CHCl_2$ ω-dichlorethylbenzene from phenylacetaldehyde.

Action of Nitric Acid on Phenylacetaldehyde.—This reaction is of interest, since the reduction of the orthonitro-compounds should yield indole directly. Phenylacetaldehyde was treated at − 10° to − 15° with nitric acid. On neutralising, and distilling the resulting product with steam, a small quantity of an oil which crystallised out in plates was first obtained, and a second substance which crystallised out in fine needles. The first substance melted at 106°, and on reduction with ammonia and zinc-dust yielded an oil, in too small a quantity for purification, but which gave all the characteristic reactions for indole. The second crystalline substance melted at 133—136°, yielded no indole on reduction, but on oxidation a nitrobenzoic acid which, from its melting point, is probably the paranitro-acid. This second substance is therefore probably paranitrophenylacetic acid.

A. B.

Derivatives of Orthamidoacetophenone. By A. BAEYER (*Ber.*, **17**, 970—973).—In former unsuccessful attempts to obtain diethylindigo and dibenzyl-indigo from ethyl- and benzyl-amidoacetophenone, the author prepared several derivatives of orthamidoacetophenone.

Orthoethylamidoacetophenone is obtained by heating 16 grams amidoacetophenone with 32 grams ethyl bromide in a closed tube for 20 hours at 100°; the red product is freed from the excess of ethyl bromide, dissolved in water, treated with soda, and distilled in steam. The ethylamidoacetophenone is thus obtained as an oil, and is purified by being converted into the nitroso-compound, and regenerated by the action of stannous chloride. It forms a platinochloride, $(NHEt.C_6H_4.COMe)_2,H_2PtCl_6$.

Orthobenzylamidoacetophenone is obtained by heating two parts of amidoacetophenone with one part benzyl chloride at 100° for three hours. Crystallised from alcohol, it forms large yellow prisms, melting at 79—81°, readily soluble in carbon bisulphide, chloroform, benzene, and ether. It is a feeble base, and is precipitated from its acid solution by water.

Orthonitrosobenzylamidoacetophenone, $COMe.C_6H_4.N(NO)C_7H_7$, is obtained by the action of sodium nitrite on a solution in sulphuric acid. It forms long colourless needles, melting at 54—55°, and is soluble in alcohol and similar solvents. Benzyl-indigo cannot be obtained by the bromination of benzylamidoacetophenone, but by treating the nitroso-derivative with concentrated sulphuric acid, colouring matters of the nature of indigo are formed, probably consisting chiefly of indigo and benzyl-indigo. The formation of indigo is to be explained on the ground that the benzyl-group is detached by the action of sulphuric acid, for, on treating the nitroso-derivative with sulphuric acid, there is a strong odour of benzaldehyde. A. B.

Orthhydroxyphenylacetic Acid and its Derivatives. By A. BAEYER and B. FRITSCH (*Ber.*, **17**, 973—975).—The authors regret that as they have been working for some time on this acid they cannot accede to Salkowski's request (*Ber.*, **17**, 504) that he be allowed to reserve the investigation of the isomeric hydroxyphenylacetic acids. Their method of preparing the acid and its internal anhydride, however, is quite different from his.

Orthhydroxyphenylglyoxylic acid is obtained by treating a solution of isatin in dilute soda with the calculated quantity of sodium nitrite, and slowly adding an excess of very cold dilute sulphuric acid. This solution of orthodiazophenylglyoxylic acid, when heated at 60°, gives off nitrogen, and the hydroxy-acid may be obtained by extraction with ether. It crystallises from a mixture of benzene and light petroleum in yellow needles, melting at about 44°. It is, however, impure, and contains salicylic acid. On treating this crude acid with sodium amalgam for several days, acidifying and extracting with ether, a crystalline compound is obtained, which appears to be orthhydroxymandelic acid. It is easily reduced by means of hydriodic acid to orthhydroxyphenylacetic acid.

Orthhydroxyphenylacetic acid crystallises from ether in colourless needles, melting at 137°, and its aqueous solution, like that of salicylic acid, gives a violet coloration with ferric chloride. On heating it, water is at first given off, and afterwards, at 236—238°, an oil distils over and crystallises. This is the *lactone of orthoxyphenylacetic acid*,  $C_6H_4<\genfrac{}{}{0pt}{}{CH_2}{-O-}>CO$. It melts at 49°, boils at 237°, and in hot water is slowly converted into the acid, more quickly in presence of alkalis.

A. B.

Action of Nitrous Acid on Amidohydroxypropyl- and Amidopropenyl-benzoic Acids. By O. WIDMAN (*Ber.*, 17, 722—727).—

Hydroxypropylhydroxybenzoic acid,

$$C_6H_3(CMe_2OH)(OH).COOH\ [1:2:4],$$

prepared by the action of nitrous acid on amidohydroxypropylbenzoic acid, crystallises in colourless flat needles or plates, melts at 173°, is sparingly soluble in cold water, moderately soluble in ether, very readily soluble in alcohol. Its aqueous solution gives a dark brown coloration with ferric chloride. It does not appear to suffer any change by boiling with hydrochloric acid; dissolved in sulphuric acid and precipitated with water, white shiny flocks are obtained, but there appears to be no formation of propenylhydroxybenzoic acid. In this respect the acid differs from the corresponding hydroxypropylbenzoic acid with its amido- and nitro-derivatives, all of which are converted into propenyl-compounds by heating with hydrochloric acid.

With amidopropenylbenzoic acid, the action of nitrous acid takes another course, the product of the reaction being *methylcinnolinecarboxylic acid*,  $C_{10}H_8N_2O_3 = COOH.C_6H_3<\genfrac{}{}{0pt}{}{CMe}{N:N}>CH$. It crystallises in small tables, or in thick rhombohedral-like crystals, melts with partial decomposition at about 230°, is insoluble in cold water, sparingly soluble in hot water or hot alcohol, readily soluble in boiling acetic acid. It yields salts with acids and bases. Together with this acid, a substance is formed in small quantity which crystallises in colourless rhombic plates, melting at 157—158°. It has not yet been obtained in quantity sufficient for careful examination.

A. J. G.

Action of Ethyl Chloroformate on Amidohydroxypropylbenzoic Acid. By O. WIDMAN (*Ber.*, 17, 1303—1308).—

If an excess of ethyl chloroformate is poured over amidohydroxypropylbenzoic acid, and the mixture boiled for a few minutes, the whole solidifies, but no evolution of gas is perceptible. After allowing the excess of ethyl chloroformate to evaporate, the product is crystallised from 50 per cent. acetic acid. *Hydroxypropylcarboxylphenylurethane*, $C_{13}H_{17}NO_5$, thus obtained, crystallises in flat colourless needles or prisms, which melt at 167°, with evolution of gas. The reaction is probably $C_{10}H_{11}O_3.NH_2 + Cl.COOEt = HCl + C_{10}H_{11}O_3.NH.COOEt$.

Ethyl dihydroxypropyldicarboxyldiphenylallophanate,

$$CO<\begin{matrix}N(COOEt).C_6H_3(C_3H_7O).COOH\\NH.C_6H_3(C_3H_7O).COOH\end{matrix},$$

is obtained by heating the body just described with ethyl chloroformate in sealed tubes at 120—130° for two hours. It may also be prepared directly from the amido-acid by using excess of chloroformate. It crystallises from acetic acid in plates, which melt above 300° with evolution of gas, and the residue resolidifies on cooling. This latter body appears to be identical with *dihydroxypropyldicarboxyldiphenylcarbamide*, $CO[NH.C_6H_3(C_3H_7O).COOH]_2$, obtained as follows: amidohydroxypropylbenzoic acid is heated with excess of ethyl chloroformate for four hours, hydrochloric acid being continuously evolved. The product is evaporated to dryness several times, first with water, and subsequently with alcohol; the residue is then washed with ether, and boiled with fuming hydrochloric acid, in which it slowly dissolves with evolution of gas; finally the solution is evaporated to dryness, and the residue boiled with water, when the carbamide-derivative remains undissolved. Crystallised from acetic acid, it forms small rhombic prisms, which melt at a very high temperature.

Several attempts were made to treat amidohydroxypropylbenzoic acid with excess of ethyl chloroformate in sealed tubes at 115—130° for about four hours. In almost all cases, however, the tubes burst during the heating, and when this was not the case they burst with great violence when the author attempted to open them, so that he was not able to obtain any of the product. L. T. T.

Ethyl Malonanilidate, Malonparatoluidic Acid, and Methyltrichloroquinoline. By L. Rugheimer and R. Hoffmann (*Ber.*, 17, 739—741).—Potassium ethyl malonate is treated with phosphoric chloride dissolved in benzene, the mixture being heated to complete the reaction; after cooling, excess of aniline dissolved in benzene is added, and the whole allowed to stand 24 hours; the benzene solution is then separated, washed with hydrochloric acid and water to remove aniline, and allowed to evaporate spontaneously, when a crystalline mass of impure *ethyl malonanilidate*, $NHPh.CO.CH_2.COOEt$, is obtained. This after purification melts at 38—39°, is readily soluble in alcohol, chloroform, and benzene, insoluble in water and light petroleum.

Malonparatoluidic acid, $NH(C_7H_7).CO.CH_2.COOH$, prepared from paratoluidine and malonic acid, crystallises in small colourless needles; melts with decomposition at 156°; but on slowly heating, it softens and fuses at a still lower temperature. Heated with phosphorous pentachloride (comp. p. 1050) it yields *methyltrichloroquinoline*, $C_9H_3MeCl_3N$, crystallising in long needles, and melting at 134°.

A. J. G.

Paranitrobenzoylacetic Acid. By W. H. Perkin, Jun., and G. Bellenot (*Ber.*, 17, 326—328).—Baeyer has lately shown (Abstr., 1883, 337) that ethyl phenylpropiolate is converted into ethyl phenylacetate by simple solution in cold strong sulphuric acid. The authors find that a similar reaction takes place with ethyl paranitropropiolate, but the sulphuric acid solution requires to be heated to 35—40°. The cooled mixture is then poured on powdered ice, when paranitrobenzoylacetic acid separates as a white amorphous mass.

Paranitrobenzoylacetic acid crystallises from benzene in almost colourless needles, melting at 135°, and giving off carbonic anhydride at the same time. It is easily soluble in alcohol, ether, benzene, chloroform, and carbon bisulphide, sparingly so in light petroleum. Its alcoholic solution gives a violet coloration with ferric chloride, the shade being redder than that obtained with the non-nitrated acid. It forms unstable salts. The *ethyl salt* is obtained by saturating a solution of the acid in absolute alcohol with hydrochloric acid. The temperature must not be allowed to rise above 10°, or decomposition sets in, paranitracetophenone being formed. The ethereal salt crystallises in almost colourless needles, which melt at 49—50°, and are soluble in ether, alcohol, and benzene.

Ethyl nitrosoparanitrobenzoylacetate is obtained by saturating a dry etheric solution of the nitro-acid with nitrous acid. It crystallises in needles melting at 220°, and soluble in alcohol, ether, and acetone.

L. T. T.

Acetyl-derivatives of Aromatic Amidosulphonic Acids. By R. NIETZKI and T. BENCKISER (*Ber.*, **17**, 707—708).—Acetic anhydride has no action on sulphanilic acid, even when boiled with it; it reacts however readily with sodium sulphanilate at 140°, the liquid solidifying on cooling to a viscid colourless mass, from which, by dissolving in the least possible quantity of water, and adding alcohol and ether, small colourless prisms of *sodium acetylsulphanilate*,

$$C_6H_4(NH\overline{Ac}).SO_3Na,$$

are obtained. This salt is very soluble in water, moderately soluble in alcohol, nearly insoluble in ether. By heating with hydrochloric acid, it is decomposed into acetic and sulphanilic acids. The lead and barium salts were also prepared; on addition of alcohol to a solution of the latter, it is precipitated as a jelly which slowly becomes crystalline. The free acid could not be isolated.

In the cases of metamidobenzenesulphonic acid, of the sulphonic acids of paratoluidine and α-naphthylamine, the free acids are not converted into acetyl-derivatives by acetic anhydride, although their salts are very readily acetylised; orthotoluidine-parasulphonic acid, on the contrary, is converted into an acetyl-derivative when heated with acetic anhydride.

A. J. G.

Constitution of Phthalyl Chloride. By E. NÖLTING and G. v. BECHI (*Ber.*, **17**, 387—388).—The formation of phthalophenone by the action of phthalyl chloride on mercury phenyl is cited in support of the unsymmetrical formula  $C_6H_4<\begin{smallmatrix}CO\\CCl_2\end{smallmatrix}>O$ for phthalyl chloride.

W. C. W.

Thiophthalic Anhydride. By C. GRAEBE and B. ZSCHOKKE (*Ber.*, 17, 1175—1177).—Thiophthalic anhydride, described by Schreder (*Ber.*, 7, 705), may be more conveniently prepared by slowly adding phthalic chloride to a cold concentrated solution of sodium hydrogen sulphide. On acidifying the solution with hydrochloric acid, the thiophthalic anhydride is precipitated. This substance melts at 114°, and boils at 284°. It is converted into phthalimide and sulphuretted hydrogen by ammonia.

Thiofluorescein is formed by warming at 40° a mixture of the anhydride with resorcinol and strong sulphuric acid. The product is extracted with boiling water, dissolved in a solution of sodium carbonate and precipitated by hydrochloric acid. The precipitate is extracted with chloroform to remove thiophthalic acid. Thiofluoresceïn is soluble in alcohol and in wood spirit. It dissolves in alkalis, forming a red solution which exhibits a dark-green fluorescence. It can be distinguished from fluoresceïn by its absorption-spectrum. By treating the acetic acid solution with bromine, a *thioeosin* is obtained.

W. C. W.

Hemlock Tannin. By C. BÖTTINGER (*Ber.*, 17, 1041—1043).—The author has prepared this acid from American hemlock tannin extract. A solution of hemlock tannin is darker in colour than a solution of oak-bark tannin of equal strength. With alkalis, sulphuric acid, or hydrochloric acid, it behaves like oak-bark tannin, but the "hemlock-red" precipitated by hydrochloric acid is darker in colour than the corresponding "oak-red." Bromine precipitates from an aqueous solution of hemlock tannin a yellow substance, soluble in alcohol, ethyl acetate, acetone, and in warm acetic anhydride. It is insoluble in chloroform, carbon bisulphide, and water, but soluble in alkalis. The results of analysis lead to the formula $C_{20}H_{14}Br_4O_{10}$, and from this it follows that the original substance has the formula $C_{20}H_{18}O_{10}$, and that hemlock tannin is a homologue of oak-bark tannin, $C_{19}H_{16}O_{10}$. In presence of hydrochloric acid tetrabromo-tannin from hemlock behaves like dibromotannin from oak-bark. It forms with acetic anhydride a penta-acetylderivative, and when dissolved in chloroform can be further brominated, with formation of a hexabromide, $C_{20}H_{10}Br_6O_{10}$. The investigation of this tannin will be continued by the author.

A. B.

Bark Tannins. By C. BÖTTINGER (*Ber.*, 17, 1123—1131).—The precipitate which is produced on the addition of bromine to the cold aqueous extracts of tannin from different sources varies in colour and in composition. Tannin from oak-bark gives a brownish-yellow precipitate, containing 28·4 per cent. Br. The hemlock and quebracho precipitates are reddish-yellow, and contain from 42·1 to 44·5 per cent. Br, whilst the mimosa, chestnut, and terra japonica compounds are pale yellow, and contain from 49·3 to 53·2 per cent. Br.

A red compound, $C_{40}H_{30}O_{17}$, is formed when hemlock tannin is warmed with strong hydrochloric or sulphuric acid. It is purified by washing with water and extracting the dry mass with ether and with hot alcohol. This substance dissolves in cold soda-lye, and also in a warm solution of sodium carbonate. It is decomposed by strong hydrochloric acid at 180°, yielding water, carbonic anhydride, methyl chloride, and a black compound. Hemlock-red forms an acetic derivative, $C_{40}H_{23}\overline{Ac}_7O_{17}$, which is insoluble in water and ethyl acetate, but is decomposed by alcohol. By the action of bromine on hemlock-red suspended in chloroform, two crystalline bromo-derivatives are obtained, viz., $C_{40}H_{20}Br_{10}O_{17}$, and $C_{40}H_{20}Br_{14}O_{17}$. The bromo-derivative of pine tannin, $C_{21}H_{14}Br_6O_{10}$, is very unstable. It is soluble in alcohol, ethyl acetate, and dilute alkalis. The acetic derivative, $C_{21}H_5\overline{Ac}_5Br_5O_{10}$, is a yellow powder, soluble in acetone and ethyl acetate. The red compound produced by the action of hydrochloric acid on this tannin yields an acetic derivative of the composition $C_{42}H_{27}\overline{Ac}_7O_{17}$, and a bromine-derivative, $C_{42}H_{24}Br_{10}O_{17}$; but if sulphuric acid is used instead of hydrochloric, the acetic derivative has the composition $C_{43}H_{26}\overline{Ac}_6O_{16}$.

Tannin from terra japonica yields the derivatives, $C_{21}H_{14}\overline{Ac}_4O_9$ and $C_{21}H_{14}\overline{Ac}_3O_8$. Oak-bark tannin appears to be a methyl salt of a condensation-product of tannin and acetoacetic aldehyde.

W. C. W.

Formation of Indigo from Orthamidoacetophenone. By A. Baeyer and F. Bloem (*Ber.*, **17**, 963—970).—Formation of *acetylorthamidoacetophenone.* The starting point for the preparation of this substance is orthamidophenylacetylene (Abstr., 1882, 623). On adding slowly 50 grams of the latter to a mixture of 200 c.c. of water and 600 c.c. concentrated sulphuric acid, the sulphate of the original base at first crystallises out, but afterwards dissolves, and the solution is then left until no phenylacetylene is to be found on testing with an ammoniacal solution of cuprous chloride. The solution is cooled with ice, neutralised with soda, and distilled in steam; the distillate is saturated with sodium chloride, and the orthamidoacetophenone extracted with ether; it is converted into the acetyl-derivative by boiling it with acetic anhydride.

By acting on acetylamidoacetophenone with bromine in aqueous or glacial acetic acid solution, a bromo-substitution-product is obtained, in which the hydrogen of the benzene-ring is replaced by bromine. If the action of bromine is direct, or in presence of concentrated sulphuric acid, hydrogen, chiefly in the side chain, is replaced; it is only from the latter that indigo is obtainable.

Esobromoacetylorthamidoacetophenone.—(For the new nomenclature of this and the following substances, see this vol., p. 998). This compound is formed from the acetic acid solution of the acetylortho-compound by the action of bromine. It forms slender colourless needles, melting at 160°, and soluble in hot alcohol, but nearly insoluble in cold. On oxidation by means of a warm alkaline solution of permanganate, it yields a red substance crystallising from alcohol, and melting at 250°; it appears to be a monobromisatin. The bromine is therefore in the benzene-ring, the formula is $COMe.C_6H_3Br.NH\overline{Ac}$, and it is the parabromo-compound in relation to the amido-group. It is therefore metabromorthacetyl-amidoacetophenone.

ω-Dibromometabromorthacetyl-amidoacetophenone,

$$CHBr_2.CO.C_6H_3Br.NH\overline{Ac}.$$

By the action of bromine on acetylamidoacetophenone in a solution of chloroform, sulphuric acid, or carbon bisulphide, or directly on the dry substance, bromo-substitution compounds are formed, in which bromine replaces hydrogen both in the benzene-ring and in the side chain. In the case of chloroform, little in the side chain is replaced, and by direct action on the dry substance the side chain substitution is the greatest. The reaction is complete when two hydrogen-atoms in the side chain, and one in the benzene-ring, are replaced. If the reaction is incomplete, intermediate products are formed which are difficult to separate. The above tribromo-derivative has been investigated: it is best formed by acting on the acetyl-compound, in presence of a little iodine, with bromine-vapour for five days, the yield being a quantitative one. It is obtained as a yellowish powder, soluble in chloroform, but only sparingly in alcohol. It becomes brown at 180°, and melts at 185° with decomposition. By oxidation with permanganate, monobromisatin is obtained, and consequently the formula of the above compound may be established. By the action of hydrobromic acid, it loses the acetyl-group, giving ω-dibromometabromorthamidoacetophenone, $NH_2.C_6H_3Br.CO.CHBr_2$, as orange-yellow needles, melting with decomposition at 140—145°, readily soluble in alcohol and ether, but sparingly in water. On heating it with acetic anhydride, the original acetyl-compound is again obtained.

ω-Dichlorometabromorthamidoacetophenone, $NH_2.C_6H_3Br.CO.CHCl_2$, is obtained by boiling the tribromacetyl-compound with concentrated hydrochloric acid, until it is dissolved. From this solution fine orange-yellow needles separate; they are soluble in alcohol, melt at 110—120°, and sublime with little decomposition at a higher temperature.

Formation of Indigo from Exobromo- and Exochloro-orthamidoacetophenones and their Derivatives.—ω-Dibromometabromorthacetyl amidoacetophenone when boiled with dilute soda solution dissolves with a brownish-yellow colour, and on cooling the solution and agitating it with air bromindigo separates. It is readily distinguished from indigo by its solubility in chloroform. By similar treatment, the less brominated substitution-products of this acetyl-compound yield either indigo or a mixture of indigo and bromindigo. The corresponding compounds which do not contain the acetyl-group behave in the same way. On acidifying the solution of the tribromo-compound in soda, after the separation of the bromindigo, bromisatin may be extracted with ether. On acidifying, however, the solution of the tribromo-compound previous to oxidation, bromindirubin is precipitated. These reactions are easily explained on the assumption that by boiling the tribromo-compound with soda, sodium isatate and indoxyl (or at any rate their bromo-substitution-compounds) are formed in the solution; bromindigo is then produced from the bromindoxyl by the action of air, but if acid be previously added, the bromisatin formed (Abstr., 1884, 76) acts on the bromindoxyl, yielding bromindirubin. The simultaneous formation of bromisatin and bromindoxyl is easily understood, since, owing to the presence of the two bromine-atoms in the side chain, compounds of an aldehydic nature may be formed, and these in alkaline solutions allow of the formation of an acid (isatic acid) and an alcohol which by loss of water yields indoxyl.

ω-Dichlorometabromo-orthamidoacetophenone behaves precisely similarly to the corresponding bromo-compound. A. B.

Chlorobenzaldehyde and Chlorindigo. By R. GNEHM (*Ber.*, **17**, 752—755).—One of the chief obstacles to the commercial success of the manufacture of artificial indigo lies in the small yield of orthonitrobenzaldehyde obtained by nitration of benzaldehyde, the main product being the meta-compound. It seemed probable that a more favourable yield of the orthonitro-compound might be obtained by nitrating some chloro-substitution derivative of benzaldehyde in which the ortho-position was still unoccupied, and that the chlorindigo finally obtained might be sufficiently like indigo to be used in dyeing. *Dichlorobenzaldehyde*, $C_7H_4Cl_2O$ (the method of preparation is not given), crystallises in snow-white crystals, melts at 57—58° (uncorr.), and boils at 230—233°. On oxidation, it yields a dichlorbenzoic acid melting at 152°, which by treatment with nitric and sulphuric acids is converted into *orthonitro-dichlorobenzaldehyde*, crystallising in nacreous plates or needles. These melt at 136—138°, and are converted into chlorindigo by treatment with acetone and caustic soda.

Tetrachlorindigo, $C_{16}H_6Cl_4N_2O_2$, closely resembles indigo in appearance; when heated it gives off violet vapours and condenses in blue needles of coppery lustre. Treated with reducing agents, it yields a tetrachlorindigo-white. The formation of an indigo vat with it is, however, attended with considerable difficulties, as it is less easily reduced than ordinary indigo, and the white is much less soluble in alkaline liquids than indigo-white. The difficulties have been so far overcome however, that satisfactory vat dyeing has been effected with it. The preparation of carmine from it is not satisfactory, as it requires more Nordhausen sulphuric acid and a higher temperature than ordinary indigo; moreover, the colours dyed with it are not equal to those obtained with indigo. A mixed di- and tetra-chlorindigo prepared from a mixture of dichloro- with monometa-chlorobenzaldehyde showed similar properties.

Amido-dichlorobenzaldehyde, $C_7H_3Cl_2O.NH_2$, prepared by reducing the nitro-compound with ferrous sulphate and ammonia, crystallises in yellow needles, which melt at 77—78°: it is sparingly soluble in water, soluble in hydrogen sodium sulphite. When heated with acetone and caustic soda, it yields dichloroquinaldine as a yellowish solid melting at 46°, boiling at 300°, soluble in mineral acids; the picrate crystallises in fine needles. Amidodichlorobenzaldehyde when heated with phenylhydrazine yields a compound which crystallises in yellow needles, melting at 200°. A. J. G.

Indirubin. By C. FORRER (*Ber.*, **17**, 975—982).—The author has continued the investigation of this substance which was first obtained by Baeyer (*Ber.*, **14**, 1745) by the action of isatin on indoxyl. Indirubin is best obtained by boiling one part of ethylic indoxylate in

100 parts of water (to convert it into indoxyl), filtering off any indigo or resinous matters which may be formed, and then boiling this solution with $\frac{3}{4}$ part isatin in 200 parts of water. On filtering and adding soda solution, indirubin separates out as a flocculent mass; when dried it is a light red-brown powder, with a green metallic lustre. It is somewhat soluble in alcohol and similar solvents with a purple-violet colour; in acetic acid and acetic anhydride, it is more soluble. Sulphuric acid converts it into a sulphonic acid.

Indirubin like indigo yields isatin on oxidation. On reduction with zinc and soda solution, it also behaves like indigo (*Ber.*, 1, 17). On reduction with zinc and acetic acid, hydroindirubin is at first formed, and this on exposure to the air in presence of alkalis is again converted into indirubin; on prolonging the reducing reaction, however, a crystalline product is obtained which remains colourless when exposed to air. The author proposes to call this *indileucin;* the results of analysis are between the formulæ $C_{15}H_{12}N_2O$ and $C_{16}H_{14}N_2O$, but from subsequent reactions the former seems to be the more likely. Indileucin crystallises from alcohol in colourless needles which at 220° become brown, and at 260° are completely decomposed. It is sparingly soluble in ether, alcohol, chloroform, and benzene, but easily in acetone and glacial acetic acid. It forms crystalline compounds with bromine and picric acid. A methyl-compound, $C_{16}H_{11}MeN_2O$, and an acetyl-compound, $C_{16}H_9N_2O\overline{Ac}_3$, have also been prepared. A. B.

Quinisatin. By A. Baeyer and B. Homolka (*Ber.*, 17, 985—987). In the authors' first paper (this vol., 78) it was left undecided whether by the union of the ω or α carbon-atoms with the nitrogen of quinisatinic acid, quinisatin was formed, that is, whether quinisatin is a lactam or a lactim (Abstr., 1883, 202). The study of the action of hydroxylamine on quinisatin shows that it is probably the ω-lactim of quinisatinic acid. (For this nomenclature see p. 998.)

Quinisatoxim is easily formed by the action of hydroxylamine chloride on quinisatin, it crystallises from alcohol in orange prisms melting at 208°, and is identical with the previously described nitroso-γ-hydroxycarbostyril (Abstr., 1883, 202).

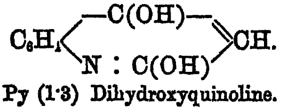
Quinisatoxim stands in the same relation to Py-[1·3]-dihydroxyquinoline (γ-hydroxycarbostyril) and to quinisatin as isatoxim does to oxindole and isatin.

$$C_6H_4<\begin{matrix}\text{——CO——}\\ N:C(OH)\end{matrix}>C:N.OH$$

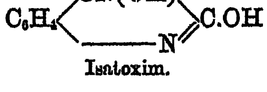
Quinisatoxim.

$$C_6H_4<\begin{matrix}\text{——CO——}\\ N:C(OH)\end{matrix}>CO$$

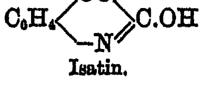
Quinisatin.



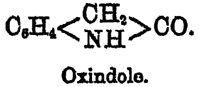
Py (1·3) Dihydroxyquinoline.



Isatoxim.



Isatin.



$$C_6H_4<\begin{matrix}CH_2\\ NH\end{matrix}>CO.$$

Oxindole.

A. B.

Indole. By A. LIPP (*Ber.*, 17, 1067—1073).—In the first part of this paper an account is given of the various researches on indole and on the means used to obtain proof of its constitutional formula. Baeyer has given it the constitutional formula  $C_6H_4\langle{}^{NH}_{CH}\rangle CH$, on the ground that it contains an imide-group. It may thus be considered as an internal anhydride derived from an hypothetical orthamidophenyl vinyl alcohol or from its ether, $NH_2.C_6H_4.CH : CH.OC_2H_5$. This substance has never been prepared, owing to the difficulty of nitrating phenyl vinyl ether without decomposition. The author has however, succeeded in preparing orthonitrochlorostyrolene, in reducing it to the amido-derivative, and from the latter obtaining indole, probably by the intermediate formation of orthonitrophenyl vinyl ether.

Orthonitrochlorostyrolene, $NO_2.C_6H_4.CH : CHCl$, is obtained as a bye-product in the formation of orthonitrophenylchlorolactic acid, (just as chlorostyrolene is obtained in the formation of phenylchlorolactic acid) by the action of hypochlorous acid on sodium orthonitrocinnamate, and subsequent treatment with soda (Abstr., 1882, 191). It crystallises from alcohol in bright yellow needles or prisms, insoluble in cold but slightly soluble in hot water, and readily soluble in hot alcohol and ether. It melts at 58°, but decomposes at a higher temperature. Warm concentrated hydrochloric acid and tin reduce it to the hydrochloride of orthamidochlorostyrolene, from which the free base may be obtained by the action of potash.

Orthamidochlorostyrolene, $NH_2.C_6H_4.CH : CHCl$, is readily soluble in alcohol and ether, very sparingly in water, and crystallises from ether in white prisms. On heating it with sodium alcoholate in a sealed tube at 160—170° for three or four hours, sodium chloride is formed, and, on opening the tube, the presence of indole may be recognised by its powerful odour, and by its reactions. On adding water to the contents of the tube, indole separates out as an oil, and may be purified by distillation in steam, and crystallisation from hot water. The indole thus obtained melts at 52°, and agrees in all its properties with that prepared from indigo or albumin. A. B.

Occurrence of Diphenyl in Coal-tar Oil. By K. E. SCHULZE (*Ber.*, 17, 1203—1204).—The presence of diphenyl in tar oil may be proved by removing phenols and amines from the portion boiling between 200° and 300°; the mono- and di-methylnaphthalenes are then converted into sulphonic acids by treatment with warm sulphuric acid, and on cooling the undissolved oil, to − 15°, diphenyl crystallises out. W. C. W.

Reactions of Triphenylmethyl Bromide. By K. ELBS (*Ber.*, 17, 700—701).—Triphenylmethyl thiocyanate prepared by mixing solutions of ammonium thiocyanate and triphenylmethyl bromide, crystallises in lustrous reddish-white prisms, melts at 137°, can be distilled, is sparingly soluble in alcohol and ether, readily soluble in chloroform.

By acting on triphenylmethyl bromide with potassium sulphide, a crystalline sulphur-compound is obtained.

By the action of potassium cyanide, the bromide is converted into the triphenylacetonitrile of E and O. Fischer (Abstr., 1879, 385). This, by reduction with zinc and hydrochloric acid, is converted into *triphenylethylamine hydrochloride*, a substance crystallising in needles which melt at 247°, and are very readily soluble in alcohol, but almost insoluble in water. The platinochloride crystallises from alcohol in large orange-red needles. *Triphenylethylamine* is crystalline, melts at 116°, dissolves sparingly in cold alcohol, readily in ether. It is very much more stable than the corresponding triphenylmethylamine.

Triphenylmethyl bromide when dissolved in benzene and boiled with sodium is only very slightly attacked. Fused with magnesium powder, it yields phenylenediphenylmethane; with powdered copper a mixture of crystalline compounds is formed. Aluminium chloride, when heated with a solution of the bromide in benzene converts it into triphenyl carbinol and a yellow resin. A. J. G.

Amido-derivatives of Triphenylmethane. By K. Elbs (*Ber.*, 17, 701—706).—A continuation of the author's researches on this subject (comp. Abstr., 1883, 1000; also Nauen, this vol., 849, and Hemilian and Silberstein, next Abstract). *Triphenylamidomethane platinochloride* is very unstable, being partly decomposed into triphenyl carbinol and ammonium platinochloride by drying or by treatment with excess of water. The hydrochloride is nearly as unstable, its aqueous solution being decomposed by boiling into ammonium chloride and triphenyl carbinol. The *oxalate* forms hard colourless granular crystals, melts at 253°, and is very sparingly soluble in alcohol. Triphenylamidomethane is most conveniently prepared by treating a solution of triphenylmethyl bromide for half an hour with a stream of dry ammonia gas and then with a current of steam, when the benzene distils, ammonium bromide dissolves in the water, and the free amine remains behind as a yellowish oil, which solidifies on cooling, and is obtained pure by a single crystallisation from ether. Triphenyl carbinol is readily obtained from triphenylamidomethane hydrochloride by treatment with potassium nitrite, or from the free amine by solution in nitric acid (sp. gr. 1·5), or concentrated sulphuric acid and subsequent addition of water, when a white precipitate of the pure carbinol is obtained. *Triphenylmethyl-benzylamine hydrochloride*, obtained by the action of benzyl chloride on triphenylamidomethane, crystallises in colourless needles, melts at 249°, is sparingly soluble in water, readily in alcohol. The free base crystallises in prisms, melts at 110°, and is readily soluble in alcohol and ether.

Triphenylmethyl-aniline, $NHPh.CPh_3$, is prepared by the action of an excess of aniline on a solution of triphenylmethyl bromide in benzene. It crystallises in colourless prisms, melts at 146°, is sparingly soluble in alcohol, soluble in ether, very readily soluble in benzene. The salts of this base are still more unstable than those of triphenylamidomethane; in most cases only aniline salts could be isolated.

Nitrosotriphenylmethyl-aniline, obtained by the action of excess of amyl nitrite on an ethereal solution of the amine, crystallises in nearly colourless concentrically grouped prisms. By very careful heating, it can be melted at about 156°; but if heated more quickly it explodes at 150°. It is but little soluble in benzene, carbon bisulphide, or alcohol, insoluble in ether. When its benzene solution is mixed with platinum chloride, it yields diazobenzene platinochloride and triphenyl carbinol. By the action of zinc chloride on a solution of the nitroso-compound, and subsequent treatment with potash, a base is obtained in the form of a dark blue powder; its hydrochloride crystallises in needles having a metallic green lustre, and the platinochloride forms a reddish-black powder.

Nordhausen sulphuric acid converts triphenylmethyl-aniline into a *sulphonic acid;* the *barium* salt, $NH(C_6H_4.SO_3).C(C_6H_4.SO_3)_3Ba_2$, forms a white crystalline precipitate, the *copper* salt,

$$NC_{24}H_{17}(SO_3)_4Cu_2,$$

a moss-green cauliflower-like mass. By treatment with sodium nitrite and acetic acid, the barium salt is converted into barium sulphate, and a crystalline sodium salt, which is very readily soluble in water, and explodes on heating.

TRIPHENYLMETHYL-TOLUIDINES. By O. WITTICH. *Triphenylmethyl-orthotoluidine*, $NH(C_6H_4Me).CPh_3$, prepared in a similar manner to the aniline compound, forms lustrous prisms, and melts at 142°.

Triphenylmethyl-paratoluidine, $NH(C_6H_4Me).CPh_3$, forms fine crystals having numerous faces, and melts at 177°. *Nitrosotriphenylmethyl-paratoluidine*, $N(C_6H_4Me)(CPh_3)NO$, obtained by the action of an excess of amyl nitrate on an ethereal solution of the base, crystallises in large yellowish prisms, melts at 145—148°, but does not explode on heating, and is sparingly soluble or insoluble in the ordinary solvents. Great difficulty was found in preparing salts of the triphenylmethyl-toluidines, on account of their ready decomposition into triphenyl carbinol and toluidine salts. A. J. G.

Triphenylamidomethane. By W. HEMILIAN and H. SILBERSTEIN (*Ber.*, 17, 741—752; comp. Elbs, Abstr., 1883, 1000; and this vol., p. 1031).—*Triphenylamidomethane*, $NH_2.CPh_3$, prepared by the action of dry ammonia gas on a solution of triphenylmethyl bromide in benzene, crystallises in colourless needles, melts at 103°, and cannot be distilled without decomposition. It is insoluble in water, moderately soluble in cold alcohol, readily soluble in carbon bisulphide, chloroform, benzene, and ether. All the salts crystallise with water of crystallisation, have a bitter taste, are readily soluble in alcohol, very sparingly soluble in water, and are precipitated by addition of water to the alcoholic solutions. They are all readily decomposed by water on gentle heating, being converted into ammonium salts and triphenyl carbinol. Alcoholic solutions of the salts are not decomposed by nitrous acid in the cold; but if heated with potassium nitrite, they readily yield triphenyl carbinol. The *hydrochloride*, $NH_2.CPh_3,HCl + x\text{aq.}$, crystallises in colourless prisms; the *platinochloride*, $(NH_2.CPh_3)_2,H_2PtCl_6 + 7\frac{1}{2}H_2O$, forms golden-yellow plates;

it slowly loses its water of crystallisation over sulphuric acid, completely at 110° (comp. Elbs, *loc. cit.*). The nitrate forms satiny-white plates, and explodes when heated; the sulphate crystallises from alcohol in nodules. A carbamide derivative could not be obtained.

Acetotriphenylmethylamine, $NH\overline{Ac}.CPh_3$, prepared by heating triphenylamidomethane very gently on the water-bath with acetic chloride or anhydride, forms slender colourless needles, melts at 207—208°, is readily soluble in ether and chloroform, less soluble in alcohol. At 100°, acetic chloride decomposes triphenylamidomethane into triphenyl carbinol, &c. Attempts to prepare the secondary amine, $NH(CPh_3)_2$, were unsuccessful. By the action of methyl iodide on triphenylamidomethane, an indistinctly crystalline white mass is obtained, from which alkalis liberate a mixture of bases, whose separation could not be effected.

Methyl-triphenylmethyl-amine, $NHMe.CPh_3$, prepared by the action of dry methylamine gas on a hot solution of triphenylmethyl bromide in benzene, crystallises in aggregates of colourless prisms, melts at 73°, very readily exhibits superfusion, is soluble in alcohol, benzene, and light petroleum, insoluble in water. The hydrochloride is obtained as a white crystalline precipitate on saturating a solution of the base in benzene with hydrochloric acid. It is readily soluble in alcohol, very sparingly soluble in water. When boiled with water, it is decomposed into triphenyl carbinol and methylammonium chloride. The *platinochloride*, $(NHMe.CPh_3)_2,H_2PtCl_6 + 6H_2O$, crystallises in yellow prisms; the water of crystallisation is only partly expelled by continued heating at 110°.

Dimethyl-triphenylmethyl-amine, $NMe_2.CPh_3$, prepared by the action of dimethylamine on triphenylmethyl bromide dissolved in benzene, crystallises in aggregates of colourless crystals resembling those of ammonium chloride; it melts at 97°, and is readily soluble in the ordinary solvents with the exception of water. The hydrochloride is obtained as a white crystalline precipitate. The *platinochloride*, $(NMe_2.CPh_3)_2,H_2PtCl_6$, is obtained as an anhydrous crystalline yellow precipitate.

Triphenylmethyl-aniline, $NHPh.CPh_3$ (comp. K. Elbs., *loc. cit.*), prepared by the action of triphenylmethyl bromide on aniline, both in solution in benzene, crystallises in slender colourless prisms, melts at 144·5°, is very sparingly soluble in alcohol, more soluble in ether and light petroleum, readily soluble in carbon bisulphide and chloroform. Concentrated acids decompose it, even in the cold, into triphenyl carbinol and an aniline salt.

Action of the Halogens on Triphenylamidomethane.—With this substance and its methyl-derivatives, iodine and, although less readily, bromine, give additive products, whilst chlorine causes their decomposition into triphenyl carbinol and ammonium chloride.

By the action of iodine on triphenylamidomethane, both in solution in carbon bisulphide, a brown liquid is formed, from which, after standing, well-formed crystals of two additive compounds are deposited, and can be separated mechanically. The compound

$$NH_2(CPh_3)I_2$$

forms large transparent dark-red prisms, sparingly soluble in chloroform, more readily in carbon bisulphide, nearly insoluble in light petroleum, very readily soluble with decomposition in alcohol. By agitation with mercury or silver, all iodine is removed, and the free base obtained. These red crystals are formed exclusively if chloroform is used in place of carbon bisulphide as the solvent. The other compound, $(NH_2.CPh_3)_2I_5$, forms black opaque prisms of copper-red metallic lustre; it loses iodine on exposure to air. It is readily soluble in warm carbon bisulphide, insoluble in light petroleum, and is decomposed by alcohol.

Only a single bromine-compound was obtained. It forms dark yellow to red crystals, of the formula $NH_2(CPh_3)Br_2$, sparingly soluble in carbon bisulphide, insoluble in light petroleum; it is decomposed by heating with alcohol or benzene.

The iodine-compound of methyl-triphenylmethyl-amine crystallises in bluish-black needles of metallic lustre. It has the formula $(NHMe.CPh_3)_2I_7$. The iodine-compound of dimethyl-triphenylmethylamine forms very small greyish-black needles. It was too unstable to obtain satisfactory analytical results. Bromine-compounds of these methylated bases and of the corresponding phenylated base could not be obtained. A. J. G.

Chrysaniline. By R. Anschütz (*Ber*,, 17, 433—437).—*Diacetyl chrysaniline*, $C_{19}H_{13}N_3\overline{Ac}_2$, is prepared by heating a mixture of crude chrysaniline and acetic anhydride at 140° in sealed tubes. The crude product is poured into water, and the resinous precipitate is extracted with boiling water. On adding hydrochloric acid to this solution, the hydrochloride is deposited. If this salt is dissolved in soda-lye and the solution poured into water, diacetylchrysaniline is precipitated; it dissolves in alcohol, forming a blue fluorescent solution, but it is insoluble in water. The *hydrochloride*, $C_{19}H_{13}N_3\overline{Ac}_2,HCl$, is obtained in yellow needle-shaped crystals when hydrochloric acid is added to a solution of the base in acetic acid. It is soluble in hot water, and the solution dyes wool and silk yellow. When silver nitrate is added to a solution of this salt, a mixture of silver chloride and diacetylchrysaniline nitrate is precipitated, from which the latter is extracted by boiling water. Pure chrysaniline is best prepared by boiling the acetyl-derivative with hydrochloric acid for several hours. The liquid is evaporated to dryness, and the residue dissolved in water. The addition of nitric acid precipitates the nitrate, from which the chrysaniline is liberated by precipitation with soda: by recrystallisation from dilute alcohol, it may be obtained in prismatic needles.

Chrysaniline is oxidised by chromic mixture with formation of acridine, of a base which melts at 148°, and a third base which is probably amidoacridine. W. C. W.

Tetraphenylethane. By R. Anschütz and J. Klein (*Ber*., 17, 1039—1041).—In a previous communication (this vol., 326), it has been stated by Anschütz that tetraphenylethane obtained from unsymmetrical tetrabromethane or from β-benzopinacoline is unsymmetrical, and that tetraphenylethane obtained from stilbene bromide, which should be symmetrical from its formation, is identical with the unsymmetrical form, and that probably an intermolecular change takes place in the stilbene bromide. It had also been found that whilst acetylidene tetrabromide and benzene in presence of aluminium chloride yielded tetraphenylethane, acetylene tetrabromide yielded anthracene, and on this ground the unsymmetrical character of tetraphenylethane was based. Anschütz and Eltzbacher have, however, since found that tetraphenylethane is also obtained from acetylene tetrabromide along with anthracene. This has caused the authors to doubt the correctness of the constitutional formula of tetraphenylethane. They have found that the tetraphenylethanes prepared in eleven different ways seem to be always identical, as shown by the measurements of the crystalline compound formed with benzene. They are therefore inclined to consider that tetraphenylethane prepared in these eleven ways is symmetrical, since out of the eleven only two methods point directly to the formation of the unsymmetrical. Its formation by the reduction of tetraphenylethylene, $CPh_2 : CPh_2$, which can only have a symmetrical formula, also points to the likelihood of the compound being symmetrical. A. B.

β-Ethylnaphthalene. By O. Brunel (*Ber.*, **17**, 1179—1180).—β-Ethylnaphthalene can be prepared by adding the requisite amount of ethyl bromide in successive portions to β-bromonaphthalene and sodium, and heating the mixture at 60°. β-Ethylnaphthalene boils at 250° and solidifies at −19°, at which temperature α-ethylnaphthalene remains liquid. The picric acid compound melts at 69°. β-Ethylnaphthalene is also formed by treating ethyl bromide and naphthalene with aluminium chloride. β-Methylnaphthalene could not be prepared by either of these methods. W. C. W.

Action of Ammonia on Nitroso-β-naphthol. By M. Ilinski (*Ber.*, **17**, 391—393).—Nitroso-β-naphthol is converted into *nitrosoamidonaphthalene*, $C_{10}H_6(NO).NH_2$, by the action of ammonia at 100°. This base is much more soluble in hot solvents than in cold, and it is decomposed by alkalis and reconverted into nitroso-naphthol. It crystallises in dark green prismatic needles, which melt at 151°. β-nitroso-α-naphthol behaves in a similar manner.

The nitroso-naphthols are decomposed by alcoholic potash at 100°, with formation of amorphous salts and evolution of ammonia.

W. C. W.

Dinitro-β-naphthol. By C. Graebe and A. Drew (*Ber.*, **17**, 1170—1172).—The dinitronaphthol which Wichelhaus and Wallach obtained by nitrating β-naphthol, can be more easily prepared from β-naphthylamine. 100 grams of strong sulphuric acid diluted with a litre of water are added to a solution of 50 grams of β-naphthylamine in a litre of water containing 35 c.c. of hydrochloric acid (sp gr. 1·19). The mixture is then diluted until it occupies 3 litres. A solution containing 25 grams of sodium nitrite is next added to the cold liquid, which soon loses its turbidity. On boiling the mixture with 400 c.c. of nitric acid (sp. gr. 1·35), nitrogen escapes and dinitronaphthol melting at 194° separates out. The potassium and sodium salts crystallise in yellow needles containing 2 mols. H_2O. They dye wool yellow. The silver salt, $C_{10}H_5(NO_2).OAg$, is sparingly soluble.

On oxidation with nitric acid or potassium permanganate, dinitro-β-naphthol yields β-nitrophthalic acid (1 : 2 : 4). The ethylic salt of β-dinitronaphthol forms pale-yellow needle-shaped crystals melting at 138°, soluble in alcohol. It is converted into dinitro-β-naphthylamine melting at 238°, by treatment with ammonia at 140°. Dinitronaphthalene can be obtained from this compound by adding sodium nitrite to its solution in dilute sulphuric acid. The dinitronaphthalene crystallises in pale-yellow needles which melt at 161·5°, and are soluble in alcohol. W. C. W.

Action of Ammonia on the Ethers of Nitronaphthol. By L. WITTKAMPF (*Ber.*, **17**, 393—395).—The ethylic salt of mononitro-β-naphthol, which is prepared by the action of nitric acid (sp. gr. 1·43) on ethyl-β-naphthol dissolved in glacial acetic acid, crystallises in pale-yellow needles which melt at 104°: it is soluble in hot alcohol or hot acetic acid. The compound is decomposed by alcoholic ammonia at 170°, yielding nitronaphthylamine melting at 127°, apparently identical with the substance Jacobson (*Ber.*, **14**, 1791) obtained from nitro-β-acetonaphthalide. W. C. W.

Azo-colours. By G. SCHULTZ (*Ber.*, **17**, 461—462).—β-Naphthol-α-monosulphonic acid will only unite with diazo-xylene to form xylene-azo-β-naphtholsulphonic acid when very concentrated solutions are employed.

A red colouring matter is formed by the action of tetrazodiphenyl (1 mol.) on an alkaline solution (1 mol.) of β-naphtholdisulphonic acid; it yields a sodium salt insoluble in alcohol. At the ordinary temperature, a similar result is obtained even if 2 mols. of the naphtholsulphonic are used, but if the mixture is warmed a blue substance is produced which is precipitated on the addition of common salt. The blue substance is soluble in water, and is turned red by alkalis. On adding acids to the alkaline solution, a purple precipitate is thrown down which turns blue when heated. W. C. W.

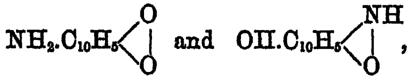
Azo-colours. By R. NIETZKI (*Ber.*, **17**, 1350—1352).—The author a short time ago (this vol., p. 1016) described a blue colouring matter obtained by the action of an alkaline solution of β-dinaphtholdisulphonic acid on the diazo-compound of his red azo-colouring matter, $NH_2.C_6H_4.N_2.C_{10}H_4(SO_3H)_2.OH$, and ascribed to it the formula $C_6H_4[N_2.C_{10}H_4(SO_3H)_2.OH]_2$. Liebermann and v. Kostanecki (*Ber.*, **17**, 878) dispute the existence of this compound, contending that it is formed if alkali alone be added to the diazotised red azo-colouring matter without any addition of β-naphtholdisulphonic acid. The author now shows that the blue coloration alluded to by Liebermann and Kostanecki is only of an evanescent character, and that no blue colouring matter can be obtained from it; but that after the action of naphtholdisulphonic acid the blue colouring matter described by him may be easily isolated. He further disproves Liebermann and Kostanecki's theory by substituting resorcinol and phenol for the naphtholdisulphonic acid. With resorcinol a reddish-violet, with phenol a magenta-red colouring matter is obtained; whereas if Liebermann and Kostanecki's view were correct, the same blue coloration must have been obtained in all cases. This blue colouring matter, in an acid bath, dyes wool and silk indigo-blue, but the colour is not permanent when exposed to the light. L. T. T.

Bromine Derivatives from Amidonaphthaquinonimide. I. By E. KRONFELD (*Ber.*, 17, 715—721).—By the action of bromine on amidonaphthaquinonimide, a mixture of substances is obtained from which the two principal products have been isolated and separated by means of the difference of their solubilities in chloroform. These stand, however, in no simple relation to the parent substance.

The substance insoluble in chloroform has the formula $C_{10}H_6Br_3NO_3$, crystallises from alcohol in compact lustrous crystals, from hot toluene in slender white lustrous needles; it melts at 213°, but at 209° the odour of bromine is marked. It has acid properties; when heated with water at 100°, it readily decomposes into phthalimide and bromoform, and at higher temperatures yields bromoform, phthalic acid, ammonia, and hydrobromic acid; the formation of formic acid was suspected but not proved. Alkalis in the cold decompose it into bromoform and phthalimide. It may be represented by the constitutional formula $C_6H_4<\begin{smallmatrix}CO.CBr_3\\C(NH).COOH\end{smallmatrix}$. By heating the tribromide for some time at the melting point, or better, by heating it with sulphuric acid at 140°, a substance is obtained crystallising in long slender pale-yellow needles of the formula $C_{18}H_{12}Br_4N_2O_2$, and melting at 237°, soluble in glacial acetic acid and hot alcohol, insoluble in water.

The substance soluble in chloroform crystallises in white plates, melts at 173°, is readily soluble in benzene and chloroform, and has the formula $C_9H_4Br_2O_2$. A. J. G.

Hydroxynaphthaquinonimide (Oximidonaphthol) and Amidonaphthaquinonimide (Diimidonaphthol). By E. KRONFELD (*Ber.*, 17, 713—714).—Of the two formulæ,



proposed for oximidonaphthol, the author considers the second to best agree with the similarity of its behaviour to that of β-naphthaquinonanilide, $OH.C_{10}H_5(NPh)O$. On adding an equivalent quantity of sodium ethylate to an alcoholic solution of oximidonaphthol, the sodium salt separates in yellow needles. An aqueous solution of this salt gives red indistinctly crystalline precipitates with calcium and barium chlorides, and with silver nitrate a voluminous dark-red precipitate of the silver salt, $OAg.C_{10}H_5(NH)O$. Neither an ethyl nor an acetyl derivative could be obtained. On boiling the calcium or barium salts with water, ammonia and hydroxynaphthaquinone are formed.

When *amidonaphthaquinonimide* is heated in glacial acetic acid solution with toluidine, it is converted into the compound

$$C_{10}H_5O(NC_7H_7).NHC_7H_7.$$

This forms red crystals, melts at 178°, is readily soluble in benzene and toluene, insoluble in ether. It readily yields salts which closely resemble those of the corresponding aniline-derivative.

A. J. G.

Action of Aniline and Toluidine on Nitro-β-naphthaquinone. By F. BRAUNS (*Ber.*, **17**, 1133—1136).—*Nitro-β-naphthaquinonanilide*, $NO_2.C_{10}H_4(OH)(NPh)O$, is deposited as a reddish-green crystalline mass when 1 part of aniline is added to a solution of 1 part of nitro-β-naphthaquinone in 10 of hot alcohol. The mother-liquor deposits yellow crystals of the composition $C_{16}H_{14}N_2O_4$. Large quantities of this substance are formed when an excess of aniline is used and the mixture boiled.

Nitronaphthaquinonanilide, melting at 247°, can be recrystallised from acetic anhydride. It acts as a strong acid, forming insoluble salts of calcium, barium, mercury, copper, and silver. It dissolves in solutions of alkalis and alkaline carbonates. The yellow aniline compound crystallises in needles melting at 186°, soluble in alcohol, benzene, and potash, but not in ammonia. It is also formed by the action of aniline on the red anilide suspended in benzene.

The bromine-derivative produced by treating nitro-β-naphthaquinone with parabromaniline forms red crystals which melt at 246°. By boiling with alcohol and aniline, it is converted into the yellow bromine-free compound melting at 186°.

Ortho- and para-toluidine also act on nitro-β-naphthaquinone, yielding a red orthotoluidine-derivative melting at 240°, and a yellow substance melting at 144°, whilst the corresponding para-compounds melt at 241° and 222° respectively. Aniline converts the nitro-β-naphtha-quinotoluidines into toluides. The orthotoluide melts at 154° and the paratoluide at 155°.

W. C. W.

Laubenheimer's Reaction. By E. ODERNHEIMER (*Ber.*, **17**, 1338—1341).—V. Meyer showed (Abstr., 1883, 1092) that Laubenheimer's colour reaction for phenanthraquinone (*Ber.*, 8, 224) was due to the presence of thiotolene (methylthiophene) in the coal-tar toluene used. The author has now investigated the colouring matter formed. 1 gram phenanthraquinone is dissolved in 160 grams glacial acetic acid, 3·5 grams of a toluene containing 15 per cent. of thiotolene (methylthiophene) is added, and 70 c.c. strong sulphuric acid poured in, the whole being well cooled. The product is allowed to stand some time and then poured into cold water, when an indigo-blue flocculent precipitate is formed; this dissolves in ether without leaving a residue, and may be purified by solution in ether and reprecipitation by light petroleum. The author believes its formula to be $C_{19}H_{12}OS$ and the reaction representing its formation:—

$$C_{14}H_8O_2 + C_5H_6S = C_{19}H_{12}OS + H_2O.$$

Sulphur determinations agree with the above formula, but the carbon has up to the present always come out 1—2 per cent. too low; the substance is extremely difficult to burn completely. The colouring matter is a deep-blue powder, having a coppery lustre when compressed. It is soluble to a violet-blue solution in alcohol, benzene, carbon bisulphide, &c., insoluble in water. It is very indifferent to most reagents. Fuming nitric acid dissolves it, and water gives a flocculent brown precipitate with this solution. When it is mixed with powdered lead chromate and heated gradually in a combustion-tube to a dull red heat, anthraquinone distils over. The methyl-group appears to take part in this reaction, as the green colouring matter obtained by V. Meyer (*Ber.*, **16**, 2972) from thiophene and phenanthraquinone yielded no anthraquinone under similar treatment. Both bodies yielded phenanthrene when distilled with zinc-dust.

Furfuraldehyde yields similar but less stable compounds with thiophene and methylthiophene; that formed with the latter body is ultramarine-blue in colour. L. T. T.

Replacement of Ketonic Chlorine-atoms by Hydrogen. By B. Lachowicz (*Ber.*, **17**, 1161—1165).—Dichlorophenanthrone is converted into monochlorophenanthrone by reduction with acetic acid and finely divided iron at 100°. At a temperature of 110°, the product of the reaction is phenanthrone. Under similar treatment, dichlorobenzil yields benzoin chloride, $C_{14}H_{11}OCl$, and deoxybenzoin. At temperatures above 90°, tolane tetrachloride is reduced by iron powder and acetic acid to a mixture of α and β tolane dichlorides.

W. C. W.

A New Synthesis of Anthraquinone. By W. Panaotovits (*Ber.*, **17**, 312—314).—The author has obtained anthraquinone by the dry distillation of calcium phthalate. The action takes place according to the equation—

$$2C_6H_4(COO)_2Ca = C_{14}H_8O_2 + 2CaCO_3,$$

and lends support to the di-ketone formula for anthraquinone. The author is now endeavouring to obtain quinone by the dry distillation of calcium fumarate. L. T. T.

Chlorinated Anthraquinones. Anthracene from Tetrachlorophthalic Acid. By G. Kircher (*Ber.*, **17**, 1167—1170).—When tetrachlorobenzobenzoic acid is treated with a mixture of equal parts of strong and fuming sulphuric acid at 100°, tetrachloranthraquinone and the disulphonic acid are formed. The product is exposed to the air in a flat basin to allow it to attract moisture, and the disulphonic acid is afterwards removed by washing with water. The residual tetrachloranthraquinone, $C_6Cl_4 \colon (CO)_2 \colon C_6H_4$, is soluble in chloroform, benzene, and carbon bisulphide. It is precipitated from these solutions by alcohol. It crystallises in yellow-coloured needles, melting at 191°. Fuming nitric acid at 140° converts the chloranthraquinone into a mixture of tetrachlorophthalic acid and a nitro-product crystallising in needles which melt at 230°.

Tetrachloranthracene is formed by the action of hydriodic acid and amorphous phosphorus on tetrachlorobenzobenzoic acid at 200°. It is deposited in white needles melting at 148°, when alcohol is added to the solution in chloroform or benzene. On oxidation with chromic acid, tetrachloranthracene yields a tetrachloranthraquinone which melts at 191°. Tetrachloranthracene is converted into dichloranthracene by the action of zinc-dust and ammonia. The dichloro-compound, melting at 255°, by oxidation yields dichloranthraquinone, melting at 261°.

Octochloranthraquinone, described by Panaotovits (this vol., p. 1039) is formed in small quantity in the dry distillation of calcium tetrachlorophthalate. W. C. W.

Oxidation of Purpurin. By C. DRALLE (*Ber.*, **17**, 376).—Schunck and Roemer (*Ber.*, **10**, 175) pointed out that an alkaline solution of purpurin is bleached by exposure to light. By extracting the colourless solution with ether, the author has detected the presence of phthalic acid. This acid is also formed when an alkaline solution of purpurin or quinazarin is oxidised by potassium ferricyanide. Alizarin, on oxidation, does not yield any crystalline compound soluble in ether. W. C. W.

α-Nitroanthraquinonesulphonic Acid and its Derivatives. By A. CLAUS (*Ber.*, **17**, 1276—1279).—In reply to Lifschütz (*Ber.*, **17**, 899) the author maintains the correctness of his previous results, and accuses Lifschütz of piracy.

Strumper has now prepared the hydroxy-acid of α-amidoanthraquinonesulphonic acid, and is investigating its derivatives. On fusing it with potash, it yields alizarin just as the nitro-derivative does. L. T. T.

Reply. By C. LIEBERMANN (*Ber.*, **17**, 1279—1280).—The author justifies his having set his students to work on this subject on the ground—1, of having worked on it previous to Claus' reservation, and, 2, that several of the results obtained by Claus and his students are incorrect. He still doubts the existence of Claus' etheric sulpho-acids, and the formation of alizarin by the fusion of the nitro-acid with potash. L. T. T.

Retene. By E. BAMBERGER (*Ber.*, **17**, 453—456).—After referring to the researches of Wahlforss (*Zeitsch. f. Chem.*, 1869, 74) and Ekstrand (*Annalen*, **185**, 75) on retene and dioxyretistene, the author points out that the latter body (which he prefers to call *retistene-quinone*) has the composition  $C_{14}H_{14}<\begin{matrix}CO\\|\\CO\end{matrix}$, and forms a series of compounds analogous to those of phenanthraquinone. Retistene-quinone dissolves in hot aqueous solutions of the alkalis, taking up water and yielding a salt of *retistene-glycollic acid*, $C_{14}H_{14}:C(OH).COOH$. On oxidation, the acid is converted into *retistene-ketone*, $C_{14}H_{14}:CO$, which yields *retistene-fluorene alcohol*, $C_{14}H_{14}:CH.OH$, on treatment with zinc and hydrochloric acid.

Retistene-quinone may easily be recognised by the blood-red coloration which is produced when a small quantity of alcoholic potash is added to an alcoholic solution of the quinone. The colour disappears if the mixture is shaken with air, but reappears again on warming, in absence of air. W. C. W.

Dioxyretistene. By A. G. Ekstrand (*Ber.*, **17**, 692—697).—Dioxyretistene has the formula $C_{32}H_{25}O_4$ or $C_{32}H_{26}O_1$, the latter, perhaps, being the more probable. By distillation with 10 times its weight of dry barium hydroxide, dioxyretistene yields a mixture of oil and crystals. The crystalline substance, $C_{30}H_{26}O_2$, after purification, is obtained in broad yellow needles, melts at 90—91°, is readily soluble in ether, alcohol, glacial acetic acid, benzene, and light petroleum, yields about half its weight of retene when distilled with zinc-dust, does not unite with hydrogen sodium sulphite, and does not appear to be attacked by boiling alcoholic potash. On oxidation with chromic acid in glacial acetic acid solution, it yields a substance of the formula $C_{30}H_{22}O_4$, crystallising in long yellow needles, melting at 151—152°, and insoluble in alkalis. Heated with zinc, this product gives a substance crystallising in small white plates, and melting at 65—66°, but the quantity was too small for further investigation.

By the action of sodium amalgam on an alcoholic solution of the substance $C_{30}H_{26}O_2$, a substance of the formula $C_{30}H_{32}O_2$ is obtained (yield 95 per cent. of theoretical). This crystallises in interlaced white needles, melts at 134°, and by heating with acetic anhydride, yields an acetyl compound, crystallising in white needles, melting at 70°, and giving numbers on analysis best agreeing with the formula $C_{30}H_{2}$-$(O\overline{Ac})_2.C_{30}H_{28}O\overline{Ac}.OH$. By oxidation with chromic acid or solution in alcoholic potash, the compound $C_{30}H_{26}O_2$ is again formed. It yields retene when heated with zinc-dust.

From the oil obtained by distilling dioxyretistene with baryta, there were isolated, retene, the compound $C_{30}H_{26}O_2$ and a hydrocarbon (or mixture of hydrocarbons) $C_{27}H_{30}$, distilling between 290—310° without showing a constant boiling point.

Dioxyretistene, when heated with acetic anhydride in sealed tubes for 24 hours at 170°, is converted into a mixture of two substances: tetracetyldioxyretistene, $C_{32}H_{22}(O\overline{Ac})_4$, crystallising in large, hard, green rhombic needles, and an anhydride of dioxyretistene, $(C_{32}H_{25}O_3)_2O$, crystallising in needles having a red metallic lustre. Both compounds are sparingly soluble in glacial acetic acid, benzene, and xylene.

A. J. G.

Isomeric Chloronitro-camphors. By P. Cazeneuve (*Compt. rend.*, **98**, 306—307).—When monochlorocamphor is treated with four times its weight of nitric acid, it yields a chloronitro-camphor, $C_{10}H_{14}Cl(NO_2)O$, which after purification by crystallisation from alcohol, melts at 95°, and has a specific rotatory power $[\alpha]_j = -6.2°$ (Abstr., 1883, 667). If the alcoholic mother-liquors from this are strongly cooled, they become semisolid from the deposition of crystals of an isomeric chloronitro-camphor, which may be purified by repeated crystallisation from alcoholic ammonia. It is indistinctly crystalline, melts at 83°, and has a specific rotatory power $[\alpha]_j = +17°$, but otherwise closely resembles its isomeride, except that it is soft and plastic,

and is very soluble in cold alcohol. With reducing agents, it gives nitro-camphor, like its isomeride.
C. E. G.

Asarone. By B. Rizza and A. Butlerow (*Ber.*, **17**, 1159—1160).—Pure *asarone* crystallises in needles or plates soluble in alcohol, ether, carbon tetrachloride, acetic acid, and in hot water. It melts at 59°, and boils at 296°. Its sp. gr. at 18° is 1·165. Asarone unites with 2 atoms of bromine to form the addition-product $C_{12}H_{16}Br_2O_3$.

The authors state that Gräger's *asarite* does not exist.
W. C. W.

Daphnetin. By W. Will and O. Jung (*Ber.*, **17**, 1081—1091).—This investigation was undertaken for the purpose of determining the constitutional formula of daphnetin. Stünkel (*Ber.*, **12**, 109) has already shown that it is probably a dihydroxycoumarin, and with a view to prove this and show it to be isomeric with aesculetin, the authors prepared its ethyl-derivatives and the products resulting from them on oxidation. By these means, they show that daphnetin stands in the same relation to pyrogallol as coumarin does to phenol, and as umbelliferone to resorcinol, and that aesculetin may possibly stand in a similar relation to phloroglucol. The results have been confirmed by v. Pechmann (*Ber.*, **17**, 929) by his synthetical formation of daphnetin by the action of malic acid on pyrogallol.

Ethyl-derivatives of Daphnetin.—These are formed by boiling an alcoholic solution of daphnetin with ethyl iodide and caustic potash. On evaporating the liquid with water, an oil separates out, which can be extracted with ether. *Monethyldaphnetin*, $C_9H_5O_3.OEt$, is found in the aqueous solution, and when crystallised from dilute alcohol, forms colourless plates, melting at 155°, and soluble in alcohol, benzene, and ether. *Diethyldaphnetin*, $C_6H_4O_2(OEt)_2$, is obtained from the ethereal extract. It crystallises from alcohol in needles melting at 72°, is soluble in alcohol, ether, and benzene, but insoluble in water. Dilute aqueous soda solution dissolves it only when heated, and from this solution acids reprecipitate it—a property in which it resembles coumarin. *Monobromodiethyldaphnetin*, $C_{13}H_{13}O_4Br$, is obtained from diethyldaphnetin by the action of bromine in bisulphide of carbon solution, and forms colourless crystals melting at 115°, and soluble in hot alcohol, in ether, and in benzene. It is insoluble in cold dilute soda solution, but on boiling it with alcoholic potash, hydrobromic acid is eliminated, and, on acidifying the solution, a new acid, diethyldaphnetilic acid, crystallises out. *Diethyldaphnetilic acid*, $C_{13}H_{14}O_5$, forms fine asbestos-like crystals melting at 154°. Like coumarilic acid and the analogous compound of umbelliferone and aesculetin, when treated with sodium amalgam, it takes up two atoms of hydrogen and forms a hydrodaphnetilic acid.

By evaporating a solution of diethyldaphnetin in caustic soda to dryness, a yellow crystalline mass is obtained, which is probably the sodium salt of diethyloxycoumaric acid. On heating this salt with ethyl iodide and alcohol in a sealed tube, a neutral oil was extracted from the aqueous solution, which was found to consist of a mixture of unaltered diethyldaphnetin and ethylic triethyldaphnetate. As it was found difficult to obtain the ether pure, it was converted into the potassium salt, and from the latter the free acid was obtained, and purified from diethyldaphnetin by crystallisation from alcohol. *Triethyldaphnetic acid*, $C_{15}H_{20}O_6$, is a white crystalline substance, melting at 193°, and soluble in hot alcohol, ether, and benzene, but insoluble in water and carbon bisulphide. It is formed in the same way as is triethylaesculetic acid, and, like the latter on treatment with sodium amalgam, readily takes up two atoms of hydrogen to form *hydrotriethyldaphnetic acid* or triethyloxyphenylpropionic acid (m. p. 85°).

On oxidising triethyldaphnetic acid with potassium permanganate, the authors obtained a substance melting at 70°, and giving the reactions of an aldehyde (triethoxybenzaldehyde), and also by further oxidation triethyoxybenzoic acid, $C_{13}H_{18}O_5$. This acid is insoluble in water, soluble in alcohol, ether, and benzene, and melts at 100·5°. On heating the silver salt in a current of carbonic acid, a distillate was obtained, which quickly solidified, and on purification was found to be a white crystalline compound body, melting at 39°, and by analysis and properties identical with triethylpyrogallol, $C_{12}H_{18}O_3$.

A. B.

Hæmatoxylin and Brazilin. By C. Dralle (*Ber.*, 17, 372—378).—*Hæmatoxylin.*—No definite products could be obtained by the action of hydrochloric, hydrobromic, or hydriodic acids, or of chlorine, methyl iodide, or nitrous acid on hæmatoxylin. Dibromhæmatoxylin, $C_{16}H_{12}Br_2O_6$, is formed by the action of bromine on a solution of hæmatoxylin in hot acetic acid. It is a crystalline substance, soluble in water and in dilute alkalis, without decomposition. It is decomposed at 120°. The acetic derivative of hæmatoxylin is also attacked by bromine, yielding a crystalline compound of the composition

$$C_{16}H_5Br_4O_6\overline{Ac}_5.$$

Brazilin appears to yield a methyl-derivative, which has not yet been isolated. Negative results only were obtained by acting on brazilin with chlorine, bromine, hydrochloric, hydrobromic, and sulphuric acids.

W. C. W.

Hæmatoxylin and Brazilin. By K. Buchka (*Ber.*, 17, 683—685).—Dralle has recently prepared dibromhæmatoxylin and tetrabromopentacetylhæmatoxylin, but states that he could not obtain crystalline compounds by the action of bromine on brazilin or acetylbrazilin (preceding Abstract).

Monobromacetylhæmatoxylin, $C_{16}H_8BrO_6\overline{Ac}_5$, prepared by adding bromine dissolved in glacial acetic acid, drop by drop, to a cold solution of acetylhæmatoxylin in glacial acetic acid, allowing to stand for some hours, precipitating with aqueous sulphurous acid, and crystallising from alcohol, forms slender colourless needles; it melts at 210°, and is soluble in chloroform, glacial acetic acid, and benzene. By heating with alkalis, it is converted into bromhæmatoxylin. By the action of bromine on a boiling solution of hæmatoxylin in glacial acetic acid, a dark red crystalline substance is obtained; it is now under investigation.

Monobromacetylbrazilin, $C_{16}H_9BrO_5\overline{Ac}_4$, prepared in a manner similar to that above described for the corresponding hæmatoxylin compound, crystallises in slender silky needles; it melts at 203—204°, is converted into bromobrazilin by aqueous potash, and on treatment with bromine at 100° is converted into a red crystalline substance, which will be further examined. A. J. G.

Action of Acetic Anhydride and Benzoic Anhydride on Pyrroline. By G. L. CIAMICIAN and M. DENNSTEDT (*Ber.*, **17**, 432—433).—In a previous communication, the authors pointed out that two isomeric compounds are formed by the action of acetic anhydride on pyrroline. Pseudacetopyrroline contains one atom of hydrogen replaceable by silver. By boiling a methyl alcohol solution of pseudacetopyrroline with hydroxylamine hydrochloride and sodium carbonate, a substance is obtained which melts at 145°, and has the constitution $HON : CMe.C_4H_3 : NH$. This shows that the formula for pseudacetopyrroline is $CH_3.CO.C_4H_3 : NH$. Acetic anhydride at 250° converts pseudacetopyrroline into a compound, $C_4H_2\overline{Ac}_2NH$, which contains one atom of hydrogen replaceable by silver. This body melts at 161°.

Benzoic anhydride resembles acetic anhydride in its action on pyrroline. It yields two compounds, one liquid, the other crystalline, melting at 75°. The latter forms a silver compound. The constitution of the solid isomeride is represented by the formula

$$C_6H_5.CO.C_4H_3 : NH.$$

W. C. W.

α-Carbopyrrolic Acid. By G. L. CIAMICIAN and P. SILBER (*Ber.*, **17**, 1150—1158).—α-Carbopyrrolic acid can be prepared by heating pyrroline with water and ammonium carbonate in sealed tubes at 140°. The product is gently evaporated to expel ammonium carbonate and pyrroline, and when cold is acidified with dilute sulphuric acid and extracted with ether. The acid is purified by recrystallisation from alcohol. If the temperature rises above 140° in the preparation of the acid, a small quantity of a second acid, probably β-carbopyrrolic acid, is also formed. The *calcium* salt of the α-acid, $Ca(C_{10}H_8N_2O_4)$, forms white scales. The *silver* salt is sparingly soluble. The *methyl* salt, $C_5H_4MeNO_2$, crystallises in needles or prisms, melting at 73°, and soluble in ether and alcohol. The *ethyl* salt melts at 39°, and boils at 231°. It dissolves freely in alcohol, ether, and benzene. Methyl tribromocarbopyrrolate is formed when bromine vapour is passed into a hot aqueous solution of methyl α-carbopyrrolate. It forms crystalline needles, melting at 210°, and soluble in ether and hot alcohol. On saponification, it yields tribrom-α-carbopyrrolic acid; this is deposited from a hot aqueous solution in needles which are freely soluble in ether, alcohol, and acetone. The acid begins to decompose at 140°.

A crystalline compound, probably $NH : C_4H_3.COO.COMe$, is obtained by the action of acetic chloride on silver carbopyrrolate suspended in light petroleum. It is decomposed by water into acetic and carbopyrrolic acids. It melts at 75°, and at a higher temperature splits up into acetic acid and pyrocoll.

The *methyl* salt of *pseudacetyl-α-carbopyrrolic acid*,

$$COMe.C_4H_2(COOMe)NH,$$

is formed when methyl carbopyrrolate is heated in sealed tubes at 250°, with acetic anhydride. It is deposited from a hot aqueous solution in glistening needles, melting at 113°, soluble in alcohol and ether. It contains one atom of hydrogen replaceable by silver. The free acid forms vitreous plates, melting at 186°; it dissolves in water, ether, alcohol, and acetone. The silver salt is sparingly soluble. The calcium salt, $Ca(C_7H_6NO_3)_2 + 7H_2O$, forms triclinic crystals. W. C. W.

Pyrroline Dyestuffs. By V. Meyer and O. Stadler (*Ber.*, **17**, 1034—1036).—The blue dyestuff obtained by the action of pyrroline on isatin (this vol., 587) has been purified as much as possible and analysed. The results of analysis agree with those of Ciamician and Silber (this vol., 740) as far as concerns the carbon and hydrogen. The quantity of nitrogen, however, found is smaller by 1·9 per cent. than that required by Ciamician and Silber's formula ($C_{24}H_{18}N_4O_3$). These authors have given no results of the nitrogen determinations. It is therefore doubtful whether the reaction is as simple as that expressed by their equation.

The authors also find that reactions with formation of dyestuffs take place between phenanthraquinone and pyrroline, and between benzoquinone and pyrroline. A. B.

Decomposition-products of the Pyrroline Series. Part I. By A. Hantzsch (*Ber.*, **17**, 1019—1032).—It has been shown by Hofmann that the ammonium-compounds of bases are often found to be capable of being split up into less complicated substances, whilst the bases themselves are not. Conine and piperidine are examples of this. The decomposition of pyridine ammonium-compounds by potash is, however, more complicated, and the compounds obtained are very unstable. In the hope of obtaining more stable decomposition-products, the author has been led to study the decomposition of the ammonium-derivatives of ethylic collidinedicarboxylate by potash and in other ways, this member of the pyridine series being chosen on account of the ease with which it can be synthetically prepared (Abstr., 1883, 83).

Methiodide of ethylic collidinedicarboxylate, $C_5Me_3(COOEt)_2N,MeI$, is obtained by heating the ether with methyl iodide for several hours in a sealed tube, dissolving the resulting ammonium-compound in alcohol, and precipitating with ether. It is readily soluble in water and alcohol, is not hygroscopic, melts at 140°, and decomposes at 160°. Silver chloride converts it into the corresponding chloride, and with platinic chloride it gives a platinochloride,

$$(C_{15}H_{21}NO_4)_2,H_2PtCl_6,$$

as an oil, which may be obtained in a crystalline form, but only difficulty. The salts of this ammonium base have an acid reaction not decomposed by ammonia, as are the salts of the non-methyl base, but the salt is precipitated unchanged by potassium carbonate. The hydroxide, $C_5Me_3(COOEt)_2N,MeOH$, is obtained by treating the chloride or iodide with silver oxide. It is an alkaline liquid, which rapidly decomposes, becoming black, and forming along with bye-products a crystalline substance, which, however, can be more readily obtained without the formation of bye-products, by decomposing a salt of the base with potash.

Decomposition of the Methyl Ammonium Salt by Potash.—When the ammonium salt of ethyl collidinedicarboxylate is heated with concentrated potash solution, a yellow oil is precipitated, which rapidly solidifies, and may be purified by crystallisation from water or ether. This substance is soluble in alcohol, ether, chloroform, and benzene, and in hot water, and melts at 81·5°. It has no odour, distils above 360° without decomposition, and is remarkable for its chemical indifference. Its aqueous solution is precipitated by alkalis, but it is unchanged by boiling with potash. It has a neutral reaction, and does not form salts with acids or bases. It is also unattacked by concentrated hydrochloric acid, or by acetic anhydride. Analysis leads to the formula $C_{11}H_{13}O_4N$. Owing to the indifference of this substance, a proof of the constitutional formula is difficult, but the ether seems to be saponified, and also to lose a molecule of water, and the author calls it *methyldicarbocollidylium dihydride.*

Action of Acids on Methyldicarbocollidylium Dihydride.—On passing dry hydrochloric acid over this dihydride, a molecule of HCl is taken up, which, however, is removed by treatment with water. On heating this hydrochloride in a current of dry hydrochloric acid gas, it distils in part, and the distillate, on being treated with water and evaporated to dryness, yields on further treatment with potassium carbonate and extraction with ether, a new crystalline compound, $C_{10}H_{13}O_2N$, soluble in the ordinary solvents, melting at 102—103°, and distilling at about 340°. It may be considered as methylmonocarbocollidylium dihydride. Like the dicarbo-compound, it is neutral and indifferent, and resists the action of alkalis and other reagents.

On acting on these carbo-compounds with concentrated sulphuric acid at 160—180°, acetic acid is given off, and a new substance is obtained, according to the equations $C_{10}H_{13}O_2N + H_2O = CH_3.COOH + C_6H_{11}ON$ and $C_{11}H_{13}O_4N + H_2O = CH_3.COOH + CO_2 + C_8H_{11}ON$. These reactions are quantitative, and the author names this compound in accordance with Baeyer's nomenclature of the isatin-compounds "*methylpseudolutidostyril,*"

$MeC\genfrac{<}{>}{0pt}{}{CH.CMe}{-CH.CO-}NMe$.

Methylpseudolutidostyril crystallises in six-sided plates, is very soluble in water, soluble in alcohol and benzene, but very sparingly in ether. It melts at about 70°, and distils without decomposition at 292°. The distillate solidifies to a white spermaceti-like mass, which is very hygroscopic. It has neither taste nor smell, and is not volatile in steam. Concentrated potash solution precipitates it from its aqueous solution, but does not attack it even on heating; on prolonged boiling, however, it is decomposed by potash, with formation of methylamine and other decomposition-products. As a tertiary base it is soluble in acetic anhydride, without evolution of heat, but is unchanged, and it forms no nitroso-compound. Although neutral, it forms salts with mineral acids; these have the formula $(C_8H_{11}ON)HX'$, and are readily converted into basic salts, $(C_8H_{11}ON)_2HX'$, in presence of ammonia: in this it resembles some derivatives of cotarnine (Abstr., 82, 315). The hydrochloride of methylpseudolutidostyril crystallises from water in long needles, of the formula $C_8H_{11}ON.HCl + \frac{1}{2}H_2O$. With fuming hydriodic acid, it forms a normal hydriodide, but on adding water a precipitate of fine yellow needles of the basic salt $(C_8H_{11}ON)_2,HI$ is formed. The platinochlorides are characteristic. On treating an alcoholic solution of the base with alcoholic platinic chloride, a crystalline precipitate of slender yellow needles is obtained, consisting of a neutral platinochloride with two molecules of alcohol of crystallisation, $(C_8H_{11}ON)_2,H_2PtCl_6 + 2C_2H_6O$. From an aqueous solution of the base, platinic chloride precipitates the same platinochloride, with 2 mols. H_2O, along with some basic salt. Chromic acid completely decomposes the base. With bromine, it forms a dibromo-compound, $C_8H_9Br_2ON$, melting at 173°, sparingly soluble in water, but soluble in alcohol and ether. Phosphorus pentachloride does not eliminate the oxygen of the base, but yields a chlorine-derivative, $C_8H_9Cl_2ON$, melting at 187°; this may also be obtained by the direct action of chlorine. With methyl iodide at 120°, a reaction takes place, but the ammonium-compound seems to be very unstable, readily decomposing into the original pseudostyril, and in this it differs from the corresponding derivative of tropine (Abstr., 1882, 217). It is not reduced by tin and hydrochloric acid, nor by sodium amalgam and acetic acid. Cold fuming nitric acid does not attack it, but at 45° a violent reaction takes place, and the pseudostyril is partly decomposed, with formation of oxalic acid, and partly converted into a nitro-derivative, which is more easily formed by boiling it with dilute nitric acid.

The action of hydrochloric acid and of potassium permanganate on methylpseudolutidostyril will form the subject of a future paper.

A. B.

Synthesis of Pyridic Hydrides. By O. DE CONINCK (*Compt. rend.*, **98**, 1438—1440).—When β-lutidine and β-collidine are heated in sealed tubes with an excess of concentrated hydriodic acid at 220° for several hours, they yield polyiodides which are very viscous brown liquids and boil at a high temperature with partial decomposition. They are either triiodides or hydriodides of di-iodides.

β-Collidine heated in sealed tubes at 130—140° with amorphous phosphorus and concentrated hydriodic acid, yields a small quantity of dihydrocollidine. This base yields a platinochloride which forms pale orange-yellow plates, readily altered by boiling water.

When treated with sodium and alcohol under certain conditions, β-lutidine yields a small quantity of a hexhydride, $C_7H_{15}N$, which boils at about 155—160°, is very hygroscopic, and can only be separated from the original lutidine with considerable difficulty. It is a colourless mobile refractive liquid, which resembles the other pyridines in appearance, and has a peculiar penetrating odour recalling that of piperidine. It combines with methyl iodide to form a crystalline compound which yields a small quantity of a cicutine, $C_8H_{17}N$, when distilled with a slight excess of potash. This cicutine probably has the constitution C_5H_9EtNMe, and is isomeric with ordinary cicutine or orthopropylpyridine hexhydride.

Under similar conditions, β collidine yields a hexhydride, $C_8H_{17}N$, boiling about 175—180°. This hydride is difficult to separate from the collidine, and is very hygroscopic. The behaviour of β-collidine on oxidation shows that it is methyl-ethyl pyridine, and the new hydride has the constitution $C_5H_8MeEtNH$, and is therefore another isomeride of cicutine. C. H. B.

Isopropylpyridines. By A. LADENBURG and L. SCHRADER (*Ber.*, 17, 1121—1123).—*γ-Isopropylpyridine* boils at 158°, and has the sp. gr. 0·9408 at 0°. It is slightly soluble in water. The hydrochloride is hygroscopic, the platinochloride has not yet been obtained in crystals. The aurochloride is deposited from hot water in orange needles which melt at 79°. The base unites with methyl iodide to form a crystalline hygroscopic compound. The aurochloride of the methyl base forms pale-yellow plates which melt at 128°. γ-Isopropylpyridine, when oxidised with potassium permanganate, yields γ-pyridinecarboxylic acid melting at 303°.

The isomeric isopropylpyridine (probably α) boils at about 167°. The platinochloride forms four-sided plates melting at 206°, which are less soluble than the corresponding γ-salt. The base appears to be identical with Hofmann's conyrine from conine (*Ber.*, 17, 825). On reduction with sodium and alcohol, it yields a base resembling conine, hence the authors consider it probable that conine is α-isopropylpiperidine. W. C. W.

Notes. By E. NÖLTING and A. COLLIN (*Ber.*, 17, 258—259).—I. *Pyridinedicarboxylic acid*, obtained by the oxidation of quinoline by potassium permanganate, has the two carboxyl-groups in the *ortho*-position, and may therefore be regarded as phthalic acid in which one CH-group has been replaced by N. Like phthalic acid, it combines with phenols. When heated at 120° with phenol and sulphuric acid, it forms a condensation-product which dissolves in alkalis to a red solution. By the action of resorcinol at 200°, it yields a body similar in character to fluoresceïn, and this on bromination gives a red colouring matter resembling eosin.

II. *Blue Colouring Matters from Rosaniline.*—It is well known that a blue colouring matter is obtained when aniline, or ortho- or para-toluidine is heated with rosaniline and benzoic acid. Metatoluidine yields a similar crystalline blue dye soluble in alcohol, insoluble in water, and giving a sulphonic acid. β-Naphthylamine, under similar conditions, also yields a blue, already described by Meldola (Abstr., 1883, 807). The authors have attempted to find some cheaper substitute for the excess of aniline at present used in preparing these colouring matters on a commercial scale. Naphthalene may be used to replace aniline, but this change has not proved commercially useful. L. T. T.

Derivatives of Quinoline and Pyridine. By O. FISHER and E. RENOUF (*Ber.*, 17, 755—764).—A continuation of the authors' researches on this subject (Abstr., 1883, 923—1146).

Oxidation of Orthoquinolinesulphonic Acid.—By the oxidation of 40 grams of this substance with potassium permanganate in aqueous solution 23 grams of quinolic acid· were obtained. Orthhydroxyquinoline (40 grams) also yields quinolic acid (20 grams) on oxidation with aqueous potassium permanganate.

Orthhydroxyhydroethylquinoline.—The preparation of this substance has been already described; it crystallises in colourless monoclinic prisms showing the combinations $\infty\bar{P}\infty$, $\infty\grave{P}\infty$, $-P$, ∞P and $\grave{P}\infty$. Axial ratios $a : b : c = 0·9711 : 1 : 1·3549$. $\beta = 72° 54'$. It melts at 76°, can be distilled unchanged in small quantity; the vapour has a penetrating odour somewhat recalling that of ethylamine. It is rapidly oxidised when its alkaline solution is exposed to air, humus-like substances being formed. Its alcoholic solution gives a dark-brown coloration with ferric chloride, and a dark greenish-black flocculent precipitate with ferrous sulphate. An acid solution gives a voluminous precipitate with potassium ferrocyanide, a pale-yellow precipitate with phosphotungstic acid, whilst with sodium nitrite an intense yellow colouring matter is formed. Its hydrochloride, "kairin," forms colourless rhombic prisms of the rhombic system, $a : b : c = 0·5945 : 1 : 0·9566$, and shows the combination ∞P , $\infty\breve{P}\infty$, $\infty\bar{P}2$, $\breve{P}12$, $\frac{3}{7}\bar{P}\infty$. With potassium dichromate, a neutral aqueous solution of kairin gives first a dark coloration, and after a few seconds a dark-violet precipitate soluble in alcohol with a mauve-like colour; with potassium ferricyanide, a dark yellowish-green coloration is produced.

Ethoxyquinoline has been already in part described (*loc. cit.*). It distils in a current of steam with difficulty, and is obtained from the distillate in long colourless needles. The sulphate, oxalate, and hydrochloride are readily soluble in water and alcohol. The picrate crystallises in sulphur-yellow needles, melts at 180—181°, and is sparingly soluble in water and alcohol.

Ethoxyhydroquinoline.—The nitroso-derivative crystallises in short prisms and melts at 113°. The hydrochloride crystallises in colourless prisms; the oxalate forms colourless cubes; the sulphate crystallises in long needles, readily soluble in water; the picrate forms orange-yellow prisms sparingly soluble in water, soluble in alcohol.

Acetylethoxyhydroquinoline, $C_{11}H_{14}NO\overline{Ac}$, prepared by the action of acetic anhydride on ethoxyhydroquinoline, forms a clear yellow oil boiling at 307°. It has a neutral reaction. On boiling it with concentrated mineral acids, the acetyl-group is eliminated.

Ethoxyhydroethylquinoline, $C_{13}H_{19}NO$, is prepared by heating ethyl bromide and ethoxyhydroquinoline for some hours under pressure at 120—130°. It crystallises in colourless silky plates, melts at 33°, boils at 266—268° under 716 mm. pressure, and is readily soluble in the ordinary solvents with the exception of water. The hydrochloride and hydrobromide form colourless plates, the sulphate crystallises in needles; all three are readily soluble. The picrate forms orange-yellow prisms sparingly soluble in alcohol and water.

Bromethoxyhydroquinoline, $C_{11}H_{14}NOBr$, is prepared by adding the calculated quantity of bromine dissolved in chloroform to a well-cooled solution of ethoxyhydroquinoline in chloroform. It forms lustrous crystals of the triclinic system $a : b : c = ? : 1 : 0·8101$ $\alpha = 107° 48'$.

$\beta = 110° 58'$; $\gamma = 85° 0'$. Some of the best formed crystals showed the combination $\infty\bar{P}\infty$, $\infty\breve{P}\infty$, $0P$, $'\breve{P}_{,}\infty$. It melts at 44·5°, and at 150° decomposes with almost explosive violence, has basic properties, and forms crystalline salts. The hydrochloride and hydrobromide crystallise in needles, the sulphate in plates: the oxalate in prisms. The picrate forms sulphur-yellow needles, melts at 107—108°, and is sparingly soluble in water and alcohol. The nitrosamine crystallises in lustrous yellow plates and melts at 86°.

Bromethoxyhydroethylquinoline, $C_{13}H_{18}NOBr$, crystallises in prisms of the monoclinic system $a : b : c = 0·7902 : 1 : 0·5828$, $\beta = 69° 55'$, and shows the combination ∞P, $\infty\text{Ꝑ}\infty$, $\text{Ꝓ}\infty$, $\frac{2}{3}\text{Ꝑ}\infty$. The hydrochloride and hydrobromide crystallise in needles; the picrate in yellow needles melting at 174°. Towards nitrous acid, the bromo-derivative acts as a tertiary base, giving an intensely yellow solution from which sodium carbonate throws down a brownish-yellow substance melting at 85—86°.

β-Hydroxypyridine, C_5H_5NO, is prepared from pyridinesulphonic acid by carefully mixing it with twice its weight of caustic potash and fusing in a silver crucible. It crystallises in very pale-yellow needles, melts at 123·5°, sublimes unchanged, and is readily soluble in water and alcohol. Its salts are very soluble. In aqueous solution, it gives a red coloration with ferric chloride; if boiled with excess of the reagent, yellowish-brown crystals separate. Sodium amalgam reduces it to piperidine, and it yields pyridine when distilled with zinc. The foregoing reactions show that it is not identical with the hydroxypyridine of Lieben and Haitinger (Abstr., 1883, 870) and Ost, or with the α-hydroxypyridine of Konigs and Geigy (*Ber.*, **17**, 589).

By treatment with bromine in aqueous solution, it yields a bromo-derivative crystallising in nodules of fine colourless needles; these melt at 58°, and yield a violet coloration with ferric chloride.

A. J. G.

Method for the Synthesis of Quinoline-derivatives. By L. Rugheimer (*Ber.*, **17**, 736—739).—Malonanilidic acid (1 part) is suspended in 10 parts of anhydrous benzene and 4 parts of phosphorous pentachloride slowly added with constant agitation; the mixture, after remaining some time in the cold, is heated on the water-bath in a vessel provided with a reflux condenser until the evolution of hydrochloric acid ceases. The benzene is first distilled off, and the residue is treated with water and sodium carbonate when trichloroquinoline distils over. *Trichloroquinoline*, $C_9H_4NCl_3$, crystallises in long colourless needles, melts at 107·5° (uncorr.), is readily soluble in benzene, light petroleum, and hot alcohol, less soluble in cold alcohol. When gently heated, it smells distinctly like quinoline. It is converted into quinoline by heating it for six hours at 240° with glacial acetic acid saturated with hydriodic acid. A. J. G.

Bases formed by the Addition of Haloïd Ethereal Salts to Quinoline. By A. Claus and P. Stegelitz (*Ber.*, **17**, 1328—1333).—It has been previously shown (Abstr., 1883, 1008) that the haloïd salts of the substituted quinolines are identical with the compound formed by the addition of the corresponding haloïd ethereal salts to quinoline. With the view of throwing light on the constitution of these bodies the authors have investigated their behaviour towards nascent hydrogen.

Quinoline ethobromide was subjected to the action of sodium amalgam, and also to that of tin and hydrochloric acid. The reaction was the same in both cases, but better results were obtained with the acid than with the alkaline solution. Two bases were formed, the one volatile with steam, the other not. The volatile base is a colourless oil, boils at 254—258° with partial decomposition, and is identical with Wischnegradsky's ethyltetrahydroquinoline (*Ber.*, **13**, 2400). It is easily soluble in alcohol and ether, almost insoluble in water. It dissolves in mineral acids, but the salts are exceedingly hygroscopic and could not be obtained in a crystalline form. The hydrochloride is dissociated even on evaporation in a desiccator over lime, and is only stable in presence of excess of hydrochloric acid. The platinochloride crystallises in golden-yellow needles having the formula

$$(C_9H_{10}EtN)_2,H_2PtCl_6,$$

and melts with decomposition at 160°. A cadmium double salt, $(C_9H_{10}EtN)_2,H_2CdCl_4$, melting at 105°, and an analogous salt with mercuric chloride which melts at 65°, were also obtained. The base combines readily with methyl iodide to form a quaternary iodide of the formula $C_9H_{10}EtN,MeI$. This forms colourless crystals melting at 179° (uncorr.), and is not acted on by alcoholic potash. Treated with silver oxide, it yields an easily soluble crystalline hydroxide. A platinochloride of the last-named base was obtained which crystallises in small yellow needles, melts at 215°, and has the formula

$$(C_9H_{10}EtN,MeCl)_2,PtCl_4.$$

The non-volatile base was obtained as a thick and almost colourless oil. It dissolves readily in dilute acids, and the solutions rapidly change to red or blue, but no crystalline salts could be obtained. Dry hydrochloric acid gas passed into an ethereal solution of the base, gives a white flocculent precipitate, which was obtained as an amorphous powder melting at 140°. It was, however, so hygroscopic that it could not be analysed. The platinochloride, which forms a bright-red powder, was the only product obtained suitable for analysis. The analytical results led to the unexpected formula $(C_9H_8EtN)_3,H_2PtCl_6$. The authors therefore consider this base to be a condensation-product from 3 mols. of ethylquinoline, with the addition of 6 atoms of H, but which is only a divalent base. The substance known as hydrodiquinoline is probably also a dibasic hydrotriquinoline. Attempts to obtain oxidation-products from the non-volatile base have, up to the present, proved fruitless, oxalic acid alone having been isolated. L. T. T.

Paraquinolinesulphonic Acid and its Homologues. By O. Fischer and C. A. Willmack (*Ber.*, **17**, 440—442).—*Paracyanoquinoline*, prepared by the action of potassium cyanide on potassium paraquinolinesulphonate, is a crystalline body which melts at 131°, and sublimes without decomposition. It dissolves in hydrochloric acid, forming a red solution. By the action of strong hydrochloric acid at 140° it is converted into *paraquinolinecarboxylic acid;* this is identical with Schlosser and Skraup's paraquinolinebenzocarboxylic acid (*Monatsh.*, 2, 526). γ-Methyl-α-quinolinesulphonic acid is obtained by boiling a mixture of paramido-meta-sulphotoluic acid, glycerol, sulphuric acid, and nitrobenzene. The crystalline mass deposited on cooling is washed with water and recrystallised from hot water. It crystallises in colourless plates sparingly soluble in water. If fused with sodium hydroxide, it yields α-hydroxy-γ-methylquinoline. This compound forms colourless plates, soluble in alcohol and in ether. It melts at 95° and sublimes without decomposition; it is also volatile in a current of steam. The hydrochloride is freely, and the platinochloride sparingly soluble in water.

α-Hydroxy-γ-methylquinoline tetrahydride crystallises in colourless needles soluble in hot benzene. The *nitroso*-derivative,

$$C_{10}H_{11}N(OH)NO,$$

forms small yellow needles. W. C. W.

Quinoxalines. By O. Hinsberg (*Ber.*, **17**, 318—323).—In a former communication (Abstr., 1883, 323) the author described a substance of the formula $C_9H_8N_2O_2$, which he obtained by the condensation of [3 : 4] diamido-toluene and oxalic acid, but was unable to obtain from it a non-oxidised base by reduction. He has now obtained the base of this substance by acting on an aqueous solution of glyoxal with [3 : 4] diamido-toluene. He has also obtained its lower homologue from glyoxal and orthophenylenediamine, and he finds that the reaction is quite general, any ortho-diamine appearing to react with any body containing the di-ketone group —CO.CO— to form derivatives of the simplest base,  $C_6H_4{<}\begin{matrix}N:CH\\N:CH\end{matrix}{>}$. He therefore proposes to call this series of compounds *quinoxalines.* The formula of quinoxaline (the lowest homologue) is undoubtedly $C_6H_4{<}\begin{matrix}N:CH\\N:CH\end{matrix}{>}$, that of the original dihydroxy-derivative, $C_9H_8N_2O_2$, is

$$C_6H_3Me{<}\begin{matrix}N:C(OH)\\N:C(OH)\end{matrix}{>}.$$

Quinoxaline, $C_8H_6N_2$, is obtained by treating an aqueous solution of glyoxal with orthophenylene diamine, or by adding the crystalline compound of glyoxal and hydrogen sodium sulphite to a solution of the diamine heated to 50—60°. The crystals dissolve readily, quinoxaline is formed, and may be separated by adding strong potash. The quinoxaline is dissolved in a little ether, dried over caustic potash, and distilled. It boils at 220—223°, and solidifies to a white crystalline mass melting at 27°. It is soluble in all proportions in alcohol, ether, benzene, and cold water, but is deposited from its concentrated aqueous solution when heated or on the addition of a caustic alkali. In odour it resembles the piperidine- more than the quinoline-derivatives. Solutions of the free base give white precipitates with silver nitrate and with mercuric chloride. Its salts with mineral acids are easily soluble; the oxalate crystallises in sparingly soluble white needles, and the platinochloride forms small yellow needles. Nitrous acid is without action, showing that the nitrogen-atoms are in the tertiary state. It is very stable against oxidising agents, but appears to form a nitro-derivative with strong nitric acid. It is easily reduced by tin and zinc.

Toluoquinoxaline, $C_6H_3Me<\substack{N:CH \\ N:CH}>$ $[CH_3 : N : N = 1 : 3 : 4]$, obtained from [3 : 4] diamidotoluene and glyoxal, is a pale-yellow liquid, which boils at 243—244°, and does not solidify at —10°. It is heavier than water, and is soluble in all proportions in alcohol, ether, benzene, and cold water. It is precipitated from its aqueous solutions by heat or the addition of a caustic alkali. In its reactions, it resembles quinoxaline, but is less stable towards oxidising agents. Its salts with mineral acids are easily soluble. The oxalate, $C_{11}H_{10}N_2O_4$, is sparingly soluble in cold water, and crystallises in needles which melt at 135—136°, but undergo slow decomposition if kept at this temperature.

Methylhydroxytoluoquinoxaline, $C_6H_3Me<\substack{N:CMe— \\ N:C(OH)—}>$, was obtained from the [3 : 4] diamido-toluene and pyruvic acid. It crystallises from dilute alcohol in small bright yellow needles, but can be obtained colourless by careful sublimation. It melts at about 200° with partial decomposition. It is sparingly soluble in water, more easily so in ether, benzene, and chloroform, very soluble in alcohol. It has both feebly basic and acid properties, dissolving in both mineral acids and in alkalis, and it gives precipitates with ammonia and barium chloride and with ammonia and silver nitrate.

Diphenyltoluoquinoxaline, $C_7H_6:N_2C_2Ph_2$, is obtained in the form of brownish silver-like scales when a mixture of [3 : 4] diamidotoluene and benzil is heated for some time on the water-bath and then diluted with water. It distils undecomposed, and melts at 111°, is almost insoluble in water, but dissolves easily in alcohol, ether, chloroform, and benzene. It dissolves in concentrated mineral acids, but the salts so formed are again decomposed on the addition of water.

Diphenylenetoluoquinoxaline,  $C_7H_6<\substack{N:C—C_6H_4 \\ | \quad\ | \\ N:C—C_6H_4}$, is prepared by pouring an alcoholic solution of [3 : 4] diamido-toluene into a warm acetic solution of phenanthraquinone. It forms bright yellow needles, which melt at 212—213°. It is insoluble in water, sparingly soluble in alcohol, easily so in ether, chloroform, and benzene. Concentrated mineral acids yield deep-red salts, which are decomposed by water.
L. T. T.

Dimethylquinaldine. By L. Berend (*Ber.*, 17, 653).—Dimethylquinaldine is obtained by the action of paraldehyde on xylidine from orthoxylene. It melts at 69—70°, is scarcely soluble in water, readily soluble in ether, alcohol, and benzene. A. J. G.

Dimethylquinaldine. By W. Merz (*Ber.*, 17, 1158).—A question of priority.

Aldehyde-collidine Hexahydride. By E. Dürkopf (*Ber.*, **17**, 1131—1132).—Aldehyde-collidine is converted into the hexahydride by the action of sodium in presence of absolute alcohol. The product is distilled, and the hydrochloric acid is added to the distillate in order to separate the hydride from the unaltered collidine. When the hydrochloride is mixed with potash and distilled in a current of steam, the hydride is obtained as an oily liquid boiling at 165°. W. C. W.

Cystine. By J. Mauthner (*Ber.*, **17**, 293—295).—By the action of water on cystine in closed tubes at 140—150°, the author has obtained an acid containing sulphur but no nitrogen. Analyses of the silver salt yielded numbers which leave it doubtful whether the acid has the formula $C_6H_{10}S_2O_4$ or $C_6H_8S_2O_4$. Carbonic anhydride, sulphuretted hydrogen, and ammonia were formed in this reaction, and a trace of mercaptan was also detected by its odour. The author will continue his investigations after the publication of Baumann's promised communication on cystine. L. T. T.

Synthesis of Piperidine and its Homologues. By A. Ladenburg (*Ber.*, **17**, 388—391).—*Methylpiperidine*, C_5H_9MeNH, isomeric with Hofmann's *methylpiperidine*, $C_5H_{10}NMe$, is formed by the action of sodium on an alcoholic solution of picoline from bone-oil. After purification by conversion into the nitroso-compound, methylpiperidine is an oily liquid which boils at 121—124°. It is soluble in water, forming a strongly alkaline solution. The aurochloride, platinochloride, and hydrochloride of this base are crystalline salts, freely soluble in water. The hydrochloride does not yield precipitates with mercuric chloride or potassium ferrocyanide. This reaction distinguishes it from its isomeride.

γ-Ethylpiperidine, prepared from γ-ethylpyridine, is sparingly soluble in water, less soluble in warm than in cold water. The hydrochloride crystallises in needles, and the platinochloride in orange-coloured plates. W. C. W.

Piperpropylalkine. By W. Laun (*Ber.*, **17**, 680—683).—In preparing piperpropylalkine, the use of sealed tubes is not necessary, it being sufficient to heat the mixture of propylene chlorhydrin and piperidine for four hours on the water-bath in a vessel provided with a reflux condenser. It boils at 194°, has sp. gr. 0·9456 at 0° and 0·9363 at 10°, vapour-density 4·79.

Piperpropylalkine methiodide, $C_8H_{17}NO,MeI$, forms a colourless somewhat hygroscopic crystalline mass, and melts at 142°. Treated with silver chloride, it yields the corresponding chloride, from which the platinochloride and aurochloride can be prepared. With moist silver oxide, the ammonium base, $NH(C_5H_9)(C_3H_6.OH)Me.OH$, is formed; this on distillation loses the elements of water, and is converted into the corresponding methylated piperpropylalkine, whose platinochloride gave numbers agreeing with the formula

$$[NMe(C_5H_9).C_3H_6.OH]_2,H_2PtCl_6.$$

The methylated base could not be isolated, as by the action of potash it is resolved into methylpiperidine and propylene glycol?

Benzoylpiperpropylalkeine, $N(C_5H_{10})C_3H_6.O\overline{Bz}$, is obtained as hydrochloride by the action of benzoic chloride on piperpropylalkine in solution in absolute ether. The picrate is a citron-yellow powder. The aurochloride, $N(C_5H_{10})C_3H_6.O\overline{Bz},HAuCl_4$, forms a canary-yellow crystalline powder.

By the action of bromine on piperpropylalkine or its hydrobromide, there was obtained, not as was expected, a compound of the formula $C_8H_{15}NBr_2$, but a substance, $C_8H_{17}NBr_2$, crystallising in colourless rectangular tables and needles. As this compound is also obtained by heating piperpropylalkine hydrobromide with concentrated hydrobromic acid in sealed tubes at 120°, it most probably has the constitution $N(C_5H_{10})(C_3H_6Br),HBr$. By shaking with silver chloride, a crystalline chlorobromide is obtained, from which a crystalline aurochloride and platinochloride were prepared, and also a picrate crystallising in sparingly soluble needles. A. J. G.

Belladonine. By G. MERLING (*Ber.*, **17**, 381—385).—The mixture of belladonine and atropine, of which commercial belladonine is composed, is boiled with baryta-water to decompose the atropine, when the belladonine, $C_{17}H_{21}NO_2$, remains as a brown resin. The auro- and platino-chlorides are insoluble in cold water. Belladonine is decomposed by boiling with baryta dissolved in a mixture of equal parts of alcohol and water, yielding tropine and an acid of the composition $C_{10}H_{12}O_3$, or probably a mixture of tropic, atropic, and isatropic acids.

The base oxytropine which Ladenburg obtained by boiling belladonine with alkalis exists ready formed as an impurity in crude belladonine. W. C. W.

Crystallised Colchicine. By A. HOUDÈS (*Compt. rend.*, **98**, 1442 1444).—Three kilos. of colchicine seeds were exhausted with 100 kilos. of alcohol of 96°, the liquid filtered, the alcohol distilled off, and the residue treated repeatedly with a 5 per cent. solution of tartaric acid, which dissolves out the colchicine, but leaves fatty and resinous matters undissolved. The filtered solution was then agitated with chloroform, the chloroform removed by evaporation, and the crude product purified by repeated crystallisation from a mixture of equal parts of chloroform, alcohol, and benzene. The yield from the seeds is about 3 grams per kilo., whilst that from the bulbs is only 0·4 gram per kilo.

The colchicine thus obtained forms nodular groups of colourless prisms, slightly soluble in water, glycerol, and ether, but soluble in all proportions in alcohol, benzene, and chloroform. It has a very bitter taste, and an alkaline reaction, contains nitrogen, and burns without residue. It is hydrated, and melts at 93°, but after drying at 100°, the melting point rises to 163°. A solution of colchicine does not reduce an alkaline copper solution, but after prolonged boiling with dilute sulphuric acid, it reduces it immediately, and in this respect resembles solanine. Colchicine combines with certain organic acids, but is decomposed when brought in contact with strong acids.

Concentrated or dilute inorganic acids dissolve colchicine and form a citron-yellow solution; nitric acid produces a transient violet coloration. Solutions of colchicine are precipitated by potash and soda, but not by ammonia. Tannin produces a white precipitate soluble on heating; platinum tetrachloride, an orange-yellow precipitate; an aqueous solution of iodine, a kermes-red precipitate; mercuric potassium iodide, a yellow precipitate; iodine in potassium iodide, a maroon-yellow precipitate.

Colchicine exerts a physiological effect only in relatively large doses. Respiration and the functions of the heart are considerably modified, and the general effect is a state of collapse, with stupor, but without insensibility. C. H. B.

Muscarine. By J. BERLINERBLAU (*Ber.*, **17**, 1139—1145).—*Muscarine* can be prepared synthetically by the following process. Monochloracetal obtained by Paterno and Mazzara's process (*Gazzetta*, **3**, 245) is heated with trimethylamine in sealed tubes at 130° for three or four days. The product is distilled in a current of steam, and the aqueous residue is digested with silver oxide to remove trimethylamine hydrochloride; the filtrate from this is then neutralised with hydrochloric acid, and the platinochloride is prepared by fractional precipitation. The first precipitate consists of octahedra and the last portion of rhombic plates. The latter have the composition $(NMe_3Cl.CH_2.CH(OEt)_2)_2PtCl_4$, *i.e.*, the platinochloride of the ethylic salt of muscarine. The octahedral crystals have the composition of muscarine platinochloride, $(NMe_3Cl.CH_2.COH)_2,PtCl_4$. The base obtained from this salt was identified as muscarine by its physiological action on the heart. W. C. W.

Putrefaction Alkaloids. By L. BRIEGER (*Ber.*, **17**, 1137—1139).—In the putrefaction of flesh, choline is converted into the more poisonous neurine. A subcutaneous injection of 0·04 gram of neurine hydrochloride is fatal to a rabbit weighing 1 kilo., but at least 0·5 gram of choline hydrochloride is required to produce a similar effect. W. C. W.

Putrefaction Alkaloids. By Z. MARINO-ZUCCO (*Ber.*, **17**, 1043—1044).—The author has shown (Abstr., 1884, 343) that Selmi's ptomaïne is neurine, and states that he is continuing his investigation of the physiological action of neurine. A. B.

Changes which Proteid Matters undergo by the Action of Pancreatic Ferment. By J. G. OTTO (*Zeit. Physiol. Chem.*, **8**, 129—148).—Well washed and finely mixed fibrin was digested with a watery solution of ox pancreas at the temperature of the room, any putrefactive changes being prevented by the addition of ether. The first decomposition-product, globulin, was separated by saturating the filtered fluid with magnesium sulphate. The coagulating point of the purified globulin dissolved in weak sodium chloride was 70—

75. Dried at 110° C. the globulin gave the following percentage composition: 0·55—0·73 ash; 53·17 C; 7·29 H; 15·8 N; 1·17 S. These numbers agree so closely with those Hammarsten found for serum-globulin that the two bodies may be considered identical; the specific rotatory power also is —48·1, which is very similar to the —47·8 Fredericq found for serum-globulin.

After removal of the globulin, the propeptone (hemialbumose) can be obtained by saturating with common salt, and adding hydrochloric acid: the purified propeptone also agrees in its chemical composition with the gastric propeptone. Both, in solution or when exposed to damp, are converted partly into a coagulable albumin.

In order to obtain the peptone, it is best to first remove the globulin and propeptone by boiling with sodium acetate and ferric chloride after slightly acidifying with acetic acid, filtering off the precipitate, and then separating the peptone with phosphotungstic acid, after the addition of $\frac{1}{8}$ the volume of strong sulphuric acid. This precipitate is decomposed with caustic baryta, and baryta-water added until the whole is distinctly alkaline, the excess afterwards removed from the filtrate by passing carbonic anhydride through the solution. The percentage composition of the pure peptone is as follows: 0·3—0·6 per cent. ash; 50·0 C; 6·81 H; 15·83 N; 1·06 S. Kossel's analysis of gastric peptone agrees very closely with this; the specific rotatory power is 65·2—66; that of gastric peptone, according to Hoffmeister, being 63·5.

The author finds, as Kühne did, that a large proportion of the peptone formed by tryptic digestion is converted into antipeptone when submitted to further digestion. J. P. L.

Physiological Chemistry.

Respiration of Air charged with Petroleum Vapour. By Poincaré (*J. Pharm.* [5], 7, 290—291).—The author has kept animals continuously in an atmosphere which was frequently charged with the vapour of petroleum. The effects observed were principally greater frequency and amplitude of the respiratory movements, a diminution of the cardiac movements, and a greater intensity of the beating of the heart. This was accompanied by cutaneous irritation, and a general tendency to sleep and languor. Guinea-pigs finally succumbed under the treatment. The autopsy showed general congestion. Workmen engaged in the distillation of petroleum complain of heaviness in the head and great irritation of the mucous membrane of the nose. W. R. D.

Source of Hippuric Acid in the Urine. By C. Schotten (*Zeit. Physiol. Chem.*, 8, 60—69).—E. and H. Salkowski, after they obtained phenylpropionic acid from sepsis of proteid matter, showed that in the living organism this was converted into benzoic acid, which, combining with glycocoll, formed hippuric acid.

The author supposes α-amidophenylpropionic acid to be a second source. To test the correctness of this view 0·7 gram of the acid was given to a dog fed for some time previously on a meat diet; from the urine only 0·01 gram hippuric acid was obtained. It cannot therefore be considered as a source.

Amidophenylacetic acid is converted into mandelic acid under similar conditions. Mandelic acid is not converted into hippuric acid as asserted in many text-books, but appears unchanged in the urine.

J. P. L.

Occurrence of Glycerolphosphoric Acid in Urine. By L. EYMONNET (*J. Pharm.* [5], 7, 134—138).—The glycerolphosphoric acid in the urine was estimated by taking advantage of the fact that it is not precipitated by the ordinary reagents for phosphates; the latter were removed from 200 c.c. of urine by magnesia mixture, and the filtered liquid evaporated to dryness, and ignited with potassium nitrate. The residue was extracted with dilute nitric acid, and the solution, after concentration, was precipitated by ammonium molybdate in the ordinary way. It is seen from the results that in the case of dogs during starvation less glycerolphosphoric acid is excreted by the urine than during the normal condition. When injected into the peritoneum as calcium glycerolphosphate, it is nearly all oxidised before being excreted by the urine, but when injected into the veins an appreciable increase in the quantity of glycerolphosphoric acid excreted by the urine is observed. A notable increase in the quantity of glycerolphosphoric acid is found in the urine of phthisical patients having abnormally fatty livers, while the liver contains much lecithin; in the case of one patient, as much as 3·38 per cent. was isolated from the fresh liver.

W. R. D.

Elimination of Hypophosphites by the Urine. By L. EYMONNET (*J. Pharm.* [5], 7, 138—140).—By injecting sodium hypophosphite into the veins of dogs, and estimating the total phosphates and unaltered hypophosphite in the urine, the author shows that the elimination of the dose is complete in about 24 hours; part of the hypophosphite is found in the urine as phosphate, and the remainder as unaltered hypophosphite, yet the quantity oxidised appears to increase in proportion to the quantity of hypophosphite administered.

W. R. D.

Knowledge of Indigo-forming Substances in the Urine. By J. HOPPE-SEYLER (*Zeit. Physiol. Chem.*, 8, 79—84).—From 25 litres of normal dogs' urine, the author obtained 1 gram of crystallised indican, and about 0·5 gram of pure phenylsulphate of potassium = 0·002 gram per cent. Indican exists in dogs' urine in sufficient quantity to be detected by Jaffe's reaction.

In order to determine whether indican underwent any change in the organism, 2·7 grams were injected into an animal; in the urine indican only was found.

Neither orthonitrocinnamic acid, orthoamidocinnamic, or orthonitrobenzaldehyde alone or with acetone produced any increase in the quantity of indican. J. P. L.

Extraction of Indigotin and Indirubin from Urine.—By A. C. Méhu (*J. Pharm.* [5], 7, 122—126).—The author has previously shown that certain colouring matters of both normal and pathological urine may be extracted by rendering the urine acid with sulphuric acid, and then adding ammonium sulphate to saturation: this method can be applied to the isolation of the indigotin and indirubin from violet or blue urine. The urine is rendered strongly acid with sulphuric acid, about 1 gram of sulphuric acid being added to 1 kilo. of urine, and then saturated with anhydrous ammonium sulphate. In this way, a mixture of indigotin and indirubin, the blue and red colouring matters of violet urine, is precipitated. These substances may be separated, as the author has previously shown, by 50 per cent. alcohol, which, in the cold, dissolves the indirubin almost exclusively. The insoluble indigotin is purified by washing with water and spontaneously drying. Indigotin is very readily soluble in hot phenol, and as the liquid cools the greater part of the indigotin is deposited in well-defined crystals. An approximate estimation of indigotin may be made by a colorimetric process, using a standard solution of indigotin in phenol to which absolute alcohol or glycerol has been added to prevent solidification. The author has determined the solubility of indigotin from indigo in various liquids. Boiling creosote (from beechwood) is a good solvent of indigotin; the solution deposits the substance in crystals as it cools. Oils of bitter almonds, turpentine, gaultheria, rosemary and amyl alcohol are also solvents of indigotin. The indigotin from violet urine is likewise soluble in oils of anise, bitter almonds, and gaultheria, forming violet solutions, but the indigotin from the two sources appears to differ when boiled with anise or oil of winter green; the indigotin from indigo is unaffected to any appreciable extent, but the indigotin from urine is decolorised. W. R. D.

A Urinary Pigment. By P. Plósz (*Zeit. Physiol. Chem.*, 8, 85—94).—When urine is boiled for some time with hydrochloric acid, a complete change occurs in the colour, indigo frequently separating out after 20 minutes. On shaking the coloured urine with ether, a red colouring matter is obtained (mixed with small quantities of benzoic acid and urobilin), to which the author has given the name of urorubin. To purify this colouring matter, the residue, after distilling off the ether, is washed several times with hot water to remove benzoic acid and some yellow colouring substances (urobilin, &c.). The residue is again dissolved in ether, and shaken with weak soda-ley to remove the last traces of urobilin. By very careful evaporation of the ethereal or alcoholic solution, urorubin can be obtained in crystalline plates; it is insoluble in water, soluble in alcohol, chloroform, and especially in ether, imparting to the solutions a garnet colour.

Strong hydrochloric and sulphuric acids slowly dissolve and decolorise it, nitric acid and alkalis more rapidly. Urorubin probably owes its origin, like indican, to sepsis in the intestine. It is formed both in acid and alkaline urine.

The urine thoroughly exhausted with ether is still of a dark colour; this can be completely removed by exhausting with amylic alcohol. The colouring matter obtained by evaporating this alcoholic solution is identical with Heller's urrhodine and Thudichum's uromelanin. From a day's urine, the author obtained 5—6 grams uromelanin.

J. P. L.

Chemical Constituents of the Thyroid Gland of Men and Oxen. By N. A. BUBNOW (*Zeit. Physiol. Chem.*, 8, 1—47).—The first 30 pages contain a complete *résumé* of the previous literature on the subject.

The author makes extracts of the fresh gland (freed from fat, &c.), with water, 10 per cent. NaCl solution, and 0·1 per cent. KHO solution, and gives in full their general reactions. From a watery extract, he obtained xanthine, hypoxanthine, and lactic acid, but no guanine. He has also analysed the soluble proteïds which he obtained by precipitating with acetic acid and purified by washing with distilled water, alcohol, and ether; the general result is that whether human or ox gland be taken the composition of the proteïd is identical: the proteïd obtained from the 10 per cent. NaCl extract and 0·1 per cent. KHO extract was higher in carbon but lower in nitrogen than that obtained from an extract of 0·1 per cent. KHO after long digestion.

J. P. L.

Composition of a Pathological Liquid. By J. REGNAULD and VILLEJEAN (*J. Pharm.* [5], 7, 201—209).—This paper contains a physiological and chemical description of a liquid obtained from an inguino-abdominal tumour. The following is an abstract of the more important chemical features of the liquid. The total quantity obtained was about 260 grams; it had an oily consistence, an amber colour, and contained suspended particles. By filtration, a perfectly clear alkaline liquid was obtained which had a sp. gr. of 1·038 at 13°. When this liquid was merely mixed with water coagulation occurred, and the mixture became nearly solid. By agitating with water the mixture again became clear, with the exception of a few flocks that still remained insoluble. When microscopically examined, the coagulum appeared to be identical with the fibrin of blood and of lymph. The flocks which remained after agitation with water, when similarly examined, appeared to be identical with the fibrin of plasma. The following table represents the results of a chemical analysis of the liquid. 100 grams contained:

Water	87·612
Fibrin	1·860
Metalbumin	6·240
Serin	2·460
Mucin	none
Peptones, &c.	0·993
Chlorides (K and Na)	0·542

Carbonates, sulphates, and phosphates of alkalis and alkaline earths	0·293

W. R. D.

Physiological Action of Borax. By F. VIGIER (*J. Pharm.* [5], 7, 301—310).—From experiments on dogs and men, the author concludes that borax has no injurious physiological action even when given in large doses. Thus 3·5 grams of borax were taken on an empty stomach; salivation became rather more copious, and the saliva was found to be more than normally alkaline, the appetite was increased. With dogs, a solution of borax was injected in the veins. doses of 1·25 gram in 5 c.c. of water being given at intervals of half an hour until 5 grams had been given. Borax was subsequently found in the saliva as well as in the urine, in fact it appears to be slowly eliminated from the system by the latter excretion. In order to detect the borax in these cases, large quantities of the urine and saliva were evaporated, and after acidifying with hydrochloric acid the flame spectrum of the liquid was examined. The ordinary tests for borates are not sufficiently delicate, and the usual flame reaction for boric acid is masked by the presence of organic matter and sodium salts.
W. R. D.

Transformation of Nitriles in the Organism. By P. GIACOSA (*Zeit. Physiol. Chem.*, 8, 95—113).—Benzonitrile enclosed in gelatine capsules and given with food to a dog, is eliminated partly by the lungs, fæces, and urine. The odour of benzonitrile in the respired air was very persistent, lasting six days after a dose of 2·4 grams. It acts as a poison, producing convulsions, has a local action on the mucous membrane of the stomach, sometimes producing large ulcers. In large doses, it paralyses respiration and death ensues. Neither benzoic, hippuric, nor any hydroxy-acids were found in the urine. The ratio between the mineral and combined acids is considerably altered; before the experiment, the ratio was nine of mineral to one of combined, $\frac{A}{B} = \frac{9}{1}$; after, $\frac{A}{B} = \frac{0·120}{1}$: the total quantity of sulphates too was diminished; before the experiment, it was about 0·390 gram per day, after, 0·117 gram.

Phenylacetonitrile acts as a very violent poison, does not give rise to any odour either in the expired air or urine, the urine is strongly acid, sometimes contains albumin, and so rich in urates and uric acid as to have a creamy consistency. Phenaceturic acid was obtained from the urine, which differs from E. and H. Salkowski's acid obtained from phenylacetic acid in having a higher melting point (Salkowski's 143°, Giacosa's 185—186°). Acetonitrile is the least poisonous; when given to a dog, part is excreted as acetic acid; after a dose of 4 grams, 0·25 gram of acetic acid was found in the urine.

Propionitrile produces violent vomiting and is very poisonous; part is eliminated unchanged by the lungs, and about one-tenth as propionic acid in the urine.

During the whole period the animals were under the influence of the nitriles, the author observed in every case (even when the urine was very acid) crystals of ammonium magnesium phosphate in large quantities; as they appear normally only in alkaline urine, it is probable the acid in the urine after feeding with acetonitrile is not acetic. The author intends to further investigate this.

J. P. L.

Fate of Iodoform and Chloroform in the Organism. By A. Zeller (*Zeit. Physiol. Chem.*, 8, 70—78).—The author has previously shown that iodoform, when applied to the abdominal cavity, may produce fatal results; as excretion is much slower than absorption, a consequent retention of iodine occurs in the blood and tissues. According to Högyes, the absorption is due to the decomposition of the iodoform and formation of a compound of iodine and albumin. The author's experiments support this view. 300 grams of an albumin solution containing 2·51 grams of iodine were given to a dog; the excretion of iodine lasted nine days, 1·626 gram being accounted for; only a very small part passes through unchanged in the fæces.

When chloroform is used as an anæsthetic, part is found after a few hours in the urine. Nothnagel found, after subcutaneous injection, bile pigments present. Kappeler, on the other hand, could not find any in 25 different cases. The present paper chiefly relates to the amount of chloroform eliminated as chloride in the urine. A dog fed on 500 grams meat daily was given in the first experiment 7 grams, in a second 9 grams chloroform, enclosed in capsules. The increase of chlorides in the first case lasted four days; in the second eight days. In the second experiment the increase amounted to 5·71 grams Cl, corresponding with 6·41 grams chloroform; consequently about one-third is exhaled by the lungs. J. P. L.

Chemistry of Vegetable Physiology and Agriculture.

Schizomycetic Fermentation. Part IX. By A. Fitz (*Ber.*, 17, 1189—1196).—In addition to Pasteur's butyric acid ferment and the micrococcus previously described by the author, a third variety of schizomycetes exists, which ferments calcium lactate to butyric acid. It is cylindrical in form, its dimensions being 0·7—1 micromm. broad and 1·8—2·4 long; cultivation in a vacuum diminishes the length, whilst the presence of free acid increases the dimensions to 1·5 micromm. in breadth, and to 7—8 in length. Not only the developed ferment but also its germs are destroyed by exposure to a temperature of 58°. The following substances undergo fermentation when brought in contact with this variety of schizomycetes; grape-sugar, cane-sugar, milk-sugar, mannitol, calcium lactate, malate, tartrate, and citrate, and also glycerol and calcium glycerate with difficulty. Erythrol, dulcitol, and quercitol are not fermented by it. In the fermentation of calcium lactate, not only butyric but also propionic acid are produced; calcium tartrate on the other hand yields succinic and acetic acids.

The author denies the statement made by Hueppe, Koch, Gaffky and Löffler, that liquids heated in a steam chamber acquire the temperature of the surrounding vapour but very slowly. He also reiterates his statement which has been denied by Duclaux that *Mucor racemosus* inverts cane-sugar. W. C. W.

Butyric Fermentation excited by Garden-soil. By P. P. DEHÉRAIN and L. MAQUENNE (*Ann. Agronomiques*, **10**, 5—9).—The authors have continued their inquiry into the products formed during the fermentation of solutions of sugar by soil bacteria. By employing 30 litres of water, 1 kilo. each of sugar and chalk, and 1 kilo. of soil, and keeping the temperature at 35°, a very energetic fermentation was produced, a large quantity of gas evolved (consisting of hydrogen with a little carbonic anhydride), and in a month the sugar had entirely disappeared, and the liquid was acid. The organism producing these changes was a very active elongated bacillus, coloured blue by iodine, and resembling *Bacillus amylobacter*. The volatile products obtained by distilling 20 litres of the liquid consisted of about 10 c.c. ethyl alcohol, 4 or 5 c.c. amyl alcohol, and a small quantity of other alcohols boiling above 140°. The lime salts produced by the fermentation were converted into ethyl salts by distillation with sulphuric acid and alcohol, and furnished about 100 c.c. acetic ether (distilling 70—79°), 25 c.c. of an ether boiling 95—102°, and furnishing an acid which was probably propionic acid, and 100 c.c. of butyric ether distilling over between 115 and 122°. The total acids in the fermented liquid were estimated as equivalent to 247 grams sulphuric acid, corresponding with 450 grams of a mixture of equal parts of acetic and butyric acids. About half the sugar employed was thus converted into these acids. It is possible that the alcohols formed were due to the coexistence of the alcoholic fermentation with the butyric. The butyric bacillus of Fitz (*Bull. Soc. Chim.*, **38**, 584) furnishes no acetic acid, and the author considers the bacilli acting in the two cases to be different. J. M. H. M.

Development of Starch-transforming Ferments in the Cells of the Higher Plants. By W. DETMER (*Ann. Agronomiques*, **10**, 45—46; from *Botan. Zeitung*, 1883, 601).—Ungerminated grains of wheat contain a little diastatic ferment, the quantity of which rapidly increases when the grains germinate in presence of oxygen. When the grain, after being soaked in boiled water, is placed in an atmosphere of hydrogen, germination still takes place to a small extent by means of intramolecular respiration; but in this case diastase is not developed, even if a little free acid (citric), which favours the production of diastase, is added. Oxygen, therefore, is necessary to the formation of diastase in the cells of the higher plants.

J. M. H. M.

Part played by Vegetable Acids in causing the Turgescence of Cells. By H. DE VRIES (*Ann. Agronomiques*, **10**, 139—141; from *Botan. Zeitung*, 1883, 849).—The turgescence of cells is to a large extent caused by the osmotic action between the crystallisable substances contained in the cell sap and the watery liquid by which the cells are surrounded. The outward pressure thus produced is very considerable, and has been estimated by Pfeffer to amount to as much as 7 atmospheres in the articulation of a bean leaf and 13 atmospheres in the pith of a sunflower stem. If increasing quantities of crystalloïds be added to the water surrounding a living cell, the turgescence of the cell is progressively diminished, until finally the tension of the enclosed protoplasmic sac becomes nil, and the sac contracts, loses water, and detaches itself from the cell-wall. The author applies the term "plasmolysis" to this phenomenon, and has determined the strength of various solutions of crystalloïds required to bring it about in the cells of different plants. With the red beet, for example, solutions of the following strengths are necessary:—Cane-sugar, 27—28 per cent.; magnesium sulphate, 26—28 per cent.; sodium sulphate, 17—18 per cent.; sodium or potassium nitrate, 6—7 per cent.; potassium chloride, 4—5 per cent.; sodium chloride, 3—4 per cent. The author believes a considerable portion of the turgescence to be produced by the vegetable acids and their compounds with mineral and organic bases, especially in the cells of young tissue. He finds that the salts of vegetable acids with inorganic bases produce 21—27 per cent. of the turgescence in the cells of the petioles of *Heracleum pubescens*, 30 per cent. in the summits of *Carum carui*, 35 per cent. in the cells of *Delphinium azureum*. Salts of vegetable acids with organic bases furnish 11 per cent. of the turgescence in monkshood, 16 per cent. in young petioles of *Rheum hybridum*, 19 per cent. in the epicotyledonous internode of a young haricot. The effect of free oxalic acid is shown in the following table:—

	Per cent. of total turgescence.		
	Rheum officinale.	Rheum hybridum.	Begonia rex.
Free oxalic acid	16	42	29·2
Potassium hydrogen oxalate	18	17·7	14·2
Calcium and magnesium oxalates	3·5	2·6	4·2
	37·5	62·3	47·6

A molecule of glucose, by furnishing 3 mols. of oxalic acid, triples its power of causing turgescence; when converted into malic acid, the augmentation is a half less. Glucose is the commonest and most important of the soluble matters causing turgescence, contributing for example 50—60 per cent. of the total effect in young petioles of *Heracleum spondylium*, and 80 per cent. in petioles of the rose. Inorganic salts do not occur in large quantities in young tissues, but certain plants accumulate them, *e.g.*, in the summits of the artichoke, potassium nitrate produces 40 per cent. of the turgescence, and in the young petioles of *Gunnera scabra* potassium chloride produces 52—

56 per cent. Potassium, on combining with an acid, increases the force of turgescence, whilst lime does not. A molecule of potassium malate, for example, has twice the osmotic force of malic acid or of calcium malate. Hence the accumulation of potassium salts in young tissues which have most need of turgescence, and their gradual replacement by calcium salts as the tissues grow older.

J. M. H. M.

Attraction between Soluble Substances in Dilute Solutions and Water. By H. DE VRIES (*Ann. Agronomiques*, **10**, 141—143).—The author measures the attraction of a dissolved substance for water by the power which its solution possesses of removing water from the protoplasmic contents of vegetable cells. The degree of concentration necessary to produce "plasmolysis" or the contraction and separation of the cell-contents from the cell-wall may be observed, or the following method may be adopted:—When the apex of a growing shoot is divided by longitudinal cuts into four filaments, these filaments become curved outwards by the tension of their component cells. If the curved ends be immersed in pure water, the curvature increases; in strong solutions of soluble substances it is lessened; and in solutions of a certain strength no alteration of the curve is produced. Solutions of various substances of such strength as to behave in the manner last mentioned are called *isotonic*, and the strength of the solution is inversely proportional to the attraction of the dissolved substances for water. *Isotonic coefficients* express the affinity for water of 1 mol. of various substances, that of a ½ mol. of oxalic acid being taken as unity:—

Cane-sugar	1·9
Inverted sugar	1·9
Malic acid	2·0
Tartaric acid	2·0
Citric acid	2·0
Tripotassium citrate	5·0
Potassium or sodium nitrate, potassium, sodium, or ammonium chloride, potassium acetate, monopotassium citrate	3·9
Magnesium malate	1·9
„ sulphate	2·0
Potassium oxalate or sulphate	3·0
„ phosphate or tartrate	4·0
„ malate or dipotassium nitrate	4·1
Magnesium citrate	3·9
„ chloride	4·3
Calcium chloride	4·3

Organic substances have thus a coefficient of 2; alkaline salts with 1 atom of metal, 3; with 2 atoms of metal, 4; with 3 atoms of metal, 5; salts of the alkaline earths derived from 1 mol. of acid, 2; from 2 mols. of acid, 4. The isotonic coefficient of a salt is the sum of the coefficients of its acid and base, these being—acids, 2; alkali metals, 1; metals of the alkaline earths, 0.

J. M. H. M.

Methods of Studying the Influence of Light on the Respiration of Plants. By G. BORNIER and L. MANGIN (*Ann. Agronomiques*, **10**, 40—41; from *Bull. Soc. Bot. de France*, **30**, 235).—The authors have verified the conclusion arrived at by a different method, that light retards respiration, by actually measuring by means of standard baryta-water the carbonic anhydride produced in a given time by plants destitute of chlorophyll. J. M. H. M.

Influence of Light on the Disengagement of Oxygen by Plants. By J. REINKE (*Ann. Agronomiques*, **10**, 38—40, and 136—137; from *Botan. Zeitung*, 1883, Nos. 42, 43, 44).—The author describes the means adopted by him to measure the oxygen disengaged by leaves in presence of light of varying intensity, by counting the bubbles of gas which escape from a given leaf surface of an aquatic plant in measured intervals of time. *Elodea*, having very thin leaves, is especially suitable. The light of the sun is reflected from a heliostat through a convex lens into a darkened chamber. The intensity of light to which the leaf is subjected then varies according to its position in the double cone of rays formed by the lens. Working in this way the author finds that the disengagement of oxygen attains its maximum with light of normal intensity (*i.e.*, at twice the focal distance of the lens, where the diameter of the cone of rays is the same as that of the lens), that it diminishes rapidly, with intensities of $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{16}$; but on the other hand remains almost constant when the intensity is 2, 4, and 8 times the normal.

The author has adopted his method of counting the number of bubbles of gas escaping from a given leaf surface of an aquatic plant (*Elodea*) in a given time to the study of the influence of light of different colours on the disengagement of oxygen by plants. The same apparatus was employed as that previously described with the interposition of a prism of known dispersive power adjusted for the minimum angle of deviation, in the path of the conical beam. The spectrum was received on a screen, composed of two vertical plates of wood, adjustable at any distance from each other. The band of coloured light passing between the wooden uprights was concentrated on the leaf by a lens, the distance between the uprights being so adjusted for each colour as to obtain an equal luminous concentration (*i.e.*, an equal number of wavelengths) in all cases. The maximum disengagement of oxygen corresponds with the maximum absorption of chlorophyll, and is situated in the red, not far from the line B; the curve descends rapidly towards the ultra-red, more slowly towards the ultra-violet, but, contrary to the experiments of Engelmann, there is no augmentation in the disengagement of oxygen, corresponding with the absorption-band commencing between the lines *b* and F, and extending over the whole of the right side of the spectrum. J. M. H. M.

Structure and Functions of the Epidermic System of Plants. By WESTERMAYER (*Ann. Agronomiques*, **10**, 37—38).—In this paper, the author insists on the importance of the epidermic layers of cells as reservoirs of water. Sometimes these cells contain more water than all the other tissues of the plant together, and in some cases the cell-walls are arranged in folds like a venetian blind, so that the volume is subject to much variation. The same *rôle* is played by the cells of the hypodermis, also destitute of chlorophyll, but, unlike the epidermic cells, originating from the periblem. When a leaf fades, these expansible cells of the epidermis and hypodermis are the first to give up their water, at the same time contracting in volume. The water of the epidermic cells absorbs the obscure heat of the sun's rays, and in Dehérain's experiments on the action of the electric light on vegetation these cells were the only ones injuriously affected (blackened).

J. M. H. M.

Contributions to the Doctrine of Thermic Constants in Plants. By Staub (*Ann. Agronomiques*, **10**, 42—43; from *Botan. Jahrb.*, **3**, 131).—The thermal constant of a plant, according to Oettinger, is the sum of the mean temperatures of the days of active vegetation from the commencement of growth to some definite phase in the plant's life, minus a certain initial temperature (*seuil*), different for different species, and determined by comparing the observations of successive years. The author objects to this, that the development of a plant depends not only on the aggregate quantity of heat which it receives, but above all on the temperature during growth, which cannot be expressed by adding together thermometric measurements.

J. M. H. M.

Means of Protecting Plants against Frost. By H. R. Goppert (*Ann. Agronomiqves*, **10**, 41—42).—Sachs maintains that plants, bulbs, and roots are killed, not by being frozen, but by too sudden and rapid thawing. The author, on the other hand, by submitting narcissus, tulip, and hyacinth bulbs and potatoes to a temperature of 1·4° below zero, and then dividing them into two lots, one being suddenly cooled to −8°, and the other plunged in water of 1°, found that the temperature of −8° killed all the bulbs, whether the subsequent thawing was slow or rapid, but that none of the bulbs cooled to −1·4° suffered any damage, the potatoes only being frozen. By experimenting with the flowers of the exotic orchids *Pajus* and *Calanthe*, which become blue by development of indigo as soon as they die, he also shows that death occurs when the flowers are frozen, and consequently that no amount of care bestowed on the thawing of frozen plants is of any avail if the frost has been sufficiently severe. The buds of some ligneous plants were found to stand freezing at −16° to −20°, and subsequent thawing at 25° without damage.

J. M. H. M.

Contents of the Cribriform Vessels of "Cucurbita Pepo." By E. Zacharias (*Ann. Agronomiques*, **10**, 138—139; from *Botan. Zeitung*, 1884, 65—73).—When a pumpkin is cut across, there exudes from each bundle of vessels a drop of liquid having an alkaline reaction; after a few hours the drop solidifies into an elastic mass. The author has collected a sufficient number of drops in a watch-glass to recognise the presence of an albuminoïd similar to fibrin, dextrin, potassium phosphate, magnesium salts, nitrites, and nitrates. The alkaline reaction is ascribed to potassium phosphate. The albuminoïd is deposited, on standing, in the form of mucilaginous threads, the separation of which is prevented by 0·2 per cent. hydrochloric acid, and by very dilute potash, but not by 10 per cent. sodium sulphate solution. Strong potash causes an immediate precipitate of white flocks, soluble in excess of water. Alcohol transforms the mucilage into a hard white opaque mass, coloured yellow by nitric acid. Copper sulphate and potash give a violet solution; ferrocyanide of potassium and ferric chloride both colour the mucilage deep blue. The mucilage is soluble in gastric juice and very dilute potash; strong potash hardens it and renders it opaque; 0·2 per cent. hydrochloric acid and 10 per cent. soda cause it to swell without dissolving; sodium chloride is without action. J. M. H. M.

Mascate Pea. By A. Riche and A. Rémont (*J. Pharm. Chim.* [5], 7, 29—32).—The seed commonly known as the mascate pea is yielded by a plant largely found in Brazil, belonging to the genus *Canavalia*, of the natural order *Papilionaceæ*. It was believed that the seeds, which are about the size of small kidney beans, could be used as a substitute for coffee. A chemical examination by the author negatived the supposition, for they were found to contain no caffeine. Experiments were then made with the roasted seeds to discover whether they could be used in the place of chicory or other roasted beans, for mixing with coffee. These experiments indicated that the canavalia seeds after roasting contain less matter soluble in water than chicory, roasted acorns, or barley, and that the aqueous solution has much less colouring power, but contains more nitrogenous matter, than the aqueous solutions of the other substances. The authors consider that as these seeds are comparatively rich in albuminoïds (5—6 per cent.), their use for mixing with coffee should be encouraged. W. R. D.

Results obtained from Experimental Plots at Grignon in 1883. By P. P. Dehérain, Boreau, and Marchal (*Ann. Agronomiques*, 10, 97—112).—The season of 1883 was characterised by great equality of temperature and a large and pretty equally distributed rainfall. The hot weather of June was favourable to the ripening of wheat, and the crop would have been generally good but for the extremely wet autumn of 1882, which hindered sowing. Oats everywhere yielded unusually large crops, and the grass and forage crops were extremely abundant, being favoured by a warm moist summer. The hot and dry August exercised a favourable influence on the quality of the sugar-beet crop and its richness in sugar, but the warm and mild September which followed produced some amount of deterioration. The disposition of the plots in the ninth year of experiment (1883) was altered, so as to include experiments on rotations, on applications of the manures which the eight preceding years have shown to be most suitable to the soil, and on laying down land with permanent pasture.

Wheat.—The same plots carried this crop for the fourth successive year (1883), and none of them had received any manure since 1881 at latest, the purpose being to ascertain the unexhausted effect of manures previously applied. In May, 1883, however, the plant appeared so poor over all the plots that it was considered advisable to top-dress half of them with nitrate of soda, but this application, made so late in the season, produced no beneficial result. The influence of the manures applied in previous years, although much lessened, is still sensible, the continuously unmanured plot producing only 14·6 hectolitres of grain per hectare, whilst the average yield of all the plots was 17·5 hectolitres. Farmyard manure ploughed in (1875—1879) continues to show much better results than when spread on the surface. Nitrate of soda, four years after application, still exerts an appreciable influence on the yield. Sulphate of ammonia still remains inferior to nitrate of soda, and Plot 32, which received a very heavy dressing (1200 kilos.) of sulphate of ammonia for three years (1875—1878) has not yet recovered the injury it received, and gives the worst yield of any plot save continuously unmanured ones. The decreasing effect of the residues of previous manuring is shown in the following table, which gives the yield of grain in quintals per hectare for each year since the application of manure was discontinued.

	1880.	1881.	1882.	1883.	Mean. 1880–83.
Unmanured	25·00	16·40	21·90	11·70	18·75
Farmyard manure ploughed in	34·06	23·92	23·44	17·42	24·71
" " spread	27·00	16·00	20·00	15·00	19·50
Nitrate of soda	27·75	21·00	21 50	14·00	21·06
Sulphate of ammonia	23·30	18·60	20·00	13·50	19·95
Blood manure (Souffrice's)	34·00	21·60	23·00	14·00	23·15
Leather manure (Coignet's)	26·00	23·20	20·00	13·00	20·5
Mean of all the plots	28·53	21·00	21·07	14·07	21·1

The percentage of nitrogen found in 1883 in three plots was 0·169, identical with the figure obtained in 1881; the authors attribute this conservation of nitrogen to the free growth of weeds, which are very difficult to keep down when so many corn crops are taken in succession.

Oats, after having been grown for eight successive years on the same plots, were in 1883 transferred to plots some of which had grown green maize for the seven preceding years, and the rest for six years with beet in 1882. On all these plots, very fine crops of oats were obtained, the continuously unmanured plot yielding 51·2 hectolitres of grain per hectare, the highest yield being 80 hectolitres from a plot which received heavy dressings of farmyard manure in 1875—1882, but nothing in 1883. On the soil of Grignon, no mixture of artificial manures gives such heavy crops as farmyard manure. Comparing the heavy crop of oats obtained in 1883 (even on the unmanured plot) with the poor yield of 1882, and with the wretched crops of wheat of 1883, the authors conclude that the chief reason for the striking improvement in the yield of oats is the fact that they have this time followed the maize crop instead of being grown again consecutively, thus allowing of a thorough cleaning of the land.

Beet in 1883 was grown upon the plots which carried oats since 1875. The best results were obtained by farmyard manure with the addition of nitrate of soda. Flesh manure (Souffrice's) gave a slightly heavier crop, but the increase was not equal to the increased cost of the manure. The greatest percentage of sugar in the roots was obtained on the continuously unmanured plot, but the greatest total weight of sugar per acre was on the plot dressed with farmyard manure and nitrate of soda.

Maize cut for fodder was also transferred to the plots which had been in oats since 1875. The unmanured plot yielded the very fair crop of 64,000 kilos. per hectare, whilst the plot which received the heaviest dressing of farmyard manure yielded 92,000 kilos. The effect of previous dressings of farmyard manure was very marked. Chloride of potassium produced a considerable increase, although potash salts do not usually benefit other crops grown on the soil of Grignon.

Sainfoin.—The sainfoin sown in 1882 on the plots which had already carried it for three years, yielded in 1882 a medium crop, in which sainfoin predominated; in 1883, however, the sainfoin was in great part replaced by adventitious grasses, so that the original intention of keeping the plots under this crop has been abandoned, and they will go into mixed seeds. The heaviest crops in 1883 were obtained on the plots which had received sulphate of ammonia or nitrate of soda in previous years. J. M. H. M.

Farmyard Manure. By A. B. Griffiths (*Chem. News*, **49**, 279—280).—The author has observed that the watery extract of farmyard manure is a very favourable medium for the production, multiplication, and sustenance of bacteria, bacilli, vibrios, &c. These organisms, along with their germs, may be completely destroyed by a solution either of ferrous sulphate, containing at least 0·0269 gram per 100 grams of water, or copper sulphate (0·0073 per 100), or of sodium chloride (5 per 100). Moreover, it is shown that the potato parasite, *Peronospora infestans*, can thrive in farmyard manure, at least as regards the unlimited production of hyphæ without any further development. This, as well as the presence of seeds of weeds in this manure, is urged as evidence against its use on arable land.

D. A. L.

Loss of Nitrogen during the Fermentation of Manures. By H. Joulie (*Compt. rend.*, **98**, 1444—1445).—During the prolonged fermentation of manure, there is a loss of nitrogen which may amount to more than 20 per cent., this loss being due entirely to the decomposition of the ammonia contained in the drainage from the manure. A certain proportion of the ammonia combines with the organic matter during fermentation, the amount thus fixed depending on the relative proportions of organic matter and ammoniacal nitrogen. The loss of ammonia is not affected by the addition of calcium phosphate, but is largely increased by the addition of calcium carbonate or sulphate. C. H. B.

Action of Superphosphates. By P. WAGNER (*Dingl. polyt. J.*, **252**, 303).—The author states that the degree of fineness of a manure is of great importance in regard to its action on the soil, but the assumption that the activity increases with the degree of fineness is erroneous. With an increase in the amount of lime contained in the soil, it is best to use finely-divided superphosphates, whilst in the case of soils poor in lime it is preferable to employ a coarser powder.

D. B.

Analytical Chemistry.

Nickel Alkali-proof Vessels. By W. DITTMAR (*Chem. News*, **50**, 3—6).—The production of nickel is referred to (comp. this vol., 129), and its use recommended for operations with caustic alkali-leys. In its resistance to the action of alkali-leys, it is equal to platinum, whilst for its cheapness, hardness, density, and lower conductivity of heat, it surpasses silver. The latter quality allows the operator to lay hold of a dish containing boiling caustic potash-ley with his bare fingers. Its density prevents the retention of potash, as is the case with silver, and its hardness gives it permanence of form. Solutions of caustic alkalis are, however, not absolutely without action on nickel, for the metal is attacked when the strength of the solutions reaches about 60 per cent. of potash (or soda). The porosity of silver may be diminished by alloying it, and a very durable and useful alloy for fusions with alkalis has the composition silver 91, gold 7, and nickel 2 per cent. The author then proceeds to show that the action of fused alkalis on metals is due to the formation of peroxides, which then constitute the destructive reagent; since experiments prove that silver, the above alloy, platinum, and nickel are not acted on in the absence of air, and fusions with alkalis may be conveniently and safely conducted in platinum vessels in an atmosphere of hydrogen or nitrogen, for which purpose an arrangement is described in the paper: the alkalis then fuse quite steadily, and do not boil up as they do when fused in air. All those metals are attacked by fused alkalis in the presence of air, silver least. Potash and baryta are more energetic than soda. Some experiments with carefully prepared lithium compounds show that the carbonate when ignited in a platinum vessel in the air attacks the metal, and is itself in greater part converted into peroxide. When heated in hydrogen or nitrogen, it does not attack the metal, but gradually loses carbonic anhydride, and with the former gas nearly pure lithium oxide (Li_2O) remains as an almost infusible solid, which does not readily combine with water; with nitrogen, part only of the carbonic anhydride is driven off. A blowpipe flame was employed to finish the lithium experiments.

D. A. L.

Dumas' Nitrogen Apparatus. By M. ILINSKI (*Ber*, **17**, 1347—1349).—The author describes a modification of Dumas' apparatus, for which he claims the following advantages:—1. Ease of construction with ordinary apparatus of a laboratory, and easy replacement of damaged parts. 2. Absence of all fragile glass parts, and of india-rubber tubing in contact with the caustic soda solution. 3. Working under a constant and very small pressure.

The apparatus needed consists of an ordinary burette, a large stoppered bottle, some glass tubing and a few corks; but the arrangement of the apparatus cannot be clearly explained without the drawing. L. T. T.

Detection of Nitrogen in Organic Compounds. By C. GRAEBE (*Ber.*, **17**, 1178).—The nitrogen in diazo-compounds cannot be detected by heating them with metallic potassium, as the nitrogen escapes before any cyanide is formed. W. C. W.

Coloured Tubes for Nesslerising. By A. A. BRENEMAN (*Chem. News*, **49**, 281—282).—From numerous observations, the author concludes that to obtain a satisfactory standard of comparison for Nesslerising, the coloured medium, best of glass, must be placed at or near the bottom of the testing tube, which is otherwise made of colourless glass. When used, it must be filled up to the mark with clear water. Such tubes are made by fusing a short piece of amber-glass tubing to a longer piece of the ordinary colourless tubing used for Nessler tubes; and when the required tint has been secured by blowing the amber glass, the tube is closed and flattened at the bottom. D. A. L.

Standard Soap Solution. By L. GARNIER (*J. Pharm.* [5], **7**, 482—483).—As standard soap solution is liable to deposit a precipitate which is not redissolved by heat, it is necessary to restandardise the solution after filtering. For this purpose, the author uses a standard solution of calcium chloride containing 0·25 gram of $CaCl_2$ in one litre of water or a solution of barium nitrate containing 0·5878 gram in one litre. The strength of the solution having been ascertained, the degrees of hardness of a water can be found by calculation in the ordinary way. W. R. D.

Phenolphthaleïn as Indicator in the Estimation of Carbonic Anhydride in Mixtures of Gases. By R. BLOCKMANN (*Ber.*, **17**, 1017—1019).—This method of estimating the carbonic anhydride in air or in mixtures of gases containing no other acids, depends on the property of free carbonic anhydride to decolorise a solution of phenolphthaleïn. The estimation of carbonic anhydride in air may be made in a 500 c.c flask by means of a dilute lime-water containing two or three drops of a solution of 1 part of phenolphthaleïn in 1000 parts alcohol (60 per cent.) The test can be made either by adding this solution slowly and agitating until decolorisation takes place, or by using a fixed quantity of the alkaline solution, and refilling the flask with air and agitating as often as is necessary to decolorise the indicator. The second method has been found the better.

A. B.

Separation of Iodine and Chlorine in the Dry Way. By J. Krutwig (*Ber.*, **17**, 341—343).—If an intimate mixture of potassium iodide with excess of potassium dichromate be rather strongly heated in a crucible, the whole of the iodine is given off, a corresponding amount of potassium chromate and chromic oxide being left in the crucible. The estimation may be made by weighing the crucible before and after heating, when the loss is iodine, or by treating the residue with water. In the latter case chromic oxide remains undissolved and may be filtered off and weighed. Sodium chloride is not attacked by potassium dichromate, so that this method may be used as a means of separating chlorine and iodine in a mixture.

L. T. T.

Liquid Paraffin as a Reagent for the Presence of Water in Alcohol, Ether, and Chloroform; and its Employment in the Preparation of Hydrobromic and Hydriodic Acids and of the Alkyl Iodides. By L. Crismer (*Ber.*, **17**, 649—652).—The "liquid paraffin" of the German Pharmacopœia, is an oily liquid consisting of a mixture of hydrocarbons of the methane series; it distils between 215° and 240° under 6 mm. pressure. It mixes in all proportions with *anhydrous* ether or chloroform, and is slightly soluble in *absolute* alcohol. The liquids so obtained are perfectly clear, provided the solvents are really anhydrous, but if water is present even in very minute quantity the liquids are turbid. Liquid paraffin dissolves phosphorus in small quantity; it is a good solvent for chlorine, bromine, iodine, the chlorides and bromides of phosphorus and the alkyl iodides, chlorides, and bromides.

As the halogens unite with ordinary phosphorus placed under liquid paraffin without danger of explosion, if the liquid is well cooled, the trihaloid-compounds of phosphorus can be conveniently prepared by aid of this substance, and further by slowly dropping the calculated amount of water into the solution of phosphorous tribromide or iodide so obtained, pure and anhydrous hydrobromic or hydriodic acid are readily formed. Finally, ethyl iodide can be readily prepared by the action of anhydrous alcohol on a solution of phosphorous triodide in liquid paraffin.

A. J. G.

Test for Hydrogen Peroxide. By M. Traube (*Ber.*, **17**, 1062—1064).—The characteristic reaction for hydrogen peroxide as given by Schoenbein, with potassium iodide, starch solution, and ferrous sulphate, requires that the liquid to be tested should be neutral. The author finds that the presence of very minute quantities of hydrogen peroxide may be detected in acid solution if a very minute quantity of cupric sulphate be added to the iodised starch solution, and then ferrous sulphate. This reaction depends on the fact that cupric iodide may exist in very dilute solution without any separation of iodine or formation of cuprous iodide (this vol., p. 962). Iodine is only separated on addition of ferrous sulphate in presence of hydrogen peroxide. A. B.

Rapid Estimation of Nitrates. By E. FALIÈRES (*Ann. Agronomiques*, 10, 125—131).—The method proposed by the author is a combination of a modification of Pelouze's process with Bruel's recently described volumetric method of estimating ferric chloride.

0·500 gram of iron in impalpable powder (iron reduced by hydrogen or very finely powdered) is placed in a flask holding about 50 c.c. and treated with 10—12 grams pure fuming hydrochloric acid. The iron dissolves almost instantaneously, especially if the flask be *very slightly* warmed, and the solution is free from traces of ferric salt. 0·200 gram *pure* sodium nitrate dissolved in 10—12 c.c. water is added to the solution of ferrous chloride, and the mixture boiled until all nitrous vapours are expelled and the liquid has cleared. It is then immediately diluted to 200 c.c. with recently boiled distilled water. For the titration 10 c.c. of this liquid are taken (= 0·010 gram $NaNO_3$), transferred to a flask of 150 c.c. capacity, diluted to 50 or 60 c.c. with boiled distilled water, and coloured deep violet by the addition of about 0·100 gram sodium salicylate. The liquid is now boiled, and sodium hyposulphite solution (4 grams per litre) is added gradually from a burette graduated to 0·1 c.c., the liquid being boiled between each addition of hyposulphite. The following reaction takes place:—

$$Fe_2Cl_6 + 2Na_2S_2O_3 = 2FeCl_2 + 2NaCl + Na_2S_4O_6,$$

and the liquid is gradually decolorised. The end point is marked by the faintest rose-tint perceptible to the eye; and the process is sensitive to 1 drop of hyposulphite. When this point is reached, a second 10 c.c. of the $NaNO_3$ is added to the decolorised liquid, and the titration repeated, the mean of the two results being taken. The value of the standard hyposulphite having thus been ascertained in terms of pure sodium nitrate, the determination of nitric nitrogen in crude nitrate of soda and potash, or mixed manures, is made in precisely the same manner as above described. Organic matter is without influence on the result. A mixture containing 10 per cent. nitrate of soda with arachida cake, sulphate of ammonia, potassium chloride, superphosphate, gypsum, and sand, gave perfectly correct results. Dried blood and guano substituted for arachida cake did not affect the correctness. J. M. H. M.

Testing for Nitric Acid and Nitrates in Vegetable Tissues. By A. ARNAUD and L. PADÉ (*Compt. rend.*, 98, 1488—1490).—Cinchonamine nitrate (this vol., 87) is almost absolutely insoluble in dilute acids, and when an acid solution of a salt of cinchonamine, preferably the hydrochloride, is mixed with a solution containing even a very small quantity of nitric acid or a nitrate, cinchonamine nitrate forms in small distinct crystals, easily recognisable under a microscope. This reaction may therefore be used for the detection and possibly estimation of minute quantities of nitrates.

This method may be successfully applied to detect nitrates in the juices of plants and also in the tissues. A section of the stalk or other organ is immersed in a dilute acid solution of cinchonamine hydrochloride (0·4 per cent.) for some time and then examined under the microscope, when crystals of cinchonamine nitrate are seen encrusting the tissues and enclosed in the cells, and their relative abundance shows the relative distribution of nitrates in the organ examined.

Cinchonamine is at present a rare product, but *Remigia purdiana*, from which it is prepared, grows abundantly in America.

C. H. B.

Commercial Assay of Native Phosphates. By Dugast (*Ann. Agronomiques*, **10**, 10—14).—The author points out that the results obtained by the "commercial" method, viz., treating the mineral with nitric or hydrochloric acid, adding ammonia, and weighing the ammonia precipitate, are liable to great variation not only with the different phosphates employed, but also with the same phosphate under different conditions of treatment. The ammonia precipitate filtered off immediately after precipitation gives results more than 1 per cent. lower than when allowed to stand three hours before filtration. Precipitation in a hot solution and the use of boiling water for washing give over 1 per cent. less than when these operations are conducted in the cold. The use of nitric acid in dissolving the mineral may be made to give higher or lower results than hydrochloric acid, according to the subsequent treatment.

Preliminary calcination of the mineral generally lowers the result. A determination made on 1 gram may be lower than one made on 5 grams by as much as 2 per cent. Besides the two oxides of iron, alumina, and lime, in combination with phosphoric acid, the precipitate carries down an excess of lime and some magnesia. The oxides of iron and alumina are not always wholly combined with phosphoric acid, hence the quantity of lime in the precipitate varies, and with it the total weight of the precipitate. J. M. H. M.

Reverted Phosphoric Acid. By T. S. Gladding (*Chem. News*, **50**, 1—3).—The present communication contains an account of experiments on the application of ammonium citrate for the determination of reverted phosphoric acid in natural phosphates, artificial soils, and natural soils. Similar experiments with artificial mixtures have already been described (Abstr., 1882, 1319—1320).

Of natural phosphates, 25 varieties were examined, and five experiments were tried with each; in each case a gram of finely-powdered phosphate and 50 c.c. of a neutral solution of ammonium citrate, sp. gr. 1·09, were corked up in a flask and digested for 30 minutes. Experiment (1), at 40°; (2), at 65°; (3), at 65° ½ c.c. 20 per cent. ammonia being added for each 50 c.c. of citrate; (4), at 65°, with 1 c.c. 20 per cent. ammonia; (5), at 65°, with 0·753 gram citric acid to every 50 c.c. of citrate solution. The results are tabulated, showing the percentage of phosphoric acid dissolved in each experiment, and the following conclusions are deduced with regard to the condition of the ammonium citrate solution. Slight acidity largely increases the solvent action on the crude phosphates; slight alkalinity, on the other hand, decreases the solvent action on all calcium phosphates, and this decrease is intensified with stronger alkalinity; the converse, however, is the case with iron and aluminium phosphates, for alkalinity increases the quantity dissolved by the ammonium citrate solution. From these conclusions, it is evident that neutral citrate solution is preferable to either acid or ammoniacal (comp. this vol., 639). The change of temperature from 40° to 65° is unimportant with natural phosphates. Artificial soils were prepared for the experiments, 5 grams of sand were mixed with 0·25 or 5 grams calcium carbonate, or 1 gram iron oxide, or 1 gram aluminium hydroxide, all freshly precipitated, or 30 grams of sand were mixed with 3 grams of brown hematite or bauxite; with the last two, a solution of 0·75 gram sodium ammonium phosphate was employed; in the other cases the quantity used was 0·5 gram, with the exception of the first, with which only 0·2 gram was taken. These mixtures were exposed in open vessels either in shade or in the sun for 72 hours; they were then divided into two equal parts and digested with ammonium citrate solution for 30 minutes, one portion at 40°, the other at 65°; with the hematite and bauxite, however, three equal parts were taken, one being treated with cold water, in addition to the above digestion. The results are thus summarised:—Ammonium citrate solution dissolves all the reverted calcium phosphate at 40°, whereas in the other experiments all the reverted iron and aluminium phosphates were dissolved at 65°, but not completely at 40°. D. A. L.

Estimation of Carbonic Anhydride in Air. By M. Ballo (*Ber.*, **17**, 1097—1101).—This method is based on the property of carbonic anhydride to decolorise a solution of phenolphthaleïn. The author, however, finds that lime-water absorbs carbonic anhydride from the air too slowly for practical purposes, and in place of it he uses a solution containing caustic potash and barium chloride. This solution when shaken with atmospheric air absorbs carbonic anhydride with much greater rapidity, and has also the advantage of preventing the formation of a bicarbonate, as the carbonic anhydride absorbed is at once precipitated as barium carbonate. The solution is made of such a strength that 1 c.c. = 1 c.c. CO_2 in 10,000 c.c. of air. The estimation is made in a flat-sided flask (this form being used for convenience in shaking) of about 500 c.c. capacity, in the following way:—The flask is filled with the air to be tested and closed with an india-rubber stopper. A quantity of the alkaline solution slightly coloured with phenolphthaleïn, sufficient for the observation of the normal quantity of carbonic anhydride in air, is run in and briskly shaken. If the quantity of carbonic anhydride is greater than the normal, decolorisation takes place in one or two minutes. A second quantity is then run in and again shaken, and the addition of these quantities of solution continued until the solution remains coloured after at least three minutes' shaking. The quantity of solution required may be more exactly measured in a second determination. In this way, in 10 or 15 minutes, the carbonic anhydride in air can be estimated with fair exactness, and the author's results differ but slightly from those obtained by Pettenkofer's method. For example, in a schoolroom, 42·6 vols. CO_2 per 10,000 of air were found using a flask of

580 c.c. capacity, and 37·6 vols. CO_2 with a flask of 800 c.c. capacity, whilst by Pettenkofer's method 42·1 vols. CO_2 were found. As a rule, however, the results of other examples given by the author are somewhat lower than those by Pettenkofer's method. By using a flat-sided flask, the labour of shaking is diminished, and the absorption is quicker in a flask of 500 c.c. than in a larger one. The solution of potash and barium chloride should not be coloured until the experiment is about to be made, as it has been observed that the coloured solution becomes decolorised after a time. A. B.

Volumetric Estimation of Carbon Bisulphide in Thiocarbonates. By E. Falières (*Ann. Chim. Phys.* [6], 2, 134—144).—The application of potassium thiocarbonate on a large scale for the destruction of the phylloxera necessitates the introduction of some simple method for their analysis, with especial regard to the coloration of the carbon bisulphide contained. Gélis has proposed to add sulphurous acid to a given volume of the solution; this precipitates the carbon bisulphide, the volume of which is measured. But this method is inexact, owing to the incomplete separation of the carbon bisulphide and the difficulty of exactly estimating the true volume. It is here proposed so to modify the process that exact results can be obtained; the method adopted is as follows:—The density of the solution is first taken, and then a volume of it corresponding to 10 grams by weight is measured off; this is mixed with its own volume of water placed in a partly closed measuring vessel, together with a few cubic centimetres of benzene, and a solution of sulphurous acid is then added gradually so as to precipitate the carbon bisulphide; this is dissolved by the benzene, the solution being facilitated by agitation. The increase in the volume of the benzene due to the carbon bisulphide is then noted, and the mass corresponding with this volume calculated and referred to the mass of the solution of sulphocarbonate originally taken. The method presents the advantages of simplicity, rapidity, and a sufficient degree of accuracy for practical purposes. In the original paper, tables are given of the values of thiocarbonate solution of different densities corresponding with a mass of 10 grams, and of the percentage of carbon bisulphide corresponding with a definite increase of volume of the benzene. V. H. V.

Separation of Strontium from Calcium. By I. Bogomoletz (*Ber.*, 17, 1058—1061).—The separation of these metals by means of a solution containing 20 per cent. of ammonium sulphate and 3 per cent. of ammonium oxalate as given by Sidersky (Abstr., 1883, 509), has been repeated and investigated. The method, in the author's opinion, is about the same, as far as simplicity goes, as Rose's ordinary method. The use of it depends on the conditions (quantity of substances, time, and temperature) which influence the reaction.

A. B.

Estimation of Alum in Wine. By P. Carles (*J. Pharm.* [5], 7, 373—376).—The author finds that the methods usually adopted for estimating the amount of alum in wine are defective, the phosphates of the alkaline earths being precipitated with the alumina. The following process is recommended:—Half a litre of wine is evaporated to dryness and the residue carbonised by ignition. The carbonaceous mass is powdered and boiled with dilute hydrochloric acid, and excess of solution of soda is added to the filtered liquid while still hot; the phosphates are thus precipitated and the alumina dissolved. The filtered liquid is treated with ammonium chloride, and after it has been boiled for a few minutes the alumina is filtered off. To free the precipitate from potassium salt, which it obstinately retains even after prolonged washing, it is redissolved in hydrochloric acid and the solution precipitated by ammonia; after being washed, the precipitate is calcined and weighed. The results are sufficiently accurate for ordinary purposes, but a part of the alumina remains as phosphate, thus instead of 0·108 gram of alumina, 0·124 and 0·131 gram were obtained. W. R. D.

Estimation of Lead in Tinplate. By P. CARLES (*J. Pharm.* [5], 7, 285—287).—It is often necessary to detect and estimate lead in the tinplate which is used in making cases for preserved fruit, foods, &c. When tin and lead are alone present, the two metals can be treated with nitric acid, when the tin remains as stannic acid, and the lead can be precipitated from the filtrate as sulphate. This process is not accurate when iron is present, as the greater part of the tin is converted into ferric stannate, which remains in the filtrate, and is precipitated with the lead sulphate when sulphuric acid is added. The author recommends dissolving the tinplate in hydrochloric acid with a little nitric acid, and after expelling all the nitric acid by ebullition, to dilute the liquid and precipitate with hydrogen sulphide. The mixed tin and lead sulphides are separated by digestion with ammonium hydrosulphide. The tin is subsequently converted into stannic acid, and the lead into sulphate. W. R. D.

Reaction to Detect the Presence of Metallic Iron. By A. v. LASAULX (*Jahrb. f. Min.*, 1884, 2, Ref., 33).—The magnetic portion of the powdered substance is treated with a solution of tungstic acid, and placed under the microscope. The smallest particles of iron are surrounded with a blue edge. Organic matter, zinc, and copper must be absent. B. H. B.

Estimation of Iron and Stannous Salts by Potassium Chromate. By L. CRISMER (*Ber.*, 17, 646—649).—A modification of Löwenthal and Stromeyer's method (*Annalen*, 171, 261), the final titration being effected by decinormal potassium chromate, with potassium iodide and starch as an indicator, instead of by potassium permanganate. A. J. G.

New Reaction for Pyrogallol. By O. NASSE (*Ber.*, 17, 1166).—Iodine gives a transient purple coloration with aqueous or alcoholic solutions of tannin, gallic acid, and pyrogallol, in presence of minute quantities of neutral or acid salts. This reaction is not exhibited by phoroglucinol, querciglucinol, or ellagic acid. The presence of salts in water may be demonstrated by the formation of the purple coloration on the addition of a mixture of gallic acid and iodine. W. C. W.

Behaviour of some Fats and Lubricating Oils with Glacial Acetic Acid. By E. VALENTA (*Dingl. polyt. J.*, 252, 296).—From a series of experiments, the author infers that most animal and vegetable fats are more or less soluble in glacial acetic acid. Equal parts of oil and glacial acetic acid were intimately mixed in a test-tube and subjected to various temperatures. Olive oil and castor oil are completely soluble at the ordinary temperature (15—20°); palm oil, laurel oil, cocoanut oil, palm-nut oil, illipe oil, olive oil, cacao butter, sesame oil, peach-kernel oil, almond oil, cotton oil, earth-nut oil, apricot-kernel oil, beef tallow, American bone fat, cod-liver oil, and pressed tallow are completely, or almost completely soluble at temperatures varying between 23° and the boiling point of glacial acetic acid, whilst rape oil and mustard oil (cruciferous oils) are imperfectly soluble in boiling glacial acetic acid. The subjoined table gives the results of experiments made with a view to distinguish various fats by warming equal volumes of fat and glacial acetic acid in a test-tube

Name of fat.	Sp. gr. at 15°.	The solution in equal parts glacial acetic acid (sp. gr. = 1·0562) is rendered turbid at	Remarks.
		Vegetable fats.	
Palm oil	—	23°	Fresh fat procured from the Brünn candle works.
Laurel oil	—	26—27°	Old rancid fat from a collection in the laboratory.
Cocoanut oil	—	40°	From the laboratory collection.
Illipe oil	0·9175	64·5°	Extracted from the seeds of Bassia longifolia.
Palm-nut oil	—	48°	Old rancid fat from the English market.
Green olive oil	0·9173	85°	Oil from second pressing, contains presumably large quantities of olive-kernel oil.
Cacao butter	—	105°	Obtained from J. Stettner.
Sesame oil	0·9213	107°	Ditto.
Peach-kernel oil	0·9241	108°	Crude oil. Hungarian source.
Almond oil	0·9186	110°	Obtained from J. Stettner from sweet almonds.
Cotton oil	0·9228	110°	Obtained from J. Stettner.
Olive oil (yellow)	0·9149	111°	Oil from first pressing, obtained from J. Stettner.
Earth-nut oil	0·9193	112°	Obtained from J. Stettner.
Apricot-kernel oil	0·9191	114°	Ditto.
		Animal fats.	
Beef tallow	—	95°	Hard tallow from Italy.
American bone fat	—	90—95°	
Cod-liver oil	—	101°	Obtained from Vienna.
Pressed tallow	—	114°	Melting point 55·8°. Very hard and pure.

until a clear solution is obtained, allowing to cool, and observing the temperature at which the clear solution is rendered turbid.

In conclusion, the author mentions that, by the aid of glacial acetic acid at 50—60°, it is possible to detect adulterations of mineral oils with resin oils, the latter being readily soluble in acetic acid, whilst mineral oils are almost insoluble in that solvent. D. B.

Assay of Quinine Sulphate. By H. BYASSON (*J. Pharm.* [5], 7, 291—294).—The author proposes the two following methods for the assay of quinine sulphate:—

Method I.—This is a modification of the method of the French Codex. An ordinary test-tube of about 15 mm. diameter is graduated with one mark (*a*) to hold 6 c.c.; a second mark (*b*) is then made above this to indicate 2 c.c. from the first mark. 0·5 gram of the quinine sulphate is introduced into the tube, and then washed ether added to the mark (*a*); sufficient solution of ammonia (0 9—0·950) is finally added to exactly reach (*b*). The tube is then fitted with an air-tight cork and well shaken. If the quinine sulphate be pure, no trace of a flock or crystal will be visible between the layers after the liquids have separated. This method is capable of detecting from 3—4 per cent. of cinchonine sulphate, 4—5 per cent. of quinidine sulphate, and from 5—6 per cent. of cinchonidine sulphate.

Method II.—In this method, Laurent's polarimeter is used. 0·5 gram of quinine sulphate is placed in a flask graduated to 50 c.c., and dissolved by the addition of dilute sulphuric acid (2 per cent. by volume). In this way a 1 per cent. (by volume) solution of quinine sulphate in dilute sulphuric acid is obtained. The 22 cm. polarimeter tube is filled with the solution, and the rotatory power of the liquid determined. Commercial quinine sulphate should possess, at 15°, a rotatory power of not less than −22° on the saccharimetrical scale. When the deviation is less than −21·8°, the quinine sulphate should be chemically examined by the first method. The following are the rotatory powers in saccharimetrical degrees of 1 per cent. (by volume) solutions of the pure sulphates of the cinchona alkaloïds. The observations were made in the 22 cm. tube of Laurent's polarimeter:—

Quinine sulphate........ = − 23·3°
Cinchonidine sulphate.... = − 16·5°
Quinidine sulphate ...... = + 26·4°
Cinchonine sulphate....... = + 22·2°

Commercial quinine sulphate usually shows a deviation of −22°. A deviation of −21·8° indicates the presence of about 5 per cent. of cinchonidine sulphate, and a deviation of −20° about 10 per cent. of cinchonidine sulphate. W. R. D.

Analysis of Flour. By A. R. LEEDS (*Chem. News*, 49, 269—273; 280—281).—The present communication contains an exposition of the inconsistencies and fallacies of certain erroneous reports, published in America, wherein various samples of flour and farinaceous preparations are condemned, mostly on evidence obtained by microscopical examinations, from which are drawn quantitative analytical conclusions. The defects of these observations and inferences are explained in detail, as also are those of a process for the determination of gluten, starch, &c., in flour, described in the same reports. In this process, the weighed quantity of flour is moistened, and the dough put into a piece of muslin and kneaded with a fixed quantity of water, the ultimate residue in the muslin being regarded as gluten. The latter part of the communication consists of comprehensive comments on the imperfections of the analytical process, Cairn's method, frequently employed for the complete examination of flour.

Technical Chemistry.

Expedients for rendering Photographic Films sensitive to Green, Yellow, and Red Rays. By H. W. VOGEL (*Ber.*, **17**, 1196—1203).—Silver tetrabromofluoresceïn is not decomposed by dilute acetic acid. It is remarkably sensitive to greenish-yellow rays. If a cadmium bromide collodion plate containing eosin is immersed in a silver solution, its sensitiveness to blue rays is very much diminished and the action of the yellow rays is greatly increased. The addition of eosin to collodion silver bromide containing a small quantity of silver iodide produces a film which is sensitive to yellow and to blue rays.

In photographing coloured objects, a yellow glass is introduced between the object and the apparatus in order to diminish the action of the blue rays. With such an arrangement, Schweinfurt green and yellow appear light. The action of orange and red rays may be increased by adding methyl-violet or aldehyde-green respectively to the silver bromide collodion.

Wet gelatine plates containing eosin are much more sensitive to yellow rays than the dry plates.

W. C. W.

Transmission of Cholera by Drinking Water. (*Dingl. polyt. J.*, **252**, 261.)—Koch has succeeded in detecting certain bacilli in the intestines of persons who have died of cholera in Egypt and Calcutta. He isolated and cultivated these bacilli, and on subjecting them to minute examination, made a number of characteristic observations in regard to their form and their development in nutritive gelatin, by means of which they can be distinguished with certainty from other bacilli. With this, it was possible to definitely decide the question, whether these bacilli are contained in the intestines of all bodies, or whether they occur only in the intestines of cholera patients. By the aid of gelatin cultivations, the presence of these organisms in the evacuations of cholera patients, as well as in the intestines of cholera corpses, was clearly demonstrated, whilst on investigating the intestines of other corpses, cholera bacilla could not be detected.

It has been shown that since 1870 a considerable reduction has taken place in the spread of cholera in Calcutta. Before 1870, the cholera carried off annually 10·1 persons out of every thousand, whilst since 1870 the death-rate has fallen to three persons per 1000. It is thought that this circumstance should receive due consideration, as it points to the means of effectually keeping off this disease. It is the unanimous opinion of the medical profession that this decrease has been effected in consequence of the introduction of waterworks in Calcutta. Koch has shown that the cholera often settles in a particular locality, and displays its greatest virulence in certain quarters. Such epidemics are frequently observed in the surroundings of the so-called "tanks," which are small ponds or wells enclosed within huts. The neighbours obtain their water supply from these tanks, and simultaneously utilise them for various purposes, such as bathing, washing clothing, cleaning domestic utensils, &c. It is worthy of note that in order to prevent the destruction of cholera bacilli, it is necessary to preserve them in a moist place. In liquids, their development is maintained for a long time, a circumstance which indicates that these germs are carried from place to place, and transmitted from person to person in a moist state only. D. B.

Hydrogen Peroxide in Medicine. By E. SONNERAT (*J. Pharm.* [5], **7**, 488—496).—The author finds that solutions of hydrogen peroxide are most stable when dilute and slightly acid with sulphuric acid, and hence recommends the use of such solutions in medicine. Thus a 1-volume solution, which was slightly acid with sulphuric acid, did not alter in strength for one month when kept in a stoppered bottle. The hydrogen peroxide of commerce is very acid in reaction, and often contains 15 grams of sulphuric acid per litre; some samples contain hydrochloric acid and barium chloride. The sulphuric acid in commercial specimens may be estimated and removed by means of a standard solution of baryta-water. The author estimates the oxygen value of these solutions by first making them alkaline with soda, and then adding manganese dioxide The operation is conducted in an Esbach's ureometer tube, and the volume of free oxygen measured in the usual way. Full details of the method are given in the original paper.
W. R. D.

Manufacture of Sulphuric Acid from Pyrites in America. By G. LUNGE (*Dingl. polyt. J.*, **252**, 293—295).—Referring to a previous communication (*ibid.*, **248**, 35), the author mentions that although American pyrites mostly contains arsenic, the Sulphur Mines Company of Virginia and the mines of the Davis Company and others yield a pyrites which is perfectly free from arsenic, so that the manufacture of pyrites acid, as compared with sulphur acid, must be more remunerative in America than in Europe. According to Voelcker, pyrites from the Sulphur Mines Company has the following composition:—

S.	Fe.	Fe_2O_3.	H_2SO_4.	SiO_2.	Cu.	As.
48·02	42·01	1·93	0·44	7·60	—	—

The author is of opinion that with the large quantities of pyrites found in America, and the fact that a number of companies have been formed with the object of working the pyrites mines, the price of pyrites acid will have to suffer considerable reduction. D. B.

Separation of Arsenic from Saline Solutions. (*Dingl. polyt. J.*, 252, 304.)—According to Glaser, of Berlin (Ger. Pat., 26,6[illegible]2, March, 1883), saline solutions contaminated with arsenic or arsenious acid are concentrated, neutralised, and treated with stannic acid, antimonic or antimonious acid or peroxide of lead, until the filtrate is free from arsenic. The precipitate is separated from the saline solution, washed with water, and treated with dilute sulphuric or nitric acid, the arsenic being dissolved, whilst the residue, after washing with water, may be used for the purification of fresh quantities of saline solutions. D. B.

Novelties in the Iron Industry. (*Dingl. polyt. J.*, 252, 243—253.)—It is generally assumed that the Bessemer process can be worked with advantage only by operating on large quantities of iron. Tunner, however, draws attention to three modes of conducting this process on a small scale. The most important process is that which has been worked since 1877, with great success, at Avesta in Sweden. The works belonging to the Jern-Contor Company contain two blast furnaces, two Bessemer converters (with two spare converters), and a rolling mill for the production of plates. The total working power amounting to from 800 to 900 e., is obtained from the River Dalelfoen. The process is described in detail in the original paper. Contrary to the generally accepted opinion that the success of the Bessemer process depends on its magnitude, Ehrenwerth infers that the process in work at Avesta proves, (1) that it is possible to obtain the temperature necessary to complete the Bessemer process with small charges and to produce a very soft metal from pig-iron, containing only a small amount of manganese and less silicon than is contained in the iron worked in the alpine districts (charcoal-Bessemer process); (2) the consumption of ferromanganese and the amount of manganese contained in the metal is less than is the case in the production of similar qualities of iron by the processes employed in Styria; (3) the Bessemer process may be applied to the continuous production of soft, fibrous iron, and is the best process for obtaining a uniform product.

The second process referred to by Tunner originates with a French firm, and is worked in France, and by Vogel and Nuth in Austria in the Murz Valley. Converters resembling the stationary ovens formerly worked in Sweden are used. The third process is the so-called pneumatic process of making wrought iron introduced by Chapin of Chicago, which consists in combining the Bessemer process with a puddling process conducted in rotary furnaces. The advantage of this process is the production of iron in the form of balls.

In order to regulate the temperature in acid convertors during the blowing, Jones (Am. Pat., 287,687, Oct., 1883) recommends the introduction of steam into the metallic bath.

According to the Société John Cockerill of Seraing (Ger. Pat., 24,971, April, 1883), it is proposed to utilise the heating furnaces of steel works for the "soaking" of steel ingots.

Cooper of Linthorpe (Ger. Pat., 25,486, Dec., 1882) effects the soaking of steel castings in an underground tunnel extending from the casting pit to the rolling mill.

Gjer's so-called "soaking pits" are used at the works of the Scranton Steel Co. From 80 to 85 per cent. of the steel ingots produced are brought to a uniform temperature in these pits, after which they are rolled into rails without further heating. D. B.

Novelties in Metallurgy. (*Dingl. polyt. J.*, **252**, 211—217.)—For the examination of commercially pure copper, Pufahl tried the galvanic deposition in a platinum dish of about 30 grams copper by two small Grove's elements. The copper was contained as sulphate in 600 c.c. of solution to which 40 c.c. nitric acid of 1·2 sp. gr. had been added. After twelve hours only 0·5 gram copper remained in the solution, which was removed by the introduction of a current from four large Meidinger's elements without carrying down arsenic or antimony. For the estimation of oxygen in copper, 10—20 grams of bright copper turnings not exceeding 1 mm. in thickness were weighed into a porcelain boat placed in a glass or porcelain tube and heated to 500° in a current of pure hydrogen gas, the turnings having been previously treated with ether in order to remove all fatty particles. The loss in weight was calculated as oxygen. If the copper contains much arsenic, the percentage of oxygen should be determined from the weight of water collected in a calcium chloride tube. Analyses of the following brands are given:—

	Wallaroo.	C.H.M.Co.	Mansfield R.	Bede.	Grange.
Copper	99·795	99·864	99·491	99·148	98·961

	99·981	100·014	99·979	100·008	99·983

According to Egleston, the extraction of gold and silver from ores by means of sodium thiosulphate has been adopted by the Old Telegraph and Lexington Mills, the works at Triumfo and of the Geddes and Bertrand Mine at Eureka in Nevada, where an impure ore of the following composition is worked up.

SiO_2.	Fe.	Zn.	Pb.	As.	Sb.	Ag.	CaO.
50·25	8·06	7·62	4·64	0·73	1·35	0·17	4·92

MgO.	S.	CO_2.	Cu. Bi.
2·40	0·96	8·30	traces.

The ore is crushed between rollers, dried in cylinders and passed through a pipe lined with magnets whereby particles of iron are removed. It is then disintegrated thoroughly, mixed with 3 per cent. of salt and roasted. At the Bertrand works, the roasting is effected in four Brückner's rotary cylinders (*ibid.*, **219**, 57), which are 2·1 m. wide, 5·8 m. long, and hold a charge of 5 tons. The roasting is completed in from eight to eleven hours, after which the ore is dropped into pits where it remains for nine hours. It is then transferred to the lixiviating apparatus, which consists of a series of vats 1·82 m. in diameter, and 0·91 m. deep, the bottom being covered with crossed wooden gratings and jute cloth between so as to form a filter. The ore is washed repeatedly with hot or cold water, and is then treated in the cold with a solution of sodium thiosulphate containing from 13 to 75 grams of salt per litre. If the ore contains gold it is preferable to use calcium thiosulphate, which is prepared by boiling lime with sulphur ($3CaO + 12S = 2CaS_5 + CaS_2O_3$), allowing the mixture to settle, and passing in sulphurous anhydride until the clear solution ceases to give a precipitate with a dilute solution of silver chloride. The action of sodium thiosulphate on silver chloride is explained by the following equation:—$2AgCl + 2Na_2S_2O_3 = 2NaCl + 2NaAgS_2O_3$, the latter is extremely soluble in water. If the ore contains from 30 to 50 ounces of silver (0·093 to 0·155 per cent.), the amount of silver in the residue should not exceed 4 ounces (0·0124 per cent.). The argentiferous solution of sodium thiosulphate is then transferred to precipitating tanks and treated with a solution of calcium sulphide, when the following change takes place:—$2NaAgS_2O_3 + 2NaCl + CaS = Ag_2S + 2Na_2S_2O_3 + CaCl_2$. The silver sulphide is collected on a series of linen filters, washed with water and dried. It is then roasted in reverberatory furnaces or heated in retorts for the recovery of the sulphur.

Aaron proposes to agitate the precipitate of silver sulphide with lime and boil the mixture, calcium polysulphide being formed, which may be used for precipitating fresh quantities of silver chloride, whilst the residual grey mass consists mainly of metallic silver.

According to Groddeck and Brookmann, basic slag often exhibits a crystalline appearance. Some specimens contain thin, brown, rectangular, transparent plates having a hardness of 3·5°, and belonging to the rhombic system, whilst in others blue crystals are found. Analysis gave numbers agreeing with the formula for tetrabasic calcium phosphate:—

	CaO.	MgO.	MnO.	FeO.	P_2O_5.
Brown crystals.	58·01	0·88	—	2·93	38·75
Blue crystals ..	56·00	—	3·00	6·00	35·00

D. B.

Purification of Methylated Spirit. By P. Cazeneuve and Chapuis (*J. Pharm.* [5], **7**, 126—130).—The authors have made experiments to discover to what extent the French methylated spirit, which is prepared by mixing wood spirit, containing about 25 per cent. of acetone, with ethyl alcohol, can be freed from its objectionable odour. By the action of nascent hydrogen from a zinc and copper couple placed in the spirit at a temperature of about 70°, the disagreeable odour is completely removed after the reaction has gone on for five or six days. The same result can be obtained by using a zinc and copper couple in the cold, but the process takes about four times as long. By distilling the mixture from a water-bath nearly odourless spirit is obtained. The result is obviously due to the conversion of the acetone into secondary propyl alcohol by the action of the nascent hydrogen. Methylated spirit purified in this way could no doubt be used in the preparation of liqueurs and other substances intended for human consumption, and hence the authors consider that some substance other than impure wood spirit must be found for admixing with ethyl alcohol. W. R. D.

Analyses of the Wines of Médéah. By BALLAUD (*J. Pharm.* [5], 7, 485—487).—The wines of Médéah (Algeria) possess all the characters of good red wines. The sp. gr. varies from 0·985—0·995, the alcoholic strength from 11—13 per cent., the total acidity calculated as sulphuric acid is from 3—4 grams per litre. These wines yield more extract (27—33 per cent.) than French wines, and an ash which contains much silica (0·84 per cent.) and potassium salts. The other constituents determined were glucose (2—3 per cent.), cream of tartar (1—2·6 per cent.), glycerol (6 per cent.). W. R. D.

Wines from Sugar. By P. CARLES (*J. Pharm.* [5], 7, 14—24).—These wines (*vins de sucre*) are produced by refermenting the grape marc with a solution of sugar. The process consists in pouring off the natural wine from the marc and adding to the latter a lukewarm solution of sugar, this mixture is then allowed to undergo natural fermentation. The resulting wine is known as secondary wine (*vin second*), wine of the second press (*goutte*), wine of the second vat (*cuvée*), wine of the marc or sugar-wine (*vin de sucre*); the last name is that most commonly used in the south-west of France. In some cases crude solution of cane-sugar or raw crystallised sugar is employed in the process, in others starch-sugar in one or other of its different forms. The author has examined a great number of samples of these secondary wines and also of the natural wines, the results of the analyses being tabulated in the original paper. The wines analysed were of the 1880 vintage, and were produced in the provinces of Gironde, Dordogne, and Lot. The important inferences from the analytical results may be thus summarised: Crystallised sugar is to be preferred in the process, both for chemical and hygienic reasons, to starch-sugar; secondary wines are normally weaker in alcohol than natural wines, and contain less extractive matter, glycerol, hydrogen potassium tartrate, and substances which reduce cupric oxide (principally dextrose), as well as less inorganic matter; they are especially deficient in tannin and colouring matter. Secondary wines also greatly lack those volatile constituents which give bouquet (*vinosité*) to natural wines. W. R. D.

Kephir. By H. STRUVE (*Ber.*, 17, 314—316).—The author gives a short historical sketch of the literature of *kephir*, showing that although this beverage has long been used in the Caucasus, and was the subject of a scientific paper just a century ago, it is only since Kern's work on the subject (Abstr., 1883, 229) that attention has been given to it by the scientific world. The author is now investigating the whole subject of kephir-fermentation. L. T. T.

Germinated Wheat. By BALLAUD (*J. Pharm.* [3], 7, 295—301).—Owing to persistent rain in the north of France during harvest time, a quantity of wheat appeared in the market which had been much wetted, and in consequence had partially germinated. The author made a chemical examination of this wheat to see how far it differed from ordinary wheat. The constituents determined were moisture, acidity, lignin, gluten, fat, glucose, fixed salts, and substances soluble in cold water and in dilute acetic acid. It is seen from the tables of results which are given in the original paper that although there is no loss or variation in the quantity of total nitrogenous matter, yet the gluten has been profoundly affected, having become black, viscous, disintegrated, and partially converted into soluble albuminoïds. An increase is observable in the quantity of glucose and lignin as well as of acid, and a decrease in the quantity of fat. The methods employed for estimating the constituents are fully described in the original paper. W. R. D.

Secret Anti-incrustators. By H. BELLMER (*Dingl. polyt. J.*, 251, 537—540).—"Lapidolyd" manufactured by Kolker Brothers in Breslau contained in 1 litre:—

	Specimen I. grams.	Specimen II. grams.	Specimen III. grams.	Specimen IV. grams.
Total residue	85·67	68 23	92·73	64·42
Sodium carbonate ..	37·77	9·64	34·48	11·58
Sodium hydroxide ..	10·60	9·60	11·66	13·60
Sodium hydroxide combined........	0·85	8·75	—	—
Organic matter (catechu)...........	28·84	31·10	35·98	31·44

Besides these substances, sodium chloride and the impurities usually present in caustic soda were found. One litre of lapidolyd is sold at 20 pfennigs, value about 4 pf.

"German incrustation solution" prepared by Patrosio in Bochum (I and II), and lapidolyd made by Neuerburg in Cologne (III) contained in one litre:—

	Na_2CO_3.	NaHO.	NaCl.	Na_2SO_4.	Organic.		grams.
I.	71·164	6·080	28·952	7·850	72·084	=	185·860
II.	84·300	15·200	8·120	5·000	27·168	=	139·788
III.	11·572	13·600	7·796	—	31·440	=	64·415

Albert in Berlin prepares an incrustation powder resembling "Paralithicon minerale" in chemical composition:—

$CaCO_3$.	NaCl.	CaH_2O_2.	NaHO.	Na_2SO_4.	SiO_2.	Fe_2O_3 and Al_2O_3.	H_2O.	Glue.
26·14	21·04	24·13	8·17	8·28	1·22	0·74	3·34	6·94

Marckmann's solution contains in 1 litre—

$BaCO_3$.	$CaCO_3$.	Sand.	Organic.	Na_2CO_3.	NH_4Cl.	NaCl.		grams.
16·2	6·6	0·6	20·1	41·3	6·7	24·6	=	116·1

The powder introduced by Schwieger in Dessau, of which 100 kilos. cost 40*s*., consists of—

Na_2CO_3.	Na_2SiO_3.	NaCl and Na_2SO_4.	Organic.	Fe_2O_3 and Al_2O_3.	Sand.	H_2O.
14·36	12·50	0·92	14·60	0·75	12·49	44·23

"Desincrustant Ragosine" consists essentially of petroleum residues, and is used as a substitute for tar for painting the sides of boilers.

The anti-incrustating composition manufactured by Petrik and Co. in Bodenbach is a concentrated solution of impure sodium carbonate coloured blue with archil and treated with organic substances containing tannic acid. It also contains caustic soda and ammonia in small quantities. Its cost is 40 Austrian florins per 100 kilos.

"Disincrustant Marseillais" is brought into commerce from Manchester at 220*s*. per 100 kilos., and consists of an extract of tannin and catechu.

An extract of chestnuts is brought into commerce from Esseg in Hungary as a preventative of boiler incrustations.

The powder prepared by Zöpfke and Rudel in Berlin (100 kilos. at 96*s*.) has the following composition:—

Na_2SO_4.	NaCl.	Na_2O.	CaO.	CO_2.	H_2O.	Glue.
15·46	14·88	12·62	28·32	8·51	14·32	5·89

The composition made by Hein in Halle is a vegetable extract containing tannin.

Hauff's solution contains mainly impure soda-ley coloured reddish-brown.

Engel recommends anti-incrustating solutions containing soda mixed with catechu; his "salt mixture" is composed of soda treated with salt.

The fluid known as Renz's "Soda caustique," is impure caustic soda.

Ulmann of Zürich sells 100 kilos. of ordinary sea-weed (*Fucus vesiculosus*) at 150*s*. under the name of "Vegetaline."

Kohn and Co.'s "Corrosiv" is mainly a mixture of soda and lime, and has the following composition:—

Na_2O.	CaO.	NaCl.	$CaCO_3$.	Fe_2O_3 and Al_2O_3.	Insoluble in HCl.	H_2O.	Loss by ignition.
16·53	3·33	4·71	38·84	1·95	2·71	17·89	14·04

Harris Hewitt's "patent block composition" is a mixture of catechu and tannin wastes.

D. B.

General and Physical Chemistry.

Electrochemical Equivalents of Silver and Copper. By F. and W. Kohlrausch (*Dingl. polyt. J.*, **253**, 32).—Comprehensive experiments show that a current of one ampère deposits per second 1·1183 mgrm. of silver, 0·3281 mgrm. of copper, or decomposes 0·09328 mgrm. of water. J. T.

Change in Volume on Melting. By R. Schiff (*Gazzetta*, **14**, 181—199, and *Annalen*, **223**, 247—268).—By means of a specially constructed dilatometer, the author has determined the specific gravities of several organic compounds at temperatures near their melting points. The following table shows the sp. gr. at the melting point, and the molecular volume of these bodies:—

	M.p.	Sp. gr.	Molecular volume at the melting point.
Dinitrobenzene	89 1°	1·369	167·66
Thymol	49·3	0·9499	157·55
Alphatoluic acid	76·4	1·0847	125·08
Nitrotoluene	54	1·1231	121·72
Anethol	21·3	0·9887	149·34
Dibenzyl	52·3	1·0423	174·21
Naphthalene	80	0·9777	130·61
Diphenyl	70·5	0·9961	154·25
Stilbene	119·2	0·9707	184·99
Phenanthrene	100·5	1·063	167·05
Ditolyl	120·8	0·9172	197·97
Acenaphthane	103	1·03	149·16
Dibromobenzene	89·2	1·8108	127·83
Dichlorobenzene	55	1·2499	117·37
Nitrophenol (ortho)	45·2	1·2915	107·64
,, (para)	114	1·2809	108·28
Benzoic acid	121·4	1·08	112·69
Stearic acid	69·5	0·8521	332·56
Dinitrotoluene	70·5	1·3208	137·51
Resorcinol	110	1·1795	93·94
Nitronaphthalene	61·5	1·2226	141·19
Benzene	4·4	0·8915	86·99
Phenol (Liebermann)	41	1·0606	88·42
Nitrobenzene (Kopp)	3	1·2029	102·03
Dibromobenzene (Körner)	−1	2·0	117·63

A close examination of these results shows that a constant alteration in composition does not produce a constant change of molecular volume at the melting point. This conclusion is directly opposed to that which Krafft (Abstr., 1882, 1272, *Ber.*; **15**, 1171) arrived at from his research on the higher paraffins. W. C. W.

Solubility of Solid Substances in Water at various Temperatures. By J. L. Andreæ (*J. pr. Chem.* [2] 29, 456—477).—The author has repeated the estimations of the solubility of sodium chloride, potassium chloride, potassium nitrate, and potassium sulphate, as there are differences in the values obtained by various authors. He details the errors which may be made in the estimations, and describes, with the aid of drawings, the apparatus he has had constructed and has used. Three methods were employed in order to obtain saturated solutions:—1st. By using an excess of the salt and agitating with water at a constant temperature: regular and constant agitation was obtained by means of a hot air motor, and continued for $1\frac{1}{2}$ hours, the salt falling through the water twice in a second. 2nd. By making a supersaturated solution, and agitating as before for $1\frac{1}{2}$ hours. 3rd. By observing the temperature at which a known weight of salt dissolved in a known quantity of water. The first two methods were employed in a large number of estimations at different temperatures, and the third was employed to determine whether an excess of salt had any influence on the solubility: it was found to have none.

From the results obtained the author has obtained the following formulæ:—

NaCl (from 4° to 80°)

$$S = 35{\cdot}63 + 0{\cdot}007889\,(t - 4) + 0{\cdot}0003113\,(t - 4)^2.$$

The solubility from 0—4° is constant.

KCl (from 4° to 60°)

$$S = 29{\cdot}33 + 0{\cdot}3206\,(t - 4) - 0{\cdot}000577\,(t - 4)^2.$$

K_2SO_4 (from 10° to 70°)

$$S = 9{\cdot}219 + 0{\cdot}19404\,(t - 10) - 0{\cdot}0003083\,(t - 10)^2.$$

KNO_3 (from 4° to 60°)

$$\log S = 1{\cdot}20412 + 0{\cdot}019877\,(t - 4) - 0{\cdot}0000882\,(t - 4)^2,$$

by the first method.

KNO_3 (from 4° to 60°)

$$\log S = 1{\cdot}20385 + 0{\cdot}019896\,(t - 4) - 0{\cdot}0000883\,(t - 4)^2,$$

by the second method.

The difference in the two formulæ only affects the numbers in the second decimal.

A. B.

Influence of Dilution on the Rate of Chemical Reactions. By W. de la Croix (*J. pr. Chem.* [2], 28, 478—489).

Combustion of Diamonds. By C. Friedel (*Bull. Soc. Chim.*, 41, 100—104).—The author has submitted to combustion some particularly pure specimens of diamond. These diamonds were nearly colourless, and when ignited yielded very little ash. The combustion was conducted in a porcelain tube in a current of oxygen; this was prepared by heating a mixture of potassium chlorate and copper oxide, and was purified by passing it over heated copper oxide and through tubes containing potash, sulphuric acid, and phosphoric anhydride. The combustion tube was connected with tubes containing sulphuric acid, phosphoric anhydride, and potash to collect the products of combustion, and was heated by a Wiesnegg grating, the diamonds being contained in a platinum boat. Full details of the construction of the apparatus, and the precautions which were observed are given in the original paper. Blank experiments were first made with the apparatus, which showed that there were no errors of importance. In the first experiment, 0·4705 gram of white Cape diamonds in small crystals was submitted to combustion. This quantity yielded 0·0007 gram of ash, which was deducted from the original weight of the diamonds. Calculating from the quantity of carbonic anhydride obtained, the atomic weight of carbon is 12·017 ($O = 16$). Assuming the diamond to be pure carbon, and taking 12 as the atomic weight of carbon, the result represents a loss of 0·0021 gram of CO_2. In the second experiment, 0·8621 gram of perfectly colourless Cape diamond in 25 or 30 fragmentary crystals was burnt; this yielded 0·0005 gram of white flaky ash. With this correction, 12·007 is obtained as the atomic weight of carbon ($O = 16$). The quantity of CO_2 obtained represents a loss of 0 0015 on the theoretical amount ($C = 12$).

In preliminary experiments, the combustion tube was of Bohemian glass, which was found to be unfitted for the purpose on account of its fusibility at the necessary temperature. In these experiments it was noticed that the partially burnt diamond was not, as is usually stated, transformed into coke, but presented a roughened and somewhat furrowed surface, much resembling in appearance a substance which had been immersed for a short time in an acid capable of attacking it. The ash obtained consisted of small white flakes, yellow in places and containing little black specks. Some of these flakes were attracted by the magnet, many were transparent, and among these were some which acted on polarised light, and therefore had retained their crystalline structure. Some of the Brazilian diamonds which were examined contained near the surface dark specks, which turned brown when heated without access of air to about the temperature of boiling cadmium. These diamonds, therefore, had probably been formed at a temperature lower than this. Dark specks were observed in other specimens which after exposure by fracture entirely disappeared before the blowpipe flame, and were probably carbonaceous. W. R. D.

Inorganic Chemistry.

Preparation of Hydrobromic Acid. By A. Sommer (*Dingl. polyt. J.*, **253**, 215, from *Jour. Soc. Chem. Industry*, 1884, 20—23).—Hydrobromic acid may be prepared by four methods:—(1) Direct combination of bromine and hydrogen; (2) Decomposition of hydrogen-compounds, such as H_2S, HI, NH_3, and oils, by bromine; (3) Decomposition of bromine compounds with fixed metalloïds (especially PBr_5); (4) Decomposition of metallic bromides by means of acids. Of the methods (1) to (3), only that with phosphorus pentabromide yields good results. The author proposes to decompose zinc bromide by sulphuric acid. The zinc bromide is easily prepared by acting on metallic zinc with bromine-water containing undissolved bromine. The solution is rapidly evaporated. To obtain the concentrated solution of hydrobromic acid ($HBr,5H_2O$, boiling at 123°), 225 parts of zinc bromide are distilled with 180 parts of water and 196 parts of sulphuric acid, reckoned as monohydrate. To free the product from sulphuric acid, barium carbonate is added and the solution again distilled.

Sulphides are easily converted into sulphates by first warming them with nitric acid and then slowly adding concentrated hydrobromic acid. J. T.

Supposed Recombination of Oxyhydrogen Mixture in the Dark. By L. Ricciardi (*Gazzetta*, **14**, 20—23).—Rosetti, Zino, and Silvestri, in opposition to the universally received opinion, have stated that the gases composing oxyhydrogen mixture recombine slowly in the dark, if water is present. The author has carefully repeated Silvestri's experiments, and finds that no recombination takes place, even after the lapse of a year. C. E. G.

Oxidation of Carbonic Oxide by Air and Moist Phosphorus. By E. Baumann (*Ber.*, **17**, 283—286).—In reply to the communication of Remsen and Keiser (this vol., 149), the author upholds the correctness of his former statements (Abstr., 1882, 691, and this vol., 14), that carbonic oxide is oxidised to carbonic anhydride by air in the presence of moist phosphorus. He describes careful and elaborate blank experiments in which a stream of air was passed over moist phosphorus; but although the current was in some cases maintained for 96 hours, no trace of carbonic acid was obtained. Immediately pure carbonic oxide was mixed with the air, formation of carbonic anhydride took place. The author adds that *every* experiment was preceded by such a blank experiment, no disconnection or rearrangement of the apparatus being made between the two. L. T. T.

Crystalline Form of Beryllium. By W. C. Brögger and G. Flink (*Ber.*, **17**, 849—850).—System hexagonal and holohedral $a : c = 1 : 1{\cdot}5801$. Observed forms, ∞P, $\infty P2$, $0P$, P, and sometimes $\frac{1}{2}P$. The habitus is either prismatic or tabular. These forms were observed on preparations made by Nilson and Pettersson, and also by Humpidge. Zinc also crystallises in holohedral hexagonal forms.

H. B.

Bismuth Subnitrate. By M. Grossman (*Arch. Pharm.* [3], **22**, 297—307).—The only satisfactory method of testing bismuth subnitrate for arsenic is to heat it so as to drive off the nitric acid, and then treat it with zinc and hydrochloric acid; the evolved gases are tested with acidified silver nitrate solution (E. Reichardt, Abstr., 1881, 195). Crude bismuth was converted into the sulphide by fusion with sulphur, and digested with caustic potash solution; the insoluble sulphide yielded a pure subnitrate. The method is, however, not suitable for manufacturing purposes, owing to the fusion of the separated sulphur during the action of nitric acid on the sulphide. The Hager-Deschamps process is the best: crude bismuth is dissolved in nitric acid, the solution poured into dilute ammonia, and the precipitated bismuth hydroxide washed with boiling water; zinc and lead present can be removed by boiling with caustic soda solution; the bismuth subnitrate obtained from the hydroxide is perfectly pure. The method of the German Pharmacopœia, 2nd edition—fusion with nitre and extraction with caustic soda—gives good results; whilst the method described in the 1st edition is uncertain. A modification by C. Schneider (Abstr., 1882, 18) yields better results, but is not sufficiently simple. H. B.

Titanium. By O. F. v. d. Pfordten (*Ber.*, **17**, 727—730).—By heating titanium sulphide, TiS_2, in a stream of dry hydrogen free from every trace of oxygen, *titanium monosulphide* is obtained as a black substance insoluble in alkalis, soluble only with great difficulty in nitric acid and aqua regia, oxidised by fusion with soda and potassium nitrate.

Attempts to prepare a corresponding monoxide by reducing titanic oxide in a stream of hydrogen were unsuccessful, the reduction not proceeding beyond the deep indigo-blue oxide, Ti_3O_5. This oxide has been prepared in the crystalline form by Deville (*Compt. rend.*, **53**, 163). Ebelmen (*Ann. Chim. Phys.* [3], **30**, 349) obtained a black powder approximating in composition to a sesquioxide.

Gelatinous Modification of Titanic Acid.—This modification can be prepared by fusing titanic acid with potassium carbonate, washing the fused mass with water until the alkaline reaction has disappeared, and then treating the mass with hydrochloric acid (of about 35 per cent.) without heating. The liquid is filtered, and the filtrate on being allowed to stand for a time gelatinises. This fact was observed by H. Rose (*Gilb. Annal.*, 1823, 73—76), but appears to have been overlooked, as it is not mentioned in the text-books. A. J. G.

Note.—Gelatinous titanic acid was described by Graham (*Chem. Soc. J.*, **15**, 256, and **17**, 325).—A. J. G.

Relation between Luteo- and Roseo-salts. By S. M. Jörgensen (*J. pr. Chem.* [2], **29**, 409—422).—In former researches, the author has shown that the luteo-chromium and luteo-cobalt salts are analogous. In this paper he shows that the luteo-salts of cobalt and chromium correspond completely with the roseo-salts of cobalt, chromium, and rhodium, only that the former contain $2NH_3$, where the latter have $2OH_2$. In a table of the numerous luteo- and roseo-salts and double salts which the author has examined, it is seen that out of 45 luteo-salts only 5 contain more OH_2 than is expressed by the above ratio, and that in 44 roseo-salts none contain less.

The following are a few out of the numerous examples given:—

Luteo-salt—		
$Co_212NH_3,(NO_3)_6$.	$Cr_212NH_3,(NO_3)_6$.	—
Roseo-salt—		
$Co_210NH_3,(NO_3)_6,2OH_2$.	$Cr_210NH_3,(NO_3)_6,2OH_2$.	$Rh_210NH_3,(NO_3)_6,2OH_2$.
Luteo-salt—		
$Co_212NH_3,6HgCl_2,2OH_2$.	$Cr_212NH_3,6HgCl_2,2OH_2$.	—
Roseo-salt—		
$Co_210NH_3,6HgCl_2,4OH_2$.	$Cr_210NH_3,6HgCl_2,4OH_2$.	—
Luteo-salt—		
$Co_212NH_3,\left\{\begin{array}{l}I_2\\2SO_4\end{array}\right.$.	$Cr_212NH_3,\left\{\begin{array}{l}I_2\\2SO_4\end{array}\right.$.	—
Roseo-salt—		
$Co_210NH_3,\left\{\begin{array}{l}I_2\\2SO_4\end{array}\right.,2OH_2$.	—	$Rh_210NH_3,\left\{\begin{array}{l}I_2\\2SO_4\end{array}\right.,2OH_2$.
Luteo-salt—		
Co_212NH_3,Co_2Cy_{12}.	Cr_212NH_3,Co_2Cy_{12}.	
Roseo-salt—		
$Co_210NH_3,Co_2Cy_{12},2OH_2$.	$Cr_210NH_3,Co_2Cy_{12},2OH_2$.	$Rh_210NH_3,Co_2Cy_{12},2OH_2$.

The following are two of the five exceptions:—

Luteo-salt—		
$Co_212NH_3,3SO_4,5OH_2$.	$Cr_212NH_3,3SO_4,5OH_2$.	—
Roseo-salt—		
$Co_210NH_3,3SO_4,5OH_2$.	$Cr_210NH_3,3SO_4,5OH_2$.	$Rh_210NH_3,3SO_4,5OH_2$.

The analogy thus shown to exist between the luteo- and roseo-salts of cobalt, chromium, and rhodium is not confined to their composition, but holds as regards their solubilities, crystalline properties, and their appearance, formation, and changes. It is only therefore by their colour and nitrogen-estimations that the corresponding salts can be distinguished. As $2NH_3 = 34$, and $2OH_2 = 36$, the percentage of metal is almost the same in the two series. In many cases the roseo-salts do not lose the·2 mols. OH_2 which are part of their constitution, without a deeper decomposition, but if they do, purpureo-salts are formed. These properties enabled the author to confirm the results of other authors.

The author describes the crystalline forms of the various salts, showing that the corresponding salts of each series have the same form. Thus the nitrato-sulphates, bromo-sulphates, and iodo-sulphates of luteo-chromium and luteo-cobalt, and roseo-chromium and roseo-cobalt, all crystallise in regular octohedrons, and the sodium pyrophosphate and sulphato-platinochloride double salts crystallise alike in bright regular six-sided plates. The platinobromides ($3PtBr_4$) of luteo-chromium and roseo-cobalt form copper-coloured precipitates of quadratic or eight-sided plates. The platinobromides ($2PtBr_4$) of luteo-cobalt and roseo-cobalt are indistinguishable, both forming long bright four- or six-sided needles, having the appearance of crystals of chromic anhydride. The mercurio-chlorides ($6HgCl_2$) in all cases form long narrow four- or six-sided needles. The ferricyanides and cobalticyanides of roseo-cobalt, roseo-chromium, and roseo-rhodium cannot be distinguished under the microscope from the corresponding luteo-cobalt and luteo-chromium salts. The auro-bromo-sulphates of roseo-cobalt, roseo-chromium, roseo-rhodium, luteo-cobalt, and luteo-chromium show dichroïsm, the colours being deep violet-blue and bright olive-green. The auro-chloro-sulphates of luteo-cobalt and roseo-cobalt are also, but in a much smaller degree, dichroic. If the nitrates of luteo-chromium or luteo-cobalt in dilute solution are precipitated by concentrated nitric acid, they crystallise in long narrow needles; if in concentrated solution by dilute nitric acid, they crystallise in quadratic plates or pyramids. The roseo-salts behave in a precisely similar way, only that in the roseo-chromium and roseo-cobalt salts the prism form predominates; in the roseo-rhodium salts, the plate form.

The luteo- and roseo-salts also resemble each other in their formation, and the author has already shown this (*J. pr. Chem.*, 23, 229). The most convenient way to prepare roseo-salts is to treat the purpureo-salt with alkalis, such as silver oxide and water, or soda, or dilute ammonia. By using concentrated ammonia and taking precautions to prevent evaporation, luteo-salts are formed, as Mills has shown (*Phil. Mag.* [4], 35, 245).

On treating roseo-haloïd salts with the haloïd acids, the corresponding purpureo-salts are formed. This property does not belong to the luteo-cobalt haloïd salts, but is possessed by the luteo-chromium salts. Luteo-chromic chloride, even with cold concentrated hydrochloric acid, forms chloropurpureo-chromic chloride. The bromide changes in the same way, more slowly with hydrobromic acid, but the action of hydriodic acid on the iodide is very slight. The author enumerates numerous other points in which the two series of salts agree. For example, many luteo- and roseo-salts are precipitated by acids with complete double decomposition (in contradistinction to the purpureo-salts); both luteo- and roseo-sulphates are capable of forming double salts, in which $1SO_4$ is replaced by $2NO_3$, $2Cl$, $2Br$, $1PtCl_6$, $1PtBr_6$, $2AuCl_4$, or $2AuBr_4$; both luteo- and roseo-nitrates form double salts, in which $4NO_3$ are replaced by $2PtCl_6$; both luteo- and roseo-chlorides form double salts with $2HgCl_2$ and $6HgCl_2$; and both form three double salts with platinic chloride containing 1, 2, or 3 $PtCl_4$.

The chief difference in properties between roseo- and luteo-salts is that roseo-salts (when not combined with mercuric chloride, platinic chloride, &c.) are dissolved by ammonia with formation of basic salts. Luteo-salts are not decomposed by ammonia, and are less soluble in it than in water.

The author proposes the following structural formulæ for these salts:—

$$\begin{array}{cc}
R_2\left\{\begin{array}{l} H_2O,X \\ H_3N,H_3N,X \\ H_3N,H_3N,H_3N,X \\ H_3N,H_3N,H_3N,X \\ H_3N,H_3N,X \\ H_2O,X \end{array}\right. & \qquad R_2\left\{\begin{array}{l} H_3N,X \\ H_3N,H_3N,X \\ H_3N,H_3N,H_3N,X \\ H_3N,H_3N,H_3N,X \\ H_3N,H_3N,X \\ H_3N,X \end{array}\right. \\
\text{Roseo-salts.} & \qquad \text{Luteo-salts.}
\end{array}$$

In these formulæ H_2O^{IV} has the same function as H_3N^{V}. The luteo-salts are therefore primary amines, the purpureo-salts partly primary amines and partly metallic salts, and the roseo-salts partly primary amines and partly primary *oxines*, that is, compounds containing tetrad oxygen, corresponding to the sulphur in the sulphines. The author states the grounds on which he bases this. A. B.

Mineralogical Chemistry.

Elasticity of Crystals of the Regular System. By K. R. KOCH (*Jahrb. f. Min.*, 1884, 2, Ref., 156).—The author has already determined the coefficients of elasticity of rock salt; he has now extended his observations to sylvine and sodium chlorate. The final results are—

	E_1.	E_2.	$\frac{E_1}{E_2}$.
KCl	4010	2088	1·92
NaCl	4030	3395	1·19
$NaClO_3$	4047	3190	1·27

The coefficients E_1 and E_2 are expressed in $\frac{\text{kilogram}}{\text{square mm.}}$. E_1 was determined from the deflection of rods, the longitudinal axis of which was perpendicular to the face of the cube, E_2 from rods perpendicular to the face of the dodecahedron. The results in the case of $NaClO_3$ are only provisional; those for sylvine, on the other hand, are exact to 0·5 per cent., from numerous observations on 15 rods from three crystals, so that the author concludes that the coefficient of elasticity of sylvine for a given direction is always the same. B. H. B.

Dilatation of Crystals on Change of Temperature. By L. FLETCHER (*Jahrb. f. Min.*, 1884, 2, Ref., 153—154).—With the view of testing the author's theory of the possible want of permanency of the thermic axes, Beckenkamp made measurements of the angles of anorthite, axinite, and orthoclase at temperatures of 20°, 80°, 140°, and 200°. From these measurements he deduced the positions of the thermic axes. He found that, whilst the variation in the case of axinite and orthoclase is within the limit of experimental errors, in the case of anorthite, the axis of minimum expansion for 20—80° forms an angle of 26½° with the corresponding axis for 20—200°. An examination undertaken by the author to test this remarkable result shows it to be due to experimental error. B. H. B.

Isomorphous Minerals which are not Chemically Analogous. By C. RAMMELSBERG (*Jahrb. f. Min.*, 1884, 2, Mem., 67—74).—Among minerals, especially among silicates, groups occur, the members of which have the same or nearly the same crystalline form, or, in other words, are isomorphous. Their constitution in some instances is perfectly analogous, whilst in others this is not the case. The latter are of special interest, as it is usually thought that isomorphous bodies must have an analogous constitution, or, in fact, that analogous constitution is the basis of isomorphism. To the silicate groups, the members of which have an analogous constitution, belong the olivine group, the augite group, the garnet group, the tourmaline group, and the group comprising epidote and vesuvian. Silicate groups, however, exist in which, notwithstanding the similar form, the constitution is not analogous. In the felspar group the difference extends from the mono- to the tri-silicates. By Tschermak's law, the nature of the lime-soda felspars is rendered clear. From the ratio $\cancel{Al}$: Si may be deduced that of Na : Ca. The two members are known from the molecular mixture of which each intermediate member is produced. It is thus shown that silicates, the constitution of which is not analogous, can be isomorphous. In the mica group, the members of which have certainly one and the same form, the constitution varies to a small extent. They are partly dibasic silicates, and partly combinations of the latter with normal silicates. The preceding remarks are supported by examinations of the groups of scapolite, chabasite and phillipsite, and they tend at the same time to show how certain chemical ideas are entirely misunderstood by many mineralogists.

Sjögren has recently described a manganese arsenate from Nordmarken, which he calls allactite, and which has the form of vivianite and cobalt-bloom, but contains 4 mols. less H_2O and 4 MnO more. Instead of writing $\left\{\begin{matrix} Mn_3As_2O_8 \\ 4MnH_2O_2 \end{matrix}\right\}$, he represents the 4MnO as replacing $4H_2O$, in order to explain the isomorphism by analogy. He should properly have written—

$$\begin{aligned} \text{Vivianite} &= H_{16}Fe_3P_2O_{16} \\ \text{Allactite} &= (H_8Mn_4)Mn_3As_2O_{16}. \end{aligned}$$

Forty years ago Hermann enunciated the law that among isomorphous compounds not of analogous constitution there are always two terminal members, from the mixture of which, in various proportions, all the others are produced. This theory has never been largely adopted, as it is based on hypotheses which cannot be proved by experiment. Tschermak's law, however, is of great scientific value, and it would not be less important to prove similar laws for other groups in which similar form is accompanied by dissimilar constitution. For this purpose, it would, however, be necessary for the two terminal members to be actually known. Unfortunately Tschermak himself, in a memoir recently published, regards the minerals belonging to the scapolite series as mixtures of two terminal members—a lime-alumina silicate and a soda-alumina silicate. The former he calls meionite-silicate, $Ca_4\cancel{Al}_3Si_6O_{25}$, and regards it as a combination of 5 mols. dibasic with 1 mol. tribasic silicate. This compound has not yet been discovered, as meionite itself contains a certain amount of the second terminal member, which he calls marialite-silicate, and regards as a compound of $2NaCl + 3(Na_2\cancel{Al}Si_6O_{16})$, in which the second member has the formula of albite. As he adopts the formula $Na_8\cancel{Al}_3Si_{18}O_{48}Cl_2$, he assumes that the O is replaced by Cl_2. If the silicate and chloride compounds are regarded in this way, the following results are obtained for sodalite:—

$$\mathrm{A}\left\{\begin{matrix}\mathrm{2NaCl}\\ \mathrm{3Na_2\cancel{Al}Si_2O_8}\end{matrix}\right\} = \mathrm{Na_8\cancel{Al}Si_6O_{24}Cl_2}.$$

$$\mathrm{B.}\left\{\begin{matrix}\mathrm{NaCl}\\ \mathrm{2Na_2\cancel{Al}Si_2O_8}\end{matrix}\right\} = \mathrm{Na_{10}\cancel{Al}_4Si_8O_{32}Cl_2}.$$

In other words, the sodalites A (Greenland, Ischia, Salem, Litchfield, Vesuvius) consist, like the meionite-silicate, of 5 mols. bibasic and 1 mol. tribasic silicate, whilst the sodalites B (Ditro, Bolivia) must contain 7 and 1 mol. respectively. The formula of apatite transposed in the same way would no longer represent a phosphate. All scapolites too must contain chlorine, which is not the case. The marialite mixture containing 4·2 per cent. chlorine is, however, up to the present time merely hypothetical. In just the same way, Fresenius traced the members of the phillipsite group from two terminal members, one of which is desmine and the other an hypothetical hydrate of the anorthite mixture. Still more arbitrary is his theory of two such terminal members in the chabasite group, as neither of them have, up to the present time, been shown to exist.

B. H. B.

Mineralogical Notes. By V. v. ZEPHAROVICH (*Jahrb. f. Min.*, 1884, **2**, Ref., 157—159).—The author gives an account of several new and interesting occurrences of minerals at localities in the Tyrol, formerly unknown in this respect. The minerals from the Zillergrund described are: harmotome, scolezite and adularia, desmine, and calcite. The minerals from the Stillupp Valley are: apatite, pericline, titanite, rutile, and laumontite. B. H. B.

Sulphur from the Fumaroles of Montecito in the Island of Ischia. By A. OGLIOLORO (*Gazetta*, **14**, 30—31).—During the observations which the author made on the gaseous emanations of Ischia, he noticed in the fumarole of Montecito, near Casamicciolo, some prismatic crystals of sulphur, apparently monoclinic, amongst those of the ordinary trimetric form. On making careful search in the same neighbourhood, he found some magnificent prismatic crystals of sulphur but little coloured and quite transparent; some of them 5 mm. long. He has submitted them to Scacchi for crystallographic measurement. C. E. G.

Cobalt-, Nickel-, and Iron-Pyrites. By L. W. McCAY (*Jahrb. f. Min.*, 1884, **2**, Ref., 161—163).—*Safflorite* from Schneeberg gave on analysis the following results:—

As.	S.	Ni.	Co.	Fe.	Bi.	Total.
66·33	0·16	27·76	0·64	trace	5·11	100·00

The radiated fibrous safflorite from Wolfgang Maasen, near Schneeberg, gave the following analytical results:—

As.	S.	Co.	Fe.	Ni.	Cu.	Bi.	Quartz.	Total.	Sp. gr.
65·02	0·49	16·00	11·20	trace	0·65	0·37	5·82	99·55	7·28

The safflorite from Bieber, the spathiopyrite of Sandberger (Abstr., 1884, 405) gave :—

As.	S.	Co.	Fe.	Ni.	Bi.	Cu.	Total.	Sp. gr.
68·27	1·30	13·12	14·38	1·88	1·24	0·26	100·45	7·26

From the author's investigations, it is clear that there is a rhombic modification of smaltine which only approaches to the formula RAs_2. The compact grey ferruginous and heavy varieties must also be regarded as rhombic modifications of smaltine. This rhombic modification was discovered by Breithaupt, whose name "safflorite" should consequently be retained.

Cheleutite.—This name was given by Breithaupt to bismuth-cobalt ore. The analyses of two specimens from Schneeberg gave :—

	As.	S.	Co.	Fe.	Ni.	Cu.	Bi.	Quartz.	Total.	Sp. gr.
I.	75·09	1·30	12·46	5·16	3·01	1·58	0·78	0·42	99·80	6·30
II.	45·30	1·10	8·42	3·08	2·18	0·72	trace	39·00	99·80	6·35

The author is of opinion that the mineral, which in composition and properties resembles skutterudite, does not belong to this species but to smaltine, as its specific gravity is so low. Under all circumstances, the name bismuth-cobalt ore must be dropped. If it is to have a special name, Breithaupt's name, cheleutite, is to be preferred.

Chloanthite from Schneeberg.—A specimen of ore described in the Freiberg collection as safflorite proved to be chloanthite, with the following composition :—

As.	S.	Ni.	Co.	Fe.	Bi.	Total.
68·40	1·06	24·95	4·20	0·69	0·21	99·51

The analysis of chloanthite from Schneeberg gave :—

As.	S.	Ni.	Co.	Fe.	Cu.	Total.	Sp. gr.
75·40	0·73	11·90	3·42	7·50	0·39	99·34	6·54

Formula R_2S_5.

Radiated mispickel, from Orawitza, formerly regarded by Breithaupt as glaucodote, and by Tschermak as alloclase, has the following composition :—

As.	S.	Fe.	Co + Ni.	Total.	Sp. gr.
45·19	19·80	33·60	1·40	99·99	6·05

Cobaltine from Schladming.—

As.	S.	Co.	Fe.	Ni.	Au.	Total.
43·12	18·73	29·20	5·30	3·20	trace	99·55

Arsenical pyrites from Hüttenberg (Hüttenbergite).—After the removal of 1·70 per cent. of bismuth, the following analytical results were obtained: —

As.	S.	Fe.	Total.	Sp. gr.
68 87	1·09	29·20	99·16	6·75

Smaltine from Schneeberg.—

As.	S.	Co.	Fe.	Ni.	Cu.	Total.	Sp. gr.
71·53	1·38	18·07	7·31	1·02	0·01	99·32	5·466

Geierite from Breitenbrunn ($7FeS_2 + 6Fe_5As_9$).

As.	S.	Fe.	Sp. gr.
61·40	6·73	31·20	31·20

Mispickel from Queropulca in Peru.—

As.	S.	Fe.	Cu.	Total.	Sp. gr.
42·54	20·96	35·03	0·47	99·00	6·069

B. H. B.

Mispickel from Auerbach. By G. MAGEL (*Jahrb. f. Min.*, 1884, 2, Ref., 166—168).—In the granular limestone of Auerbach, three different types of mispickel occur. The crystals belonging to type I are of rather frequent occurrence. They attain a size of 1—4 mm., sometimes 5—9 mm., and exhibit the usual simple forms of mispickel: ∞P, $\frac{1}{4}\breve{P}\infty$, $\bar{P}\infty$. Of these $\frac{1}{4}\breve{P}\infty$ predominates. The analysis gave the following percentage composition:—

S.	Fe.
20·339	35·812

Cleavage ∞P.

The crystals belonging to type II are extremely rare. They attain a size of 3—5 mm., sometimes 6—9 mm., and are columnar. The faces observed were the following: ∞P, $\frac{1}{2}\breve{P}\infty$, $\breve{P}\infty$, $\bar{P}2$, $\bar{P}\infty$, $2\breve{P}\infty$, and the new face $\frac{2}{3}\breve{P}\infty$. Cleavage along ∞P could not be observed; distinct basal cleavage. The mean of two analyses gave:—

S.	As.	Fe.	Total.
19·911	44·106	35·041	99 058

The mispickel of types I and II agree very well with the series of Arzruni and Baerwald (Abstr., 1884, 404):—

	Axis *a*.	S found.	S calculated.
Mispickel from Ehrenfriedersdorf....	0·67811	19·761	19·748
,, Auerbach (type II)..	0·67830	19·911	19·794
Plianian	0·67960	20·080	20·099
Mispickel from Sala................	0·68066	20·410	20·351
,, Auerbach (type I)....	0·68185	20·639	20·530
,, Joachimsthal........	0·68215	20·520	20·701

Type III is, unfortunately, only represented by a single specimen.

To two crystals crossing along $\bar{P}\infty$, a third is added according to the same law, forming a drilling. The crystals exhibit the faces $\frac{1}{2}\bar{P}\infty$, $\breve{P}\infty$, ∞P.
B. H. B.

Crystallised Voltzine. By G. CESARO (*Jahrb. f. Min.*, 1884, 2, Ref., 166).—On the surface of a mixture of blende and galena, the author found crystals resembling radiated antimony glance needles. They are flat, compressed, rectangular needles, bounded above by rhombic octahedra, translucent, of a pale orange colour, and with waxy lustre. The physical and chemical properties are those of blende, except that the crystals contain rather less sulphur. The author supposes that the mineral is either a pseudomorph of blende after antimony glance, or, as is more probable, crystallised voltzine.
B. H. B.

Occurrence of Iron in Mexico. (*Dingl. polyt. J.*, 252, 527.)—In the province of Durango, the so-called Cerro de Mercado iron mountain occurs, which is 1100 m. long, 335 m. wide, and 195 m. high, and represents a mass of about 200 million tons of ore. The ore which exists under this mountain is said to contain more iron than the quantity obtained in England during 350 years. The following analysis gives the average composition of this ore:—

Fe_3O_4.	FeO.	MnO.	TiO_2.	CaO.	MgO.	SO_3.
2·071	77·571	0·113	0·710	5·050	6·364	0·212

P_2O_5.	SiO_2.	Loss on ignition.	Other ingredients.
3·041	7·760	1·984	1·124

The pig iron produced from this ore contained 0·771 per cent. silicon, 0·428 per cent. sulphur; the bar iron showed 0·105 per cent. silicon and 0·193 per cent. phosphorus.
D. B.

Pitchblende and Xenotime from Norway. By W. C. BRÖGGER (*Jahrb. f. Min.*, 1884, 2, Ref., 170—171).—*Pitchblende from Moss.*—The forms observed were: O, and ∞O. Colour black; streak greenish-black. H. = 6. Sp. gr. 9·03. The analysis gave the following results:—

SiO_2.	UO_3.	UO_2.	PbO.	FeO.	CaO.	H_2O.	Total.
0·31	38·23	50·42	9·72	0·25	0 21	0·70	99·84

corresponding with the formula $R_5O_{12} = 3RO_2 + 2RO_3$.

Xenotime occurs frequently in many pegmatite veins in various parts of Norway. The occurrence at Narestö, near Arendal, is especially remarkable. It there forms aggregates on chloritic magnesia mica. The dark brown crystals exhibit the forms P, ∞P, 3P3. Xenotime may easily be distinguished from monazite, which accompanies it, by its prismatic cleavage. The character of the double refraction of xenotime is positive.
B. H. B.

A Uranium Mineral from Moss, and on the Occurrence of Uranates Generally. By C. W. Blomstrand (*J. pr. Chem.* [2] 29, 191—228).—The mineral, which was found at Ånneröd, in the vicinity of Moss in Norway, is iron-black in colour, sp. gr. 8·73, hardness 5—6. Fracture, splintery. The following results were obtained on analysis:—

U_3O_8.	SiO_2.	PbO.	ThO.	CeO.	YO.	FeO.	CaO.	H_2O.
80·97	0·81	8·41	5·64	0·38	2·42	1·26	0·30	0·83 = 101·02

The mineral, which has been named bröggerite by the author, is closely related to cleveite The author points out that, according to our present knowledge, the natural uranates, of which pitchblende may be taken as the type, are built up according to the formula $3RO,UO_3$, in which the uranic oxide uniformly appears as an ortho-acid, whilst the basic portion of the molecule is principally composed of uranous oxide, the latter being, however, always partially replaced by lead or some kindred metal. For true pitchblende or uranine the most probable formula is shown to be $7UO_2,PbO,5UO_2 = U_7Pb(UO)_5$ or $UPbO_6U + 2U_3(O_6U)_3$. Of the thoruranines there are two forms known—(1) bröggerite, for which the formulæ $UO_2,RO,UO_3 = URO_6U$, or $6URO_6U + U_3(O_6U)_2$ are suggested; and (2) cleveite, $UO_24RO,2UO_3 + 4aq = UR_4(O_6U)_2 + 4aq$. P. F. F.

Herderite. By A. Weisbach (*Jahrb. f. Min.*, 1884, 2, Mem., 134—136).—The analysis of a specimen of herderite from Ehrenfriedersdorf, in the collection of the Freiberg School of Mines, gave the following results:—(I.) The results obtained by Hidden in the analysis of herderite from Stoneham, Oxford Co., Maine (Abstr., 1884, 827), are added (II.)—

	CaO.	Be_2O_3.	Al_2O_3.	Fe_2O_3.	P_2O_5.	Loss.
I.	34·06	8·61	6·58	1·77	42·44	6·54
II.	33·21	15·76	—	—	44·31	6·72

The herderite from Stoneham has also been analysed for the author by Winkler, who found in 101·7 mgrms.—

CaO.	Be_2O_3.	Al_2O_3.	Fe_2O_3.	P_2O_5.	H_2O.	Total.
33·67	14·84	2·26	1·18	41·51	6·59	100·05

For the substance free from aluminium and iron the formula would be: $Ca_8Be_4P_6O_{27} + 4H_2O$, demanding—

CaO.	Be_2O_3.	P_2O_5.	H_2O.
34·13	15·34	43·23	7·30

B. H. B.

Richellite. a New Mineral Species. By G. Cesàro and G. Despret (*Jahrb. f. Min.*, 1884, 2, Ref., 179).—At Richelle, near Visé, a mineral occurs which has the following composition:—

P_2O_5.	Fe_2O_3.	Al_2O_3.	CaO.	H_2O.	HF.	Total.
28 78	28·71	1·81	5·76	29·43	6·11	100·60

On heating it, the substance suddenly gave off fumes of hydrofluoric acid, changing from its original bright yellow colour to a brownish-red, and no longer contained any fluorine. The authors, therefore, conclude that fluorine was not present as CaF_2. The mineral, formerly regarded as a variety of delvauxite, is, therefore, new. It forms bright yellow masses, with resinous lustre. H. = 2—3. Sp. gr. 2. Its tenacity is very weak. The water given up at 100° (23·33 per cent.) is free from hydrofluoric acid. Before the blowpipe, it fuses easily to a black, slightly magnetic enamel. It is easily soluble in acids, and gives a distinct fluorine reaction. The mineral is associated with halloisite, allophane, and a greenish iron phosphate. The authors calculate from their analyses that richellite contains 2 mols. P_2O_5, 2 mols. R_2O_3, 1 mol. CaO, 3 mols. HF, and 16·6 mols. H_2O, and they are of opinion that the fluorine is combined with iron.

B. H. B.

Natural Hydrous Double Sulphates. By J. BLAAS (*Jahrb. f. Min.*, 1884, 2, Ref., 163—165).—In the neighbourhood of Madeni Zakh, in Persia, the hydrous double sulphates, voltaite, metavoltine, and botryogen occur as decomposition-products of a trachytic rock containing iron pyrites.

Voltaite.—The crystals appear to be regular, with the combination O, $\infty O \infty$, ∞O, mOm. Colour greenish-black. Streak greyish-green. Fracture conchoidal. Greasy lustre. Brittle. H. = 2—3. Sp. gr. 2·6. Soluble with difficulty in cold water. The analysis gave the following results:—

SO_3.	Fe_2O_3.	Al_2O_3.	FeO.	MgO.	K_2O.	Na_2O.	H_2O.	Total.
49·12	13·85	3·72	5·24	7·35	2·37	1·62	16·60	99·87

Formula $3Al_2O_3,7Fe_2O_3$. This analysis does not exactly agree with the analyses of voltaite by Abich and Tschermak.

Metavoltine.—System hexagonal. Colour sulphur-yellow. H. = 2·5. Sp. gr. 2·53. The analysis gave the following results:—

SO_3.	Fe_2O_3.	FeO.	K_2O.	Na_2O.	H_2O.	Total.
46·90	21·20	2·92	9·87	4·65	14·58	100·12

Molecular proportion of $SO_3 : Fe_2O_3 : RO : H_2O = 13 : 3 : 5 : 18$; RO being $3FeO,7K_2O,5Na_2O$. From this the formula

$$5RO.3R_2O_3.12SO_3+18H_2O$$

is deduced.

Botryogen forms compact, crystalline masses of brownish-violet colour and glassy lustre. Streak violet-white, brittle, transparent in thin plates. H. = 2·5. Sp. gr. 2·138. Soluble in cold water to a brownish-violet solution. On the addition of sulphuric acid the colour disappears. The analysis gave:—

SO_3.	Fe_2O_3.	FeO.	MgO.	H_2O.	Total.
40·95	20·50	4·12	3·59	30·82	99·98

Formula $RSO_4 + Fe_2(SO_4)_3 + 13H_2O$, in which R = 5Fe,7Mg.

This analysis agrees with the composition of roemerite, except that in the latter R is replaced by 2Zn,7Fe, and that the percentage of H_2O is also rather smaller. The author consequently regards botryogen and roemerite as identical.
B. H. B.

Conversion of Rutile into Ilmenite. By A. v. Lasaulx (*Jahrb. f. Min.*, 1884, 2, Ref., 165—166).—The author describes the pseudomorphs of titanic iron after rutile from Vannes. The alteration begins by the addition of FeO, and the separation of $FeTiO_3$, more FeO subsequently enters the isomorphous mixture with the $FeTiO_3$, and titanic iron is finally formed containing more Fe_2O_3 than FeO. The author supposes that $FeTiO_3$ is replaced by Fe_2O_3, and that every variety of titanic iron could be formed in this way. He therefore regards all titanic iron produced in the same way from rutile as isomorphic mixtures of $m(FeTiO_3)$ and $n(Fe_2O_3)$, and not as mixtures of Fe_2O_3,Ti_2O_3. Probably, two varieties of titanic iron must be distinguished: (1) original $(FeTi)_2O_3$; and (2) $FeTiO_3$, of undetermined crystalline form, originating from rutile.
B. H. B.

Melanophlogite. By G. Spezia (*Jahrb. f. Min.*, 1884, 2, Ref., 177—178).—Minute cubes and crystalline aggregates of melanophlogite occur implanted on a thin coating of opal covering sulphur crystals from Sicily. The cubes become black on the surface when heated. This black colour is due to carbon. Melanophlogite also occurs, like the opal, covering sulphur crystals, or in the form of small stalactites; an analysis of the latter form was made with 0·1196 gram, the results being as follows:—

SiO_2.	SO_3.	C.	Fe_2O_3.	Loss on ignition.
89·46	5·60	1·33	0·25	2·42

B. H. B.

The Felspars of Pantelleria. By H. Förstner (*Jahrb. f. Min.*, 1884, 2, Ref., 171—176).—The volcanic island of Pantelleria consists of (1) phonolites and liparites in beds; (2) rocks of the oldest crater, consisting of older and more recent augite-andesites; (3) rock of the most active period of eruption; pantellerite, a dacite-like rock with triclinic felspar. Most of the felspars described are from this rock. (4) Rock of the most recent craters, felspar-basalt. The trachytic rocks of the island are very rich in felspar. The felspar crystals frequently separate out by weathering. Among these, orthoclase crystals are rare; they all have a larger percentage of sodium than usual, whilst a larger percentage of potassium is met with in the plagioclase. The paper gives elaborate details of the crystallographic and optical characters of the following felspars: (1) monoclinic felspar (soda orthoclase) from the white liparite of the Lake Bagno dell' Aqua, and from Cala Porticello; (2) triclinic felspars (microcline albite series). These occur in the rocks which are more recent than liparite, and which contain no orthoclase. The felspars described in detail are plagioclase from the older augite-andesite, plagioclase from the augite-andesite lava, and plagioclase from the pantellerite lava.
B. H. B.

Rubellan. By M. W. Hollrung (*Jahrb. f. Min.*, 1884, 2, Ref., 168—170).—The crystals of rubellan from the basalt-lava of the Laacher See are of a reddish-brown colour, and variable in their physical properties. Sp. gr. 2·50—2·86. They cleave easily in one direction, and all are optically biaxial. The microscopic examination shows that rubellan is not a purely homogeneous substance, but contains inclusions of various kinds. The chemical analysis of three specimens gave the following results:—

	SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MgO.	K_2O.	Na_2O.	H_2O.	Total.
I.	35·90	0·65	15·34	27·69	3·24	11·31	1·59	1·38	3·31	100·41
II.	36·97	0·80	17·94	22·81	1·50	11·97	1·60	1·42	3·61	98·62
III.	37·09	1·24	17·02	25·96	1·19	11·53	2·01	0·38	4·66	101·08

Hot hydrochloric acid, after 15 hours' action, dissolved:—

	I.	III.
Al_2O_3........	14·83 per cent.	17·74 per cent.
Fe_2O_3	30·18 ,,	22·31 ,,
MgO........	12·13 ,,	11·61 ,,

The mica substance always contained a quantity of iron-ochre. A constitutional formula cannot be calculated for rubellan, as it is not homogeneous, but merely an alteration-product of mica or augite.

B. H. B.

Synthesis of Pyroxene. By C. Doelter (*Jahrb. f. Min*, 1884, 2, Mem., 51—66).—The assumption by silicates of the form $R''R'''_2SiO_6$ explains very satisfactorily the complicated constitution of the pyroxenes, and has, on that account, been largely adopted. No exact evidence for it, however, exists. It is of interest, therefore, to investigate experimentally the question whether, by fusing together diopside and Al_2O_3 or Fe_2O_3, pyroxenes may be obtained, the constitution of which cannot be explained by the assumption of the silicate $R''O,R'''_2O_3,SiO_2$, and, secondly, to find out whether those silicates crystallise, and whether they agree with pyroxene. All the experiments were effected in a Leclerq-Forquignon furnace in platinum crucibles with 4—6 grams of the substance. The result of the expements was that the silicates $R''O$, R'''_2O_3, SiO_2, which have, up to the present time, been regarded as purely hypothetical compounds, crystallise and exactly resemble in their properties the augites produced by the fusion of natural augites. With the exception of the solubility, which is generally greater than that of the augites produced in nature, these artificial products perfectly coincide with the natural augites, and consequently the theory, according to which such silicates are actually present in these natural augites, receives renewed support.

B. H. B.

Hydrated Double Silicate of Zinc and Aluminium. By G. Cesaro (*Jahrb. f. Min.*, 1884, 2, Ref., 177).—The author found a new mineral on smithsonite of unknown locality. It formed fibrous lamellar masses of yellowish-white colour, which could be scratched with the finger nail, and could be separated into fibres like asbestos.

The mineral has a silky lustre, is fusible to a white enamel, and gelatinises with nitric acid. The analysis gave the following results:—

SiO_2.	Al_2O_3.	ZnO.	CuO.	H_2O.	CaO.	CO_2.
20·1	13·9	47·0	trace	13·2	2·0	3 8

B. H. B.

Analysis of the Water of a Thermal Spring in the Island of Pantellaria. By G. BRIGNONE (*Gazzetta*, 14, 42—54).

Organic Chemistry.

Hydrocarbons from American Petroleum and their Derivatives. By G. LEMOINE (*Bull. Soc. Chim.*, **41**, 161—166).—Schorlemmer having isolated two isomeric octanes from American petroleum, the author has investigated the higher homologues in order to discover whether corresponding isomerides were present. The petroleum used in the investigation was a fraction obtained by distillation on the large scale, and having the mean density of the nonane studied by Pelouze and Cahours (0·74 at 15°). This liquid was submitted to a series of fractional distillations in Le Bel and Henninger's apparatus. The fractions were purified from olefines by treatment with bromine and subsequent distillation in a vacuum. The proportion of olefines present was about 30 per cent. The octane, nonane, and decane obtained in this way were substantially the liquids described by Pelouze and Cahours. Chlorine-derivatives of these hydrocarbons were obtained by the action of chlorine below 65°. The derivatives, after purification, were converted into the alcohols by heating them with alcoholic potassium acetate in sealed tubes at 156°. The acetate thus obtained was saponified with potash in the usual way, and the alcohol separated from the corresponding olefine by fractional distillation. The constants determined were boiling point, density, and vapour-density.

Octane.—This hydrocarbon and its derivatives have already been described by other investigators. In the present instance, the octane was isolated merely for the purposes of comparison. It was obtained by four distillations, and was not treated with bromine. B. p. 121° at 779 mm., 82° at 212 mm.; 63° at 110 mm., 31° at 27 mm. Pelouze and Cahours give 116—118° as the boiling point at ordinary pressures. The two octanes examined by Schorlemmer boiled at 119—122° and 122—125°. The density of the liquid was 0·732 at 12·1° (0·725 at 15°, Cahours). Vapour-density 4·03, determined at 179°. An analysis of the hydrocarbon showed that it contained 84·6 per cent. of carbon, 15·1 of hydrogen.

Nonane.—Prepared by seven distillations of the original petroleum and subsequent treatment with bromine, followed by five distillations in a vacuum. B. p. 135—137°; sp. gr. 0·742 at 12·4° (0·741 at 15°, Cahours); vapour-density 4·59, determined at 180°. An isomeride was obtained by ten fractional distillations, followed by two successive treatments with bromine and five fractional distillations in a vacuum. B. p. 129·5—131·5°; sp. gr. 0·743 at 0°, 0·734 at 12·7°, 0·731 at 16°, 0·725 at 24·7° (0·741 at 15°, Cahours); vapour-density 4·47, determined at 190°.

Monochlorononane.—This was prepared from the second isomeride (b. p. about 132° at 759 mm.; sp. gr. 0·730 at 23·8). B. p. 180—184° (196° with partial decomposition, Cahours); sp. gr. 0·911 at 23·3°, 0·908 at 25·8 (0·899 at 15°, Cahours); vapour-density taken at 231·6° with partial decomposition, 5·94.

Nonylic Alcohol.—This was prepared from a nonane boiling between 130—135°. B. p. 186—189°. (The alcohol—b. p. 200°—examined by Pelouze and Cahours was prepared from nonane boiling at 136—138°). Sp. gr. 0·855 at 18·5°. An ultimate analysis gave C 75·7 per cent., H 13·3 per cent.

Nonylene.—This body was separated from the alcohol by fractional distillation. B. p. 133—136° (140° Wurtz); sp. gr. 0·853 at 18·4°. This olefine is isomeric with that obtained from metaoleic acid (b. p. 110°) by Fremy.

Decane.—Obtained by 15 fractional distillations of the petroleum, and purification of the liquid by bromine, followed by two distillations in a vacuum. B. p. 151—160° at 757 mm., 67·5° at 36 mm. (at the ordinary pressure 160°, Pelouze and Cahours; 155—157°, Wurtz; 155—160°, Cloëz); sp. gr. 0·764 at 0°, 0·753 at 15·6, 0·751 at 17°, 0·739 at about 35·5 (0·757 at 15°, Cahours; 0·760 at 15°, Cloëz); vapour-density 4·95, determined at 200·7°.

Monochlorodecane.—This was prepared from the decane just described (b. p. 155°). B. p. 201—203° (200—204°, Pelouze and Cahours); sp. gr. 0·908 at 19°.

Decylene.—Monochlorodecane, purified by three fractionations, was heated for 17 hours at about 110° with an excess of alcoholic potash. The product was treated with water, the hydrocarbon dried by calcium chloride, and rectified by distillation. B. p. 159—174° (158—160°, Pelouze and Cahours); sp. gr. 0·855 at 14°.

Decylic Alcohol.—This was prepared by the general method from monochlorodecane, and was separated from decylene by fractional distillation. After two rectifications, it boiled at about 200°. Sp. gr. 0·858 at 18·5°. A combustion gave C 76·1, H 14·2.

The author intends to verify and complete these results, using another specimen of petroleum. The hydrocarbons described above appear to be isomeric with those obtained by Krafft from the fatty acids.

W. R. D.

Chlorine-derivatives of Dibromodinitromethane. By S. N. Losanitsch (*Ber.*, **17**, 848—849).—It has been shown previously that dibromodinitromethane reacts with alkaline hydroxides to form salts; thus $CBrK(NO_2)_2$ is formed with potassium hydroxide (Abstr., 1883, 564). Chlorine passed through an aqueous solution of this compound causes the separation of *chlorobromodinitromethane*, $CBrCl(NO_2)_2$, as an oil. By the action of potash on this in alcoholic solution, the crystalline compound $CClK(NO_2)_2$ is formed: by passing chlorine into its aqueous solution, it is converted into *dichlorodinitromethane*, $CCl_2(NO_2)_2$, an oily body, first described by Marignac. H. B.

Higher Homologues of Acetylene. By F. KRAFFT (*Ber.*, **17**, 1371—1377).—The author has previously described a number of higher members of the paraffin series (Abstr., 1882, 1271), and of the olefine series (this vol., 572), prepared in a state of purity by synthetical methods. From the higher olefines he now obtains the corresponding members of the acetylene-group as follows:—The olefine is dissolved in several times its weight of carbon bisulphide, cooled by a freezing mixture, and one molecular proportion of bromine diluted with carbon bisulphide added slowly and with constant shaking. The resulting dibromide, after evaporation of the carbon bisulphide, is heated with alcoholic potash in open vessels, precipitated by water, and again heated with alcoholic potash in closed vessels for four to five hours at 150°. The acetylenes prepared in this way may be purified by two to three distillations under reduced pressure. They combine eagerly with bromine.

Dodecylene dibromide, $C_{12}H_{24}Br_2$, is a colourless liquid of faint odour, it can be solidified by means of liquid sulphurous anhydride, and then melts at — 15°. *Dodecylidene*, $C_{12}H_{22}$, is a colourless liquid, boils at 105° under 15 mm. pressure, and can be solidified by strong cooling, and then melts at — 9°. Its sp. gr., compared with water at 4°, is 0·8030 at 0°, 0·7917 at 15°, and 0·7788 at 32·5°.

Tetradecylene bromide, $C_{14}H_{28}Br_2$, melts at 0°. *Tetradecylidene*, $C_{14}H_{26}$, forms a crystalline mass, melts at + 6·5°, and boils at 134° under 15 mm. pressure. Sp. gr. = 0 8064 at 6·5°, 0·8000 at 15·2°, and 0·7892 at 30°.

Cetene bromide, $C_{16}H_{32}Br_2$, is a crystalline substance melting at 13·5°. *Hexadecylidene*, $C_{16}H_{30}$, crystallises in hard lustrous tables, melts at 20° and boils at 160° under 15 mm. pressure. Sp. gr. = 0·8039 at 20°, 0·7969 at 30°.

Octadecylene bromide. $C_{18}H_{36}Br_2$, crystallises in silvery tables, melts at 24°, and is sparingly soluble in alcohol. *Octadecylidene*, $C_{18}H_{34}$, crystallises in large plates, melts at 30°, and boils at 184° under 15 mm. pressure. Sp. gr. = 0·8016 at 30°.

The physical properties of these members of the acetylene series are compared in the following table:—

		Melting point.	Sp. gr. at the melting point.	Boiling at 15 mm.
Dodecylidene ..	$C_{12}H_{22}$	— 9°	d_{-9} = 0·8097	105°
Tetradecylidine.	$C_{14}H_{26}$	+ 6·5°	$d_{6\cdot5}$ = 0·8064	134°
Hexadecylidine.	$C_{16}H_{30}$	20°	d_{20} = 0·8039	160°
Octadecylidene.	$C_{18}H_{34}$	30°	d_{30} = 0·8016	184°

From this table it will be seen that the law put forward by the author as to the density of the normal paraffins and olefines immediately above the point of fusion (Abstr., 1882, 1272; this vol., 572), also holds good for the higher members of the acetylene series.

'Equal volumes of fused acetylenes have (very nearly) equal weights." In all three series a difference in composition of C_2H_4 is equal to a difference of about 35·7 in the molecular volume of the liquid immediately above its fusing point. A. J. G.

The so-called Rubeanhydric Acid (Cyanogen Bisulphydrate). By R. Wollner (*J. pr. Chem.* [2], **29**, 129—131).—The author has prepared this compound, $C_2N_2H_4S_2$, by passing dry cyanogen gas into an alcoholic solution of sodium sulphydrate; on adding hydrochloric acid, the cyanogen bisulphydrate is precipitated. If the solution, after treating it with cyanogen, is allowed to stand for some hours, decomposition takes place, and on adding hydrochloric acid no precipitate is obtained. The author considers the free acid to be an imido-derivative, $[C(NH).SH]_2$, of the as yet unknown thioxalic acid, $(CO.SH)_2$. J. I. W.

Action of Iodine on Potassium Seleniocyanate. By A. Verneuil (*Bull. Soc. Chim.* **41**, 18—20). Chlorine, bromine, and iodine act on an aqueous solution of potassium seleniocyanate forming red crystalline precipitates. The compounds are not easily isolated unless precautions be taken to avoid excess of the halogen. In studying the action of iodine on potassium seleniocyanate, the author uses a liquid containing 93 parts of iodine and 120 of potassium iodide dissolved in 100 parts of water. 15 c.c. of this liquid suffice to completely react with 10 grains of potassium seleniocyanate dissolved in 100 c.c. of water. As the iodine solution is gradually added, a red crystalline precipitate is thrown down; this is filtered off and the liquid allowed to stand without access of air when more crystals are deposited. The total yield is about 50 per cent. of the potassium seleniocyanate operated on. The crystals dried by pressure or over sulphuric acid contain selenium, cyanogen, potassium, water, and iodine. The latter, which is present to the extent of about 4 per cent., the author regards as an impurity from adhering cyanogen iodide. Leaving this out of consideration, the results lead to the formula $K(CN)_3Se_4,H_2O$. The other products of the reaction are potassium iodide and cyanogen iodide, both of which remain dissolved in the aqueous liquid. The decomposition is probably expressed by the equation $4KCNSe + 2I_2 + H_2O = K(CN)_3Se_4,H_2O + 3KI + CNI$. The new compound forms ruby-red crystals having an odour of hydrocyanic acid and hydrogen selenide. The crystals, when treated with water or exposed to moist air, are at once decomposed, producing principally potassium seleniocyanate and free selenium. When heated to 120°, they are decomposed, yielding potassium seleniocyanate, selenium, and cyanogen. The compound is insoluble in ether, chloroform, and carbon bisulphide. Admixture with absolute alcohol causes the deposition of selenium and the formation of a new body which remains in solution, but can be obtained in brown crystals by evaporating the liquid in a vacuum. This compound is potassium per-seleniocyanate, $K(CN)_3Se_3$. It is at once decomposed by water, but is dissolved by absolute alcohol. When this compound is heated, it yields potassium seleniocyanate, selenium, and cyanogen. W. R. D.

Preparation of Ethereal Salts by Double Decomposition. By G. Bertoni and F. Truffi (*Gazzetta*, **14**, 23—29). Bertoni had previously found (*Gazzetta*, 1882) that when amyl nitrite is digested with ethyl or methyl alcohol double decomposition takes place with formation of ethyl or methyl nitrite and regeneration of amyl alcohol. The authors in this paper give the results obtained with normal propyl alcohol (b. p. 97°) and isobutyl alcohol (b. p. 107°). The amyl nitrite employed was prepared from fermentation amyl alcohol boiling between 128° and 132°.

Propylic nitrite.—Amyl nitrite and propyl alcohol in molecular proportions were placed in a flask furnished with a four-bulb fractioning tube, and gradually heated, collecting the portion which came over below 64°; this, after being dried with fused calcium nitrate and submitted to fractional distillation, gave pure propyl nitrite (b. p. 57°), which was subsequently completely reconverted into propyl alcohol by digestion with methyl alcohol. It was found that 51·6 per cent. of the propyl alcohol was converted into the nitrite.

Isobutyl nitrite.—On heating a mixture of amyl nitrite and isobutyl alcohol in the manner described above, isobutyl nitrite was obtained boiling at 66—70°, the proportion of the alcohol converted, however, being only 37·8 per cent. in this instance. Several repetitions of these experiments were made, and from the results and those obtained in the former research, he deduces the following:—

Limit of the Formation of Nitrites by Double Decomposition.

Methyl alcohol = 100 per cent.
Ethyl „ = 85 „
Propyl „ = 52 „
Isobutyl „ = 37 „

The limit of etherification decreases with the molecular weight, and moreover this decrease is regular, for if we consider the difficulty of separating the whole of the propyl and isobutyl nitrites formed, it is more than probable that the numbers found are somewhat too low: if we make that for propyl alcohol 55 and for isobutyl alcohol 40, the limits become 100, 85; 55 and 40 per cent. respectively, and the differences 100 − 85 = 15; 85 − 55 = 30 = 2 × 15; and 55 − 40 = 15. The author also draws attention to the fact that the differences between the boiling points A of the alcohols, and of the corresponding nitrites B, is in almost every case 40°.

C. E. G.

Second Anhydride of Mannitol. By A. Fauconnier (*Bull. Soc. Chim.* **41**, 18—20). In addition to the reactions described in a former Abstract (Abstr., 1883, p. 305), the following have been investigated. The body appears to be isomeric with the mannide of Berthelot, and for this reason is called by the author *isomannide*. It is dextrorotatory, a solution in ethyl alcohol is more dextrorotatory than an aqueous solution, and the solution in methyl alcohol has a still greater rotatory action. Gaseous hydrochloric acid does not act on isomannide either in the cold or at 100°, even in presence of zinc chloride, but when an aqueous solution of the substance is saturated with the gas at 0°, and the liquid heated in a sealed tube for some days at 100° *mannitol dichlorhydrin*, $C_6H_{12}O_4Cl_2$, is formed. In addition to the diacetyl-derivative previously described, a mono-derivative, $C_6H_9O_3.\overline{Ac}O$, has been produced by the action of acetic chloride: it is a colourless liquid boiling at 185—187° under a pressure of 25 mm., insoluble in water, soluble in ether. When isomannide is heated with methyl iodide and concentrated potash solution, a monomethyl-derivative, $C_6H_9O_3.OMe$, is formed in crystals which melt at 44—45°. A diformic-derivative, $C_6H_8O_2(CHO_2)_2$, was obtained by the action of formic acid on isomannide. It forms crystals which melt at 115°, and are very soluble in warm alcohol, slightly in cold water, more so in ether. It is decomposed when distilled under the ordinary pressure, carbonic oxide being evolved and isomannide formed.

From the reactions of isomannide, the author concludes that it is a saturated body the molecule of which contains no doubly linked carbon-atoms. The two alcoholic hydroxyl-groups are not in the vicinity of one another. The other two atoms of oxygen are each united to two different carbon-atoms constituting two  $\vdots\underset{\diagdown O \diagup}{C\text{——}C}\vdots$ groups.

If it be admitted that the constitution of mannitol is symbolised by a symmetrical open chain, the following formula represents the reactions of isomannide—

$$OH.CH_2.\underset{\diagdown O \diagup}{CH\text{—}CH} : \underset{\diagdown O \diagup}{CH\text{—}CH}.CH_2.OH.$$

This formula however needs further confirmation by a study of the oxidation-products of isomannide of which so far only oxalic acid has been obtained. W. R. D.

Action of Cupric Hydroxide on Sugars. Part II. By J. Habermann and M. Honig (*Monatsh. Chem.*, **5**, 208—216). (See Abstr., 1883, 38).—*Galactose.*—This sugar was prepared according to Soxhlet's method (*J. pr. Chem.* [2], **21**, 269) from milk-sugar; clear proof was obtained that the second sugar formed at the same time was dextrose. In this, as in all other cases of oxidation with cupric hydroxide, the products were the same whether the oxidation was effected in neutral or alkaline solution, the presence of alkali merely accelerating the reaction. The products of the oxidation of galactose are carbonic anhydride, formic acid, a very small quantity of glycollic acid, a relatively larger quantity of lactic acid, and a non-volatile acid (or mixture of acids) insoluble in ether, whose calcium salt is amorphous and insoluble in alcohol.

With regard to the course of the reaction, the cupric hydroxide begins to be decolorised soon after the commencement of boiling; it had changed to yellowish-green in half an hour and in one hour to nearly pure reddish-yellow. Evolution of carbonic anhydride commences with the beginning of change of colour in the copper oxide, but at first there is not much evolved. With the portions of cupric hydroxide added later reduction is more quickly effected, and carbonic anhydride is copiously evolved.

With *milk-sugar*, the course of the reaction is similar to that observed with cane-sugar, inversion apparently preceding oxidation. The products are identical with those observed in the case of galactose, but the amount of glycollic acid formed exceeds that of the lactic acid.

With *maltose*, the reduction of the cupric oxide proceeds very quickly. Three stages can be observed in the reaction, the first evidently during inversion, the second and third similar to those seen in the case of grape-sugar. The products both in their qualitative and quantitative relations are identical with those from dextrose.

The oxidation of *Sorbin* occurs more quickly and energetically than that of any other sugar. The products are: 1, Carbonic anhydride in large quantity; 2, Formic acid in relatively large amount; 3, a very small quantity of a brown substance soluble in ether, and consisting of a mixture of an indifferent resinous substance with an acid whose barium salt forms a brown amorphous mass; and 4, an acid of the empirical formula $C_3H_4O_6$. This acid may possibly be glyceric acid, but the authors have not yet sufficient evidence to speak positively.

Mannitol and dulcite have no action on cupric hydroxide either in neutral or alkaline solution. A. J. G.

Rate of Reduction of Fehling's Solution by Sugars. By F. URECH (*Ber.*, 17, 1539—1543).—With a view to determine the composition of invert milk-sugar, the author has experimented on the rate of reduction of Fehling's solution by dextrose, levulose, invert sugar from saccharose, milk-sugar, invert milk-sugar, and various mixtures of the same. He concludes that invert milk-sugar must consist either of dextrose and galactose, or of lactoglucose and galactose. Which of these views is correct must be decided by determining the rate of reduction by galactose and by mixtures of dextrose with galactose. L. T. T.

Action of Alkalis on Invert-sugar, Dextrose, and Milk-sugar. By F. URECH (*Ber.*, 17, 1543—1547).—The action of alkalis tends to diminish the reducing power of these sugars.

L. T. T.

Birotation of Glucose and Milk-sugar. By F. URECH (*Ber.*, 17, 1547—1549).—The sparing solubility of milk-sugar in water makes the rapid determination of its birotary power difficult. The highest ratio the author has obtained is 1 : 1·62. With glucose at low temperatures, the author has obtained ratios up to 1 : 2·19. From a comparison of the results obtained with glucose and milk-sugar, he believes the birotation-ratio with milk-sugar would certainly be as much as 1 : 2, if it could be determined correctly. The rotation diminishes from the moment of solution, and the rate of diminution increases with rise of temperature. L. T. T.

Inversion of Cane-sugar. By W. Ostwald (*J. pr. Chem.* [2], **29**, 385—408).—The author has determined the velocity with which cane-sugar is inverted by various acids. The method of experiment was to take 10 c.c. of a solution of sugar (40—50 per cent.), and dilute it with 10 c.c. of a normal acid solution (1 equiv. per litre). The liquid was then heated at 25°, and at the end of each hour the amount of sugar inverted was estimated by the polariscope. The experiments were carried out with 32 acids, and the velocity of the reaction was found to vary with the different acids. The formula representing the progress of the reaction is the same as that found for the action of acids on methyl acetate (this vol., 581): $\log b - \log (b - x) = a . c . t$; where a represents the amount of the acid and

is constant, b the amount of sugar used, and x the amount of sugar inverted in the time t. The results found for the constant $a.c$ are in the case of each acid and each observation very close.

The relation between the constants of inversion and the affinities of the acids is well marked. In the table (p. 1113) is given, in the first column, the value for c in the case of each acid, referred to HCl = 100; in the second the square root of the number is given referred again to HCl = 100; and for comparison in the third column the square root of the velocity in the decomposition of methyl acetate.

The author also gives a table of the values of $\log \frac{b}{b - x}$ for all values of $\frac{x}{b}$ between 0·001 and 0·999 for the use of those who may wish to pursue similar investigations. A. B.

Action of Bromine in Alkaline Solution on Amines. Part V. By A. W. Hofmann (*Ber.*, 17, 1406—1412).—A continuation of the author's work on this subject (Abstr., 1882, 822, 950, and 1052). In the last paper, the formation of nitriles in this reaction was mentioned, the author being then of opinion that this was due simply to the elimination of water from the amide, but on examination of the nitrile it was found that it contained 1 carbon-atom less than the amide, that is, it corresponded to the amine formed in the reaction, and doubtless is derived from it by the removal of 4 hydrogen-atoms. The reaction was worked out most fully with the amide of nonylic acid; this, on treatment with bromine and alkali, yielded octylamine, octylnonoxylcarbamide, and octonitrile, the yield of the latter being from 25—30 per cent. On heating octonitrile with sulphuric acid it is converted into an octylamide (caprylamide), identical with that obtained from caprylic acid, or the acids derived from heracleum oil and from cocoanut oil; the identity of the two acids last named with caprylic acid being thus established. By treatment with alkali and bromine, octylamine can be converted, in part into heptylnitrile, and further by successive conversions into amide and nitrile, the successive amides and nitriles down to normal valeramide were prepared; scarcity of material then prevented the reaction being carried further. A. J. G.

Some New Alkines. By L. Berend (*Ber.*, 17, 510—512).—*Tetramethylallylalkine*, $C_3H_5(OH)Me_4N_2$, is obtained by heating symmetrical dichlorohydrin with dimethylamine; the product is treated with potassium hydroxide, and then extracted with chloroform. It is a liquid boiling between 170° and 185°. Its platinochloride crystallises in yellow, silvery leaflets, sparingly soluble in water. Its benzoylalkeine forms a platinochloride crystallising in orange-red tables, very little soluble in water.

Tetrethylallylalkine, $C_3H_5(OH)Et_4N_2$, obtained from diethylamine and symmetrical dichlorhydrin, is a colourless, highly refractive liquid boiling at 234·5°. It has a sp. gr. of 0·9002 (H_2O at 4° = 1), and is identical with that obtained by Reboul (Abstr., 1884, 578) from epichlorhydrin. Its platinochloride crystallises in prisms, soluble in water. The platinochloride of the benzoylalkeïne is obtained as an orange-coloured powder.

The *tetrethylallylalkine* obtained from unsymmetrical dichlorhydrin is a liquid; its aurochloride crystallises in leaflets, and is sparingly soluble in water. Its benzoyl-derivative forms a platinochloride crystallising in orange-red needles, and is more soluble in water than its isomeride.

Trimethylenediethylalkine, $C_7H_{17}NO$, obtained from trimethylenechlorhydrin and dimethylamine, is a colourless, strongly refractive liquid, having a sp. gr. 0·9199 at 4° and boiling at 189·5°. The author has prepared its platino- and auro-chlorides, also the platinochloride of the benzoylalkeine. P. P. B.

Acetoximes of the Fatty Series. By E. Spiegler (*Monatsh. Chem.*, **5**, 241—243; and *Ber.*, **17**, 1574).—These experiments were made to ascertain if ketones of high molecular weight behaved with hydroxylamine in a manner similar to those of low molecular weight. The result showed the nature of the reaction to be identical, although as was to be expected it proceeded more slowly. The ketones were dissolved in alcohol, mixed with an excess of hydroxylamine, and heated for some days on the water-bath.

Methylnonylacetoxime, $C_{11}H_{23}NO = C_9H_{19}.CMe:NOH$, prepared as above from methyl nonyl ketone, forms snow-white minute prisms or long slender needles, and melts at 42°.

Myristoxime, $C_{27}H_{55}NO = C(C_{13}H_{27})_2NOH$, prepared from myristone (dimyristyl ketone), is a white amorphous substance melting at 51°.

Stearoxime, $C_{35}H_{71}NO = C(C_{17}H_{35})_2NOH$, prepared from stearone (distearyl ketone), forms an amorphous substance similar in appearance to stearin, and melts at 62—63°. A. J. G.

Optical Rotatory Power of Leucine. By J. Lewkowitsch (*Ber.*, **17**, 1439—1440).—The author has found leucine in aqueous solution to be lævorotary, whilst in a recent paper Mauthner (*Zeits. Physiol. Chem.*, **7**, 22) states that leucine from caseïn is dextrorotary. In a private communication, Mauthner has since admitted that leucine is lævorotary in aqueous solution, whilst in acid or alkaline solution, on the contrary, it is dextrorotary. A. J. G.

Derivatives of Succinimide. By G. L. Ciamician and P. Silber (*Gazzetta*, **14**, 31—38; and *Ber.*, **17**, 553—559).—*Dichloromaleïmide* may be prepared by acting on succinimide with chlorine (*Gazzetta*, **13**, 413, and this vol., 292), but not more than 25 grains of the imide should be employed in each operation; the yield is 52 per cent. of the theoretical. When an alcoholic solution of dichloromaleïmide is allowed to evaporate spontaneously it is deposited in well-defined crystals belonging to the trimetric system; these have been measured by La Valle with the following results:—

$$a : b : c = 0{\cdot}99224 : 1 : 1{\cdot}59336.$$

Observed forms 001, 010, 100, 334, 111. Combinations the same. Cleavage easy, parallel to 001.

When dichloromaleïmide is heated with phosphorus pentachloride for 24 hours at 200°, and the liquid product poured into water and distilled in a current of steam, a compound, C_4Cl_7N, passes over along with some unaltered dichloromaleïmide, whilst resinous matters, dichloromaleïmide and dichloromaleic acid, remain in the retort. In order to separate the new substance from the imide which accompanies it, the oil is separated from the aqueous portion of the distillate and boiled two or three times with fresh quantities of water, using a reflux condenser; in this way most of the imide is dissolved out, and after a final distillation in a current of steam, the oil is allowed to solidify over sulphuric acid, pressed between paper and distilled under diminished pressure. It then forms a white opaline waxy mass, which melts at 70—73°, and distils without decomposition at 143—144° under a pressure of 20 mm., and at 261° at 754 mm. with partial decomposition. It is exceedingly soluble in alcohol, ether, and glacial acetic acid, but almost insoluble in boiling water. It is converted into tetrachloropyrroline, C_4Cl_4NH, by the action of zinc and hydrochloric acid. The authors assign to the new chloride C_4H_7N the constitution  $\left.\begin{array}{l} CCl_2.CCl_2 \\ | \\ CCl_2.CCl \end{array}\right\rangle N$, and remark that it closely resembles the perchloride of perchloropyrocoll (this vol., 292) both in chemical and in physical properties. The authors endeavoured to displace the chlorine in tetrachloropyrroline by hydrogen, but the results were not very satisfactory; sodium amalgam and acetic acid had no action, neither was any change produced by boiling it with zinc-dust and potash solution, unless the latter was very concentrated, and the action very prolonged; under these circumstances, however, an oil was obtained on distilling the product with steam, but of so unstable a character that it could not be distilled alone. When the compound C_4Cl_7N is heated with hydriodic acid and phosphorus, it is converted into a reddish-brown resinous matter, probably "pyrrol-red."

Dibromomaleïmide, $C_4Br_2O_2 : NH$.—By acting on succinimide with bromine, Kisielinski obtained monobromofumarimide, and a compound melting at 225° which he regarded as dibromosuccinimide. The authors have repeated Kisielinski's experiments, and find that the substance melting at 225° is really dibromaleïmide, as might be expected from the results obtained by the action of chlorine on succinimide. The most convenient way of preparing it is to allow bromine (25 grams) to drop slowly on the succinimide (10 grams) heated at about 160° in a retort; hydrobromic acid is evolved, and the residue, after being pulverised, is washed with water to remove monobromofumarimide, and crystallised two or three times from boiling alcohol with the aid of animal charcoal. It then yields the dibromomaleïmide in a state of purity: this is insoluble in water, but easily in ether and in boiling alcohol. Well developed crystals belonging to the monoclinic system are obtained by allowing an alcoholic, or still better an acetone solution of the substance to evaporate spontaneously. These have been measured by La Valle, who finds:—

$$a : b : c = 1·434208 : 1 : 0·964913$$
$$= 119·59°$$

Observed forms, 100, 101, 110, $\bar{1}11$.

Combinations, 100, 001, 110, $1\bar{1}1$; 100, 110, $1\bar{1}1$.

Cleavage perfect and easy parallel to 001.

Plane of the optic axes 010.

The dibromomaleïmide, when boiled with potash until ammonia ceases to be evolved, is decomposed with formation of *dibromomaleïc acid*, $C_4Br_2O_3$, which may be isolated by acidifying the aqueous solution with sulphuric acid and extracting with ether. It melts at 123—125°, and has all the properties of the acid obtained from succinic acid by Kekule, and from pyromucic acid by Hill. When distilled in a current of carbonic anhydride, it yields the corresponding anhydride; this melts at 114—115°, and is reconverted into the acid by boiling with water. The *barium salt*, $C_4Br_2BaO_4,2H_2O$, and the *silver salt* were prepared. C. E. G.

Action of Zinc Propyl and Zinc Isobutyl on Butyl Chloral. By K. Garzarolli-Thurnlackh and A. Popper (*Annalen*, **223**, 166—169).—Trichlorobutyl alcohol and propylene are formed by the action of zinc propyl on butyl chloral.

Trichlorobutyl alcohol is also formed when butyl chloral is acted on by zinc isobutyl. Zinc propyl and isobutyl resemble zinc ethyl in their action on butyl chloral. Zinc isobutyl boils at 166°, not at 186° as stated by Cahours. W. C. W.

Preparation of Chloral. (*Dingl. polyt. J.*, **252**, 343).—According to Page, a larger yield is obtained when the alcohol used for the preparation of chloral is treated with 5 per cent. ferric chloride or thallium chloride previous to the introduction of chlorine. The resulting liquid, consisting of a mixture of chloral, hydrate of chloral, and chlorinated ethanes, which can be separated by fractional distillation, is subjected to distillation, ferric chloride or thallium chloride remaining in the residue. The chlorinated ethanes which come over at a temperature above 100° are purified by fractional distillation, the mixture of chloral and hydrate of chloral is distilled over calcium carbonate, treated with the requisite quantity of water, and the resulting hydrate of chloral recrystallised from the chlorinated ethanes previously obtained. D. B.

Action of Acid Chlorides on Chloral Allylate. By V. Oliveri (*Gazzetta*, **14**, 13—14).—Oglioloro (*ibid.*, **4**, 463) regards chloral allylate —prepared by the action of allyl alcohol on chloral—as containing alcoholic hydroxyl, its constitution being expressed by the formula $CCl_3.CH(OH).O.CH_2.CH : CH_2$; other chloral alcoholates having analogous formulæ. In order to obtain evidence on this subject, the author submitted the allylate to the action of acetic and benzoic chlorides.

Acetic chloride acts on chloral allylate in the cold, but it is necessary to heat the mixture for a short time at 100° in order to complete the reaction. The product, after being washed with water, dried over calcium chloride, and purified by fractional distillation, is a colourless, oily, highly refractive liquid, which boils at 105° to 107°. The results of the analysis correspond with the formula

$$CCl_3.CH(O\overline{Ac})\ OC_3H_5,$$

The action of benzoic chloride is less energetic. and it is necessary to heat the mixture; the product is shaken with sodium carbonate solution to remove benzoic acid, rapidly separated, washed with water, dried, and distilled. The distillate is an oily liquid boiling at 225—227°, and has all the properties of allyl benzoate. In the case of benzoic chloride, therefore, it would seem that the reaction is

$$CCl_3.CH(OH).OC_3H_5 + \overline{Bz}Cl = \overline{Bz}O.C_3H_5 + CCl_3.CHO + HCl.$$

C. E. G.

Action of Zinc Ethyl and Zinc Methyl on Chlorinated Aldehydes. Part III. By K. Garzarolli-Thurnlackh (*Annalen*, **223**, 149—165).—*Methyl trichloropropyl carbinol*, $C_5H_9Cl_3O = CHMeCl.CCl_2.CHMe.OH$, prepared by the action of zinc methyl on butyl chloral diluted with ether, crystallises in silky needles which melt at 50·5°, and under a pressure of 41 mm., boils at 123°. It is soluble in alcohol and ether.

The *acetate* is a colourless liquid boiling at 227°. Its sp. gr. at 11·5 is 1·3048. The alcohol is oxidised by treatment with nitric acid, yielding carbonic anhydride and trichlorobutyric acid. On oxidation with chromic mixture, methyl trichloropropyl ketone boiling at 192° is formed. On further oxidation, the ketone splits up into acetic and hydrochloric acids and carbonic anhydride.

If the alcohol is treated with zinc and hydrochloric acid, or with iron powder and acetic acid, it is converted into methyl monochlorallyl carbinol, $C_5H_9ClO = CHMe\,\vdots\,CCl\,CHMe.OH$; this is a colourless liquid boiling at 158°, sp. gr. 1·08821 at 14·1°. It yields acetic acid and carbonic anhydride on oxidation. The acetate boils at 172° and the chloride at 143°. The chloride unites with bromine, forming *methyl-monochlorodibromopropyl-carbinyl chloride*, a heavy liquid boiling between 140° and 145° under 31 mm. pressure.

W. C. W.

Occurrence of Valerolactone in Pyroligneous Acid. By M. Grodzki (*Ber.*, **17**, 1369).—The author has isolated from the higher boiling fractions of crude pyroligneous acid a substance agreeing in all respects with the description of valerolactone given by Fittig and Messerschmidt (Abstr., 1882, 35). A. J. G.

Phosphine-derivatives of the Aldehydes. By A. de Girard (*Ann. Chim. Phys.* [6], 2, 1—66).—The close analogy between the hydrogen-derivatives of nitrogen and phosphorus, rendered closer by the recent discovery of phosphonium chloride and hydroxyl, points to the possible isolation of organic derivatives of phosphorus hitherto unknown.

With a view of preparing phosphorus analogues of the aldehyde-ammonias, the author has particularly studied the action of phosphonium iodide on the aldehydes. The products of the reaction are combinations of 4 mols. of the aldehyde with 1 mol. of phosphonium iodide, of which those of ethylic, propionic, valeric, and œnanthylic aldehydes are well-defined crystalline substances. These are designated by the names of *tetrahydroxethylidene-*, *propylidene-*, *amylidene-*, and *œnanthylidene-phosphonium iodides*.

Tetrahydroxethylidene-phosphonium iodide, $(CHMe.OH)_4PI$, obtained from parethaldehyde and phosphonium iodide, crystallises in white prisms, which gradually lose hydriodic acid. It is soluble in water and alcohol, insoluble in ether and chloroform. Its solutions give a maroon-coloured precipitate with copper sulphate, and a yellow precipitate with silver nitrate. It is converted by a concentrated solution of potash into the corresponding hydroxyl-derivative,

$$(CHMe.OH)_4P.OH,$$

crystallising in rhombohedric laminæ; this readily loses a molecule of water, being converted into a substance of the composition

$$(CHMe.OH)_3PIMe.COH,$$

an oily liquid, which on evaporation forms a confusedly crystalline mass. The liquid is soluble in water and alcohol, sparingly soluble in ether. It readily reduces potassium permanganate and solutions of silver salts, with formation of silver phosphate and acetate.

The corresponding derivatives of propaldehyde resemble those of ethaldehyde in their chemical and physical properties.

Tetrahydroxamylidene-phosphonium iodide, $(C_5H_{10}.OH)_4PI$, prepared from phosphonium iodide and valeraldehyde, crystallises in rhombohedric laminæ melting at 119°. It is converted by potash into the corresponding hydroxyl-derivative of the formula $(C_5H_{10}O)_3PH_4.OH$, which crystallises in white prisms melting at 125—126°, insoluble in water. The derivatives of œnanthaldehyde resemble those of valeraldehyde. Similarly chloral hydrate forms *dihydroxy-chloral-phosphine*, $(CCl_3.CHO)_2PH_3$, crystallising in small hard prisms, which melt at 143°. It is soluble in water and alcohol. It reduces salts of silver, and is decomposed by potash into hydrogen, hydrochloric, formic, and hypophosphorous acids. The corresponding butyl-derivative, $C_4Cl_3H_6O.PH_3$, crystallises in white prisms, which melt at 96°. It is soluble in alcohol and ether, and readily reduces salts of silver.

The products of the reaction of phosphonium iodide on isobutylic, benzoic, and salicylic aldehydes and acetone were also examined, but were not obtained in a sufficiently definite form. V. H. V.

Vapour-density of Tertiary Amyl Compounds. By N. MENSCHUTKIN and D. KONOWALOFF (*Ber.*, 17, 1361—1364).—In some experiments made by the authors on the decomposition and dissociation of the tertiary amyl compounds by heat, it was found that the nature of the substances in contact with the liquid or vapour exercised a very great influence on its dissociation. It was found, for instance, that amyl acetate gave the normal vapour-density in Hofmann's apparatus at 158°, whilst at the same temperature in a Victor Meyer's air-displacing apparatus, on the bottom of which was placed some asbestos to break the fall of the bottle containing the substance, the density was but little above half the normal, whilst on replacing the asbestos by mercury, or by using an empty apparatus, numbers only slightly below the normal were obtained. It was found that bottles with ground glass stoppers exerted a similar decomposing influence; even the difference in the amount of ground surface in two bottles having different sized stoppers caused a most marked difference in the vapour-densities determined by their aid under conditions otherwise identical. A. J. G.

Methyl-propyl-acetic Acid. By C. LIEBERMANN and S. KLEEMANN (*Ber.*, **17**, 918—921).—The methyl-propyl-acetic acid from saccharose (Abstr., 1883, 1078), although believed to be identical with Saytzeff's methyl-propyl-acetic acid (*ibid.*, 408), shows some points of difference. To confirm the identity, methyl-normal-propyl-acetic acid was prepared. Ethylic methyl-acetoacetate is heated with normal propyl iodide and sodium alcoholate, and on removing the alcohol and adding water an oil separates, boiling at 214°. This is the *ethylic* salt of methyl-normal-propyl-acetoacetic acid; its sp. gr. is 0·9585 at 15°. When heated with alkalis, it yields methyl-normal-propyl-acetic acid, an oily liquid boiling at 193—194°, and having a sp. gr. of 0·9217 at 25° (the acid from saccharose 0·9231, Saytzeff's 0·9227). Neither the free acid nor its derivatives act on polarised light, although they contain an asymmetrical carbon-atom. The lead salt is a heavy oil; only twice was it obtained crystalline, once in the form described by Saytzeff, and once as described by Liebermann and Scheibler (Abstr., 1883, 1078); the crystals melt at 43°. The zinc salt melts at 72°, as described by Kelbe and Warth, who prepared their acid from resin oil (vol. **42**, 711), and the calcium salt has also the properties mentioned by them.

Methyl-normal-propyl-acetic acid is therefore identical with the acids previously prepared by Liebermann and Schiebler, by Saytzeff, and by Kelbe and Warth. H. B.

α-β-Diisonitrosobutyric Acid. By M. CERESOLE and G. KOECKERT (*Ber.*, **17**, 819—825).—The action of reducing agents on the various isonitroso-compounds may be classified as follows:—(1.) All isonitroso-compounds that are reduced to amides are acids, and the isonitroso-group stands in the α-position to the carboxyl-group. It is also possible that bodies containing isonitroso- and hydroxyl-groups attached to adjacent carbon-atoms undergo reduction in a similar manner. (2.) Those isonitroso-compounds which yield a ketine on reduction contain the isonitroso-group attached to a carbon-atom, that is, united to a ketone-carbonyl-group. (3.) Those isonitroso-compounds which do not contain carboxyl- or carbonyl-groups, or do not contain them in the α-position to the isonitroso-group are incapable of easy reduction. α-β-diisonitrobutyric acid is

$$CMe(NOH).C(NOH).COOEt,$$

and according to the above rules but one of its isonitroso-groups should be capable of reduction. The authors have made experiments to prove this, and communicate the results obtained thus far.

Ethyl α-β-diisonitrosobutyrate is prepared by the action of hydroxylamine on an aqueous or alcoholic solution of ethyl isonitroso-acetoacetate. It melts at 140° with decomposition, and may be crystallised from water or ether, &c. By saponification with soda and treatment with sulphuric acid, *α-β-diisonitrosobutyric acid* is obtained; it is crystalline. The barium salt, $[CMe(NOH).C(NOH).COO]_2Ba + 2\frac{1}{2}H_2O$, is soluble in water, whilst the silver salt, $C_2Me(NOH)_2.COOAg$, is almost insoluble.

During the action of hydroxylamine on ethyl isonitrosoacetoacetate, another body is also formed. It is soluble in ether, but having a strongly acid reaction is dissolved by shaking with barium carbonate and water. It may be isolated by acidifying and extracting with ether. It is colourless, melts with decomposition at 132—133°, and is an *external anhydride of α-β-diisonitrosobutyric acid*, $C_8H_{10}N_4O_7$. The barium salt, $BaC_8H_8N_4O_7 + \frac{1}{2}H_2O$, is deep red in colour, and soluble in water and alcohol. The silver salt forms a red-brown precipitate, $C_8H_8N_4O_7Ag_2$, insoluble in water. Hence it follows that this anhydride is a dibasic acid, and the union of the two molecules must have taken place through two of the isonitroso-groups. Three constitutional formulæ are possible. H. B.

Dehydracetic Acid. By W. H. PERKIN, jun., and C. BERNHART (*Ber.*, 17, 1522—1527).—When hydroxylamine in excess acts on a concentrated solution of potassium dehydracetate, dehydracetoxime, $C_7H_8O_3 : CNOH$, is formed. It is a colourless crystalline substance, soluble in alcohol; and this solution gives an intense purple coloration with ferric chloride. With phenylhydrazine, dehydracetic acid yields *dehydracetophenylhydrazine*, $C_8H_8O_3N.NHPh$, which crystallises in lustrous yellow tables, softening at 200°, and melting with decomposition at 207°. It is soluble in alkaline carbonates, and is reprecipitated by acids. A small quantity of a second compound was also obtained, which melts at 160°, but has not yet been investigated. Monobromodehydracetic acid was obtained by dissolving the acid in chloroform, adding a little iodine and then excess of bromine, and heating for half an hour at about 50—60°. It is thus prepared in a purer state than by Oppenheim and Precht's method (this Journal, 1876, ii, 506). It forms colourless prisms melting at 136—137°. When allowed to remain for 14 days at 35—40° with excess of alcoholic potash, it yields *hydroxydehydracetic acid*, $C_8H_7O_4.OH$. This forms a colourless microcrystalline mass melting at 250—255° with total decomposition. Ferric chloride gives an intense reddish-violet coloration. It is readily soluble in ammonia, and gives a pale-yellow amorphous silver salt of the formula $C_8H_6O_5Ag_2$. Hydroxydehydracetic acid therefore seems to be bibasic. When heated with acetic anhydride, it yields an *acetate* which is crystalline, and melts at 165—167°. With ferric chloride it gives a pale-yellow coloration.

By very careful treatment with *cold* moderately concentrated potash, the authors succeeded in obtaining a small quantity of a thick oil easily soluble in water. When distilled with steam, this yielded acetone, and was probably acetoacetic acid, which had been formed according to the equation—

$$C_8H_8O_4 + 2H_2O = 2(COMe.CH_2.COOH).$$

L. T. T.

Trichlorophenomalonic Acid. The Constitution of Benzene. By A. KEKULÉ and O. STRECKER (*Annalen*, **223**, 170—197).—In a research on the action of sulphuric acid and potassium chlorate on benzene (*Annalen*, **140**, 317; **142**, 129; **143**, 315; **149**, 257; and **155**, 217), Carius discovered *trichlorophenomalonic acid*, an unstable compound which is decomposed by warm baryta-water, yielding phenaconic acid. Carius afterwards stated (*Ber.*, **4**, 928) that phenaconic acid and fumaric acid are identical. Krafft (*Ber.*, **10**, 797) repeated these experiments, and arrived at the conclusion that trichlorophenomalonic acid was nothing else than trichloroquinol. The authors, however, find that trichlorophenomalonic acid is obtained when the directions given by Carius are closely followed, as a slight variation in the process has a great influence on the results. For instance, if the flask containing the mixture of potassium chlorate, sulphuric acid, and benzene is briskly agitated so as to thoroughly mix its contents instead of merely keeping the liquid in a state of rotation, trichloroquinol is produced instead of trichlorophenomalonic acid. Trichlorophenomalonic or β-trichloracetoacrylic acid, $CCl_3.CO.CH : CH.COOH$, agrees in its properties with the acid described by Carius, but differs from it in composition. It is decomposed by warm baryta-water, with the formation of chloroform and *maleic* not fumaric acid,

$$C_5H_3Cl_3O_3 + H_2O = CHCl_3 + C_4H_4O_4.$$

Trichlorophenomalonic acid unites with bromine, forming the compound $C_5H_3Cl_3Br_2O_3$, which crystallises in the triclinic system. It is soluble in alcohol, ether, and chloroform, and melts at 97·5°. On boiling it with milk of lime, (inactive) calcium tartrate is formed.

Trichlorophenomalonic acid is also formed by the action of sulphuric acid and potassium chlorate on quinone. If monochloroquinone is represented by the formula $C_6H_3ClO_2$ ($O : Cl : O = 1 : 4 : 5$), the formation of trichlorophenomalonic acid, $\overset{(5)}{C}Cl_3.\overset{(4)}{C}O.\overset{(3)}{C}H : \overset{(2)}{C}H.\overset{(1)}{C}OOH$, can easily be represented by the following equation:—$C_6H_3ClO_2 + 2HClO_2 = C_5H_3Cl_3O_3 + H_2CO_3$, as $\overset{(5)}{C}Cl.\overset{(4)}{C}O.\overset{(3)}{C}H : \overset{(2)}{C}H.\overset{(1)}{C}O$ is common to both the formulæ. As this reaction can be much more easily explained by means of the "*ring*" than by the "*prism*" formula for benzene, the authors regard this as further evidence in support of Kekulé's hypothesis of the constitution of benzene.

W. C. W.

Normal Hydroxyvaleric Acid. By A. MENOZZI (*Gazzetta*, **14**, 16—19).—The acid was prepared from butaldehyde by first heating it with the necessary quantity of hydrocyanic acid of 40 per cent. in sealed tubes; the reaction takes place with slight development of heat, and is completed by heating the mixture first at 50—60° and finally at 100°. The product, which is the nitrile of normal hydroxyvaleric acid, is saponified by the cautious addition of hydrochloric acid, and the action completed by diluting with water and boiling the mixture for two hours; the hydroxy-acid is then extracted by shaking the solution with ether. In order to purify the crude acid, it is neutralised with potash or soda, and the hot solution precipitated with zinc sulphate, when *zinc hydroxyvalerate*, $(C_5H_9O_3)Zn,2H_2O$, is deposited in an amorphous form, but becomes crystalline after a time; the zinc salt is but sparingly soluble even in boiling water, and is deposited from the solution as it cools in long lustrous needles which lose their water of crystallisation at 100°. The free acid may be obtained by decomposing the zinc salt with hydrogen sulphide, and concentrating the solution at first at a gentle heat, and then in a vacuum over sulphuric acid, when it solidifies to a crystalline mass consisting of thin transparent plates; these melt at 31° and sublime at about 70°.

The *calcium salt*, $(C_5H_9O_3)_2Ca$, obtained by neutralising the acid with calcium carbonate, crystallises in tufts of small needles which are moderately soluble in water, less so in alcohol. The *cadmium salt*, $(C_5H_9O_3)_2Cd$, obtained by treating cadmium carbonate with the acid or by precipitation, is nearly as insoluble as the zinc salt. The *silver salt* is easily soluble in hot water, sparingly in cold, and crystallises in lustrous, colourless prims. The *ethyl salt* obtained by the action of ethyl iodide on the silver salt is a limpid liquid of agreeable odour, and boils at 190°. C. E. G.

A New Method of Formation of Pyrotartaric Acid. F. BEILSTEIN and E. WIEGAND (*Ber.*, 17, 840—842).—Lactic acid and pyrotartaric acid stand to each other as secondary alcohol and ketone—CHMe(OH).COOH and COMe.COOH. By the action of bromine, lactic acid is converted into tribromopyrotartaric acid, and it is now shown that lactate of lime treated in dilute solution with potassium permanganate is converted into calcium pyrotartarate—the free acid was isolated, and the barium salt analysed. A new reaction for pyrotartaric acid is that when heated with ammoniacal silver solution it is oxidised with formation of a mirror, with silver oxide it is converted almost quantitatively into silver acetate and carbonic anhydride. Pyrotartaric acid heated with dilute sulphuric acid at 150° is converted into acetaldehyde and formic acid, lactic acid yields acetaldehyde and carbonic anhydride. Probably, this last reaction may explain the ease with which pyrotartaric acid undergoes polymerisation.

H. B.

Malonic and Tartronic Acids. By M. FREUND (*Ber.*, 17, 780—786).—The author refers to a previous paper (this vol., p. 728).

Potassium ethylmalonate, COOEt.CH_2.COOK, cannot be prepared by Van't Hoff's method, but by proceeding in the manner described by the author it can be obtained quite pure. Bromine acts on an aqueous solution of this salt in the same manner as on malonic acid itself, carbonic anhydride and an ethereal salt of brominated acetic acid being formed. By the slow addition of bromine to an acetic acid solution of malonanilide, a white crystalline substance is formed which is *symmetrical malontribromanilide*, $CH_2(CO.NH.C_6H_2Br_3)_2$; it melts at 145—146°, and when heated with nitric acid at 200° yields symmetrical tribromaniline. Using an aqueous solution of malonamide and the calculated amount of bromine, *dibromomalonamide*, $CBr_2(CONH_2)_2$, separates as a heavy white powder; it is scarcely soluble in cold water or alcohol. By boiling it with silver oxide and water, it is not converted into mesoxalamide, but into ammonium mesoxalate; milk of lime cannot be used instead of silver oxide, and caustic potash gives but a very poor yield. On adding calcium chloride to the aqueous solution a crystalline precipitate of *hydrated calcium mesoxalate* falls,

$$C(OH)_2(COO)_2Ca + 3H_2O.$$

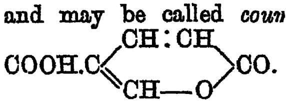
If mercuric oxide be used in place of silver oxide, the compound $C_3N_2H_2O_2Br_2Hg$ is formed; this is a heavy white powder quite insoluble in alcohol and water. When dimethylmalonamide is treated with bromine in aqueous solution, it also yields a dibromide, $CBr_2(CO.NHMe)_2$, *dibromodimethylmalonamide*, crystallising well and melting at 162°.

Conrad and Bischoff, by acting on ethyl malonate with chlorine, and on the ethyl monochloromalonate with potash, prepared the potassium and from that the calcium salt of tartronic acid. By acting on this salt with absolute alcohol and hydrochloric acid gas, the author has prepared *ethyl tartronate*, $CH(COOEt)_2.OH$, a liquid boiling at 218—219° and soluble in ether. When shaken with aqueous ammonia, *tartronamide*, $CH(CONH_2)_2OH$, is formed and crystallises out; it melts at 198°. H. B.

A Condensation-product of Malic Acid. By H. v. PECHMANN (*Ber.*, **17**, 936—938).—In the Abstract (p. 1174) reference is made to a condensation-product of the half-aldehyde of malonic acid. Experiments made to isolate this aldehyde failed, but the condensation-product referred to was obtained. It is formed thus:

$$2(CHO.CH_2.COOH) = 2H_2O + C_6H_4O_4,$$

and may be called *coumalinic acid.* Its constitution is probably



$$COOH.C\begin{cases} CH:CH \\ CH—O \end{cases}CO.$$

Malic acid is heated with sulphuric acid or zinc chloride until the evolution of gas has ceased, and on adding water to the product the new acid separates for the most part. It is isomeric with an acid recently prepared by Ost. It forms prisms melting at 205—207° with decomposition, and only sparingly soluble in cold water; when treated with alkalis it is converted into an acid with absorption of water, if warmed a body smelling like crotonaldehyde is obtained and finally fumaric acid. *Methyl coumalinate*, $C_5H_3O_2.COOMe$, crystallises from ether, melts at 74°, and boils at about 260°; its vapour-density is normal, and it volatilises with steam. H. B.

Salts of Mesotartaric Acid. By S. PRZYBYTEK (*Ber.*, **17**, 1412—1415).—Some doubt having been thrown on the identity of mesotartaric acid and the acid $C_4H_6O_6$, prepared by the author from erythrol, it being in particular stated that the salts of the two acids differ, the author has carefully examined both the acids and their salts, and completely confirms his first statement as to the identity of the two acids.

Calcium mesotartrate, $C_4H_4CaO_6 + 3H_2O$, forms characteristic lance-shaped crystals. It is somewhat soluble in glacial acetic acid, 100 parts of acid dissolving 0·028 part of the salt at 18°, and 0·085 at 100°. Hydrogen potassium mesotartrate, $C_4H_5KO_6$, can be obtained in needles or lance-shaped crystals by evaporating the aqueous solution very slowly and gradually precipitating by addition of alcohol. The descriptions given of the other salts agree with those already published.

Unsuccessful attempts were made to convert the inactive acid into dextro- and lævo-rotary modifications. A. J. G.

Constitution of Fatty Acids. By C. SCHMIDT and A. COBENZL (*Ber.*, **17**, 599—603).—With a view of obtaining an insight into the constitution of the fatty acids, the authors propose to submit to careful investigation the dry distillation of their different salts. Potassium hydrogen mucate and normal potassium mucate have already been investigated; the former yields pyromucic acid, whilst the latter yields dehydromucic acid. P. P. B.

Higher Homologues of Acetic Chloride. By F. KRAFFT and J. BÜRGER (*Ber.*, **17**, 1378—1380).—These compounds were prepared from the corresponding pure fatty acids by heating equal molecular weights of the acid and of phosphorous pentachloride in the water-bath; the phosphorous oxychloride formed was removed by heating at 150° under 15 mm. pressure, when the acid chloride was left in a nearly pure state.

Lauryl chloride, $C_{12}H_{23}OCl$, is a colourless liquid distilling at 142·5° under 15 mm. pressure; it solidifies to a crystalline mass when cooled with liquid sulphurous anhydride, and again melts at − 17°. It has the characteristic odour of the acid chlorides, and is readily decomposed on exposure to moist air. By heating it with phenol and paracresol respectively, it yield *phenyl laurate*, $C_{18}H_{28}O_2$, crystallising from alcohol in nacreous plates, melting at 24·5°, and boiling at 210° under 15 mm. pressure, and *paracresyl laurate*, $C_{19}H_{30}O_2$, of similar appearance, but melting at 28°, and boiling at 219·5° under 15 mm. pressure.

Myristyl chloride, $C_{14}H_{27}OCl$, is a colourless liquid; after solidification in a freezing mixture, it melts at − 1°. It boils at 168° under 15 mm. pressure, without essential alteration. *Phenyl myristate*, $C_{20}H_{32}O_2$, melts at 36°, and boils at 230° under 15 mm. pressure. *Paracresyl myristate*, $C_{21}H_{34}O_2$, melts at 39°, and boils at 239·5° under 15 mm. pressure.

Palmityl chloride, $C_{16}H_{31}OCl$, melts at 12°, and boils, with slight decomposition, at 192·5° under 15 mm. pressure. *Phenyl palmitate*, $C_{22}H_{36}O_2$, melts at 45°, and boils at 249·5° under 15 mm. pressure. *Paracresyl palmitate* melts at 47°, and boils at 258° under 15 mm. pressure.

Stearyl chloride, $C_{18}H_{35}OCl$, forms a lustrous white crystalline mass, which melts at 23°. Under 15 mm. pressure, it commences to distil at 215°, but marked decomposition ensues on carrying the distillation further. *Phenyl stearate*, $C_{24}H_{40}O_2$, melts at 52°, and boils at 267° and 15 mm. pressure. *Paracresyl stearate*, $C_{25}H_{42}O_2$, melts at 54°, and boils at 276° and 15 mm. pressure. A. J. G.

Trichloromethylsulphonic Chloride. By G. McGowan (*J. pr. Chem.* [2], 29, 138—139).—Loew describes the action of aqueous ammonia on trichloromethylsulphonic chloride, stating that nitrogen is liberated from the ammonia, and "that the hydrogen combines with the chlorine according to the equation," $3CCl_3.SO_2Cl + 8NH_3 = 3CCl_3.SO_2NH_4 + N_2 + 3NH_4Cl$. The author has studied the above reaction under the most varying circumstances, and has always found that nitrogen is evolved, and that the ammonium salt of trichloromethylsulphonic acid is formed. By substituting aniline for ammonia the corresponding anilide is obtained. J. I. W.

Derivatives of Isethionic Acid. By R. Hübner (*Annalen*, **223**, 198—235).—When the product of the action of sulphuric anhydride on ether is poured into water, two layers of liquid are formed. The aqueous solution contains ethionic acid, which is converted into isethionic acid by boiling, and the ethereal solution contains hydrogen ethyl sulphate, ethyl methionate, and ethionate.

The first product of the action of sulphuric anhydride on ether is ethyl sulphate, which is converted into hydrogen ethyl sulphate, carbyl sulphate, and ethionic acid by the prolonged action of the sulphuric anhydride. In order to avoid the formation of methionic acid, the sulphuric anhydride vapours are passed into ether at 0°, until the ethereal layer sinks when poured into water. The whole of the product is then poured into water, and the ethyl sulphate is quickly washed, dried, and again treated with sulphuric anhydride. The aqueous solutions are boiled and neutralised with barium carbonate, to convert the ethionic acid into barium isethionate.

The following salts of monochlorethanesulphonic acid,

$$CH_2Cl.CH_2.SO_3H,$$

which was first obtained by Kolbe (*Annalen*, **122**, 38), have been prepared: the *barium* salt, $(C_2H_4ClSO_3)_2Ba + H_2O$, crystallises in monoclinic plates, the *lead* salt in prisms containing 2 mols. H_2O, the *ammonium* salt in anhydrous monoclinic prisms. The *copper* and *zinc* salts form monoclinic plates, containing 3 and 4 mols. H_2O respectively. The *sodium* salt crystallises in deliquescent plates, containing 1 mol. H_2O. The *potassium* salt forms anhydrous needles. The *magnesium*, *manganese*, and *ferrous* salts contain 4 mols. H_2O. The *calcium* salt contains 2 mols. H_2O.

The *sodium* salt of *monethoxyethanesulphonic acid*, $EtO.(CH_2)_2.SO_3H$, is formed by the action of chloroethanesulphonic chloride,

$$CH_2Cl.CH_2.SO_2Cl$$

(1 mol.), on an alcoholic solution of sodium ethylate (3 mols.), and also by acting on sodium chlorethanesulphonate with an equivalent quantity of an alcoholic solution of sodium ethylate. The barium salt of ethoxyethanesulphonic acid, $(C_4H_9SO_4)_2Ba + H_2O$, crystallises in colourless needles, freely soluble in water. The lead salt forms anhydrous plates, the potassium salt anhydrous prisms, the zinc salt hygroscopic plates containing 6 mols. H_2O, and the copper salt non-hygroscopic plates containing 6 mols. H_2O. The sodium salt crystallises in small prisms containing ½ mol. H_2O. The free acid was obtained as a thick syrup (sp. gr. 1·359 at 21°), which appears to be capable of crystallisation.

The *ethylic* salt of *ethoxyethanesulphonic acid*, $EtO.C_2H_4.SO_3Et$, is obtained by acting on chlorethanesulphonic chloride (diluted with ether) with dry sodium ethylate.

Ethoxyethanemonethyldisulphuric acid, obtained in attempting to prepare ethoxyethanesulphonic acid by the action of sulphuric acid and alcohol on the sodium salt, forms a series of salts which are very soluble in water. Many of them, *e.g.*, those of ammonium and zinc, are very hygroscopic. The barium salt forms silky scales containing 1 mol. H_2O. The lead salt crystallises in anhydrous needles. The copper salt crystallises with 4 mols. H_2O. The acid is metameric with Engelke's diethylisethiondisulphonic acid (*Annalen*, **218**, 269). It is, however, dibasic, whilst Engelke's acid is monobasic. It is decomposed by prolonged boiling with water, yielding alcohol, sulphuric acid and ethoxyethanesulphonic acid.

W. C. W.

Action of Chlorine on Sulphonic Derivatives and Organic Oxysulphides. By W. Spring and C. Winssinger (*Ber.* **17**, 537—540).—In continuing their investigation of the action of chlorine on sulphonic derivatives (Abstr., 1882, 938; *ibid.*, 1883, 659), the authors find that in a strong light chlorine reacts with amylsulphonic acid, forming *monochloramylsulphonic acid* and a chlorinated derivative of amyl. The continued action of chlorine expels the sulphonic group. When amylsulphonic acid is heated in sealed tubes with iodine trichloride it gives *monochloramylsulphonic acid*, *trichloropentane*, $C_5H_9Cl_3$, *tetrachloropentane*, $C_5H_8Cl_4$, and *chlorosulphonic acid*. When an excess of iodine trichloride is employed, then *mono-* and *di-chloramylsulphonic acids* are formed together with amylene chlorides, C_2Cl_6, C_2Cl_4, sulphonic chloride, and hydrochloric acid. The formation of a dichlor- and the non-formation of a trichlor-amylsulphonic acid show how the introduction of a third atom of chlorine brings about the expulsion of the sulphonic group.

Diamylsulphone is but little acted on by chlorine even in sunlight, whereas, when heated with iodine trichloride, it yields *monochlorodiamylsulphone*, $C_5H_{10}Cl.SO_2.C_5H_{11}$, boiling at 330°, *dichlorodiamylsulphone*, $(C_5H_{10}Cl_2)_2SO_2$ or $C_5H_9Cl_2.SO_2.C_5H_{11}$, and a considerable quantity of the *amylene tri-* and *tetra-chlorides*, together with sulphonic chloride. Here also the sulphonic group can exist even in presence of two chlorine-atoms.

Chlorine in presence of water reacts with amyl oxysulphide,

$(C_5H_{11})_2SO$, forming *amylsulphonic chloride*, $C_5H_{11}.SO_2Cl$, *amylsulphonic acid*, *monochloramylsulphonic acid*, *diamylsulphone*, *valeraldehyde*, *valeric acid*, *monochlorovaleric acid*, *valeric chloride*, a mixture of *amylene tri-* and *tetra-chlorides* and hydrochloric acid. The derivatives of valeric acid owe their production to the action of the amylene tri- and tetrachlorides, thus :

$$C_5H_9Cl_3 + H_2O = C_5H_9OCl + 2HCl$$
$$2C_5H_9OCl + H_2O = (C_5H_9O)_2O + 2HCl.$$

The action of chlorine on amyl oxysulphide may be represented by the following equations :—

(1.) $(C_5H_{11})_2SO + 4Cl_2 + H_2O = C_5H_{11}.SO_2Cl + C_5H_9Cl_3 + 4HCl.$
(2.) $(C_5H_{11})_2SO + Cl_2 + H_2O = (C_5H_{11})_2SO_2 + 2HCl.$
(3.) $C_5H_{11}.SO_2Cl + H_2O = C_5H_{11}.SO_3H + 2HCl.$
(4.) $C_5H_9Cl_3 + H_2O$ (*vide* above).

The amylsulpho-compounds have a greater tendency to form chlorinated derivatives than their lower homologues. P. P. B.

Derivatives of Uric Acid. By F. MYLIUS (*Ber.*, **17**, 517—527). —*Sarcosine-uric Acid*, $C_8H_9N_5O_4$.—This compound, described by Baumann (*Ber.*, 7, 1152), is easily prepared by heating 2 parts of a mixture of uric acid and 3 of sarcosine at 210°. It crystallises from water in colourless crystals containing 2 mols. H_2O. It gives the murexide reaction, reduces alkaline copper solutions slowly, and is oxidised by potassium permanganate. It possesses both basic and acid characters, forming an unstable acetate and formate, and its ammoniacal solutions are precipitated by silver nitrate and lead acetate. When its solution in potassium hydroxide is heated at 110°, it is resolved into uric acid and sarcosine. Its constitution is expressed by the formula $C_5H_3N_4O_3.CO.CH_2.NHMe$.

Bromosarcosine-mesouric acid, $C_8H_7N_4O_5Br$, is forming by digesting the aqueous solution of sarcosine-uric acid with bromine; its formation is represented as follows :— $C_8H_9N_5O_4 + 2Br + H_2O = C_8H_7N_4O_5Br + NH_4Br$. The bromine in this compound is in the same active condition as in the bromo-derivatives of the acid amides (Hofmann, Abstr., 1882, 950, 1052); it is easily replaced by hydrogen, *e.g.*, by treatment with hydrogen sulphide or ammonia, thus :—

$$C_8H_7N_4O_5Br + H_2S = C_8H_8N_4O_5 + S + HBr,$$
$$3C_8H_7N_4O_5Br + 8NH_3 = 3C_8H_8N_4O_5,NH_3 + 2N + 3NH_4Br.$$

Acids are without action on this bromide, but it exhibits acid characters; it dissolves, for instance, in baryta-water, and is reprecipitated by acids. If, however, a large excess of baryta-water is used, it is decomposed, barium bromide and an insoluble barium salt being formed. The bromine in this compound most probably replaces an atom of hydrogen in the sarcosine group, and to it the author assigns the constitution $C_5H_2N_3O_4.CO.CH_2.NBrMe$.

Sarcosine-mesouric acid is the acid obtained by the action of reducing agents on the bromide. It resembles sarcosine-uric acid, differing from it in being more easily soluble in water. It crystallises in rhombic tables or needles, and is insoluble in alcohol. It forms salts with acetic and formic acids, and also with bases; its silver salt, $C_8H_6N_4O_5Ag_2$, is formed on adding ammonia to a mixture of silver nitrate and its ammonium salt. It is a powerful reducing agent, reducing solutions of salts of gold and alkaline copper solutions. When oxidised by potassium permanganate, it yields a mixture of acids containing some oxalic acid. Treated with bromine-water, it yields the bromosarcosine-mesouric acid, and a corresponding chlorine compound when treated with chlorine-water. It yields sarcosine when fused with potash. P. P. B.

Action of Nitrous Acid on Furfurbutylene. By P. Toennies and A. Staub (*Ber.*, **17**, 850—858).—The boiling point of pure isobutyric anhydride is 181·5°, and its sp. gr. is 0·9574 at 16·5°. By the action of furfuraldehyde on isobutyric anhydride and sodium acetate, furfurbutylene, $C_4H_3O.CH:CMe_2$, is obtained; its boiling point is 153°, and its sp. gr. is 0·9509 at 145°. Some furfuracrylic acid,

$$C_4H_3O.CH:CH.COOH,$$

is also formed during the reaction, so that a portion of the sodium acetate and isobutyric anhydride must react to form acetic anhydride, which gives rise to the furfuracrylic acid; consequently sodium acetate can only be used in Perkin's reaction when the anhydride employed is acetic anhydride.

An acetic solution of furfurbutylene, mixed with sodium nitrite and then poured into a strong caustic soda solution, yields a yellow crystalline mass, melting at 94°. It is $C_4H_3O.CH<\substack{CMe_2\\ N_2O_3}>$. When this compound is gradually added to tin and hydrochloric acid it yields two reduction-products. One of these, *furfurbutylene oxide*,

$$C_4H_3O.CH<\substack{CMe_2\\ —O—}>,$$

is an oil which volatilises easily, it is soluble in water, boils at 186°, and does not change in the air; it does not react with acetic anhydride, so that it contains no hydroxyl-group, neither does it give any of the reactions of the ketones. The residual solution from which the furfurbutylene oxide has separated, after the tin has been removed and the solution concentrated, gives crystals of the composition

$$C_4H_3O.C(NH_3Cl)<\substack{CMe_2\\ —O—}>,$$

and yielding a well-crystallised platinochloride. Its reactions are those of a primary amine. When it is boiled with tin and hydrochloric acid, ammonium chloride and furfurbutylene oxide are formed;

this explains the formation of the oxide during the first reduction. On treating the hydrochloride with acetic anhydride it yields an acetyl-derivative, melting at 153° and boiling at 305—310°. Strong caustic soda solution added to the hydrochloride separates the free base, $C_4H_3O.C(NH_2)<\begin{smallmatrix}CMe_2\\ —O—\end{smallmatrix}>$, an oil soluble in water and having a feeble odour. It boils at 215—220°, and distils easily with aqueous vapour: in both cases it loses part of its water, leaving a base,

$$C_4H_3O.<\begin{smallmatrix}CMe_2\\ —N—\end{smallmatrix}>;$$

this is crystalline, easily soluble in water and volatilises with steam; it melts at 142° and boils at 300—310°. With acetic anhydride and nitrous acid it reacts as a tertiary base. The solution of the hydrochloride is decomposed on boiling; it yields a well-crystallised platinochloride. H. B.

The Thiophene-group. By L. Weitz (*Ber.*, 17, 792—801).—A sample of benzene that had been purified *only* by distillation, and had never been treated with acid, was examined for contained thiophene; but it was found to contain no more thiophene than ordinary benzene. The distillation of the crude lead thiophenesulphonate and ammonium chloride is best carried out in an iron retort.

Thiophene when treated with chlorine (comp. Abstr., 1883, 1091) readily yields a mixture of the *monochlorothiophene*, C_4H_3ClS, and the *dichlorothiophene*, $C_4H_2Cl_2S$, which are separated and purified by distillation; they boil at 130° and 170° respectively. The *tetrachlorothiophene* is formed by passing chlorine through the dibromide; when pure it forms large crystals melting at 36°.

The following salts of thiophenesulphonic acid have been examined:—$C_4H_3S\ SO_3Na + H_2O$; $(C_4H_3S.SO_3)_2Ba + 3H_2O$; $C_4H_3S.SO_3Ag + 3H_2O$; $(C_4H_3S.SO_3)_2Pb + H_2O$; $(C_4H_3S\ SO_3)_2Ca + ?H_2O$; they are very soluble in water, and some are hygroscopic. *Thiophenesulphonic chloride*, $C_4S_3S.SO_2Cl$, is formed by the action of phosphorous chloride on the sodium salt; it is a liquid boiling at over 200°, with decomposition, and not readily decomposed by water. On one occasion, crystals were formed melting at 28° and boiling without decomposition; they had the same composition as the liquid chloride. When an alcoholic solution of thiophenesulphamide is treated with silver nitrate and ammonia, it deposits *silver thiophenesulphamate*, $C_4H_3S.SO_2.NHAg$, in iridescent scales. Aniline acts on thiophenesulphonic chloride to form *thiophenesulphanilide*, $C_4H_3S.SO_2.NHPh$, crystallising from ether and melting at 96°. Sodium ethylate acts on the chloride to form the *ethylic thiophenesulphonate*, $C_4H_2S.SO_3Et$, a yellowish oil. The zinc salt of *thiophenesulphinic acid* is formed when an alcoholic solution of thiophenesulphonic chloride is treated with zinc-dust. The product is washed with water to remove zinc chloride, the zinc thiophenesulphinate converted into the sodium salt by sodium carbonate, and the solution after removal of the zinc carbonate by filtration is concentrated, acidified with hydrochloric acid, and extracted with ether; the free acid crystallises in needles when exposed over sulphuric acid in a vacuum; it melts at 67°. The salts, $C_4H_3S.SO_2Ag$, $(C_4H_3S.SO_2)_2Ba + 2H_2O$, and $(C_4H_3S.SO_2)_2Zn + 3H_2O$, are described.

All these derivatives have the strongest resemblance to the corresponding benzene-derivatives, but are distinguished by giving the indophenine reaction. • H. B.

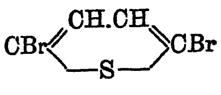
Homologues of Thiophene. By V. MEYER and H. KREIS (*Ber.*, **17**, 1558—1563).—V. Meyer and G. Dyson find that iodine and iodic acid, or, still better, iodine and mercuric oxide, act on thiophene even at ordinary temperatures. Iodine, in the calculated proportion, is added to crude thiophene, and then mercuric oxide added gradually, without cooling, until all the iodine is dissolved. By varying the amount of iodine used, polysubstituted compounds can be obtained. *Moniodothiophene*, C_4H_3SI, is a colourless oil, boiling at 182° uncorr., and resembling iodobenzene in all its properties. *Diiodothiophene* forms white crystals melting at 40·5°.

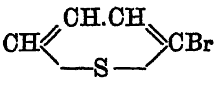
Making use of moniodothiophene thus prepared, the authors have synthesised several homologues of thiophene by the Würz-Fittig method. The directions given by Fittig and König (*Annalen*, **144**, 278) for the preparation of homologues of benzene were exactly followed. The following compounds were obtained:—

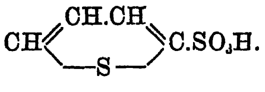
	B. p.	Rel. density.
Methylthiophene (thiotolene), C_4H_3SMe	113°	1 019
Ethylthiophene, C_4H_3SEt	132—134°	0·990 at 24°.
Propylthiophene (norm.), C_4H_3SPr ..	157·5—159·5°	0·974 „ 16°.
Butylthiophene (norm.), $C_4H_3S.Bu$ ..	181—182°	0·957 „ 19°.

All show Laubenheimer's reaction, but a *very* little only must be taken (a drop on a glass rod), and diluted with much water, otherwise brown resinous compounds are formed. The tint obtained in the reaction becomes blue in the higher homologues. All resemble the corresponding benzene-derivatives very closely both in boiling point and properties. The authors have not yet determined as to whether the above methylthiophene is identical with that isolated from coal-tar oils. L. T. T.

Isomerism in the Thiophene Series. By V. MEYER (*Ber.*, **17**, 1563—1566).—If the formula  $CH \lt \begin{array}{c} CH.CH \\ S \end{array} \gt CH$, proposed by the author be correct, thiophene should yield two series of monosubstitution compounds. The great analogy between benzene and thiophene in the formation of substitution-products renders it probable that in *dibromothiophene* the two bromine-atoms are in the positions which are separated by the greatest number of carbon-atoms, and that consequently in the monosubstitution-derivatives with negative radicals the radical is attached to the carbon nearest to the sulphur atom.

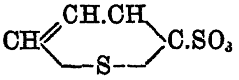




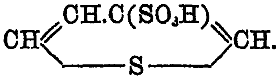


In this case, the sulphonic acid obtained from dibromothiophene should yield, when dibrominated, a monosulphonic acid isomeric with that obtained by the direct sulphonation of thiophene. This is indeed the case; Langer's acid (next page) is isomeric with the α-acid previously described. The formation of an anhydride from Langer's dibromothiophenedisulphonic acid points—from analogy with phthalic acid—to the two sulphonyl-groups being on neighbouring carbons, which would also be the case if the above view of the constitution of thiophene be correct. The constitution of the α- and β-acid would then be—

α



β



L. T. T.

Dithienyl. By R. Nahnsen (*Ber.*, **17**, 789—790).—By passing thiophene through a tube heated just to redness, condensation takes place as with the benzene hydrocarbons, and *dithienyl*, $(C_4H_3S)_2$, is formed. It crystallises from alcohol in white plates melting at 83°. With isatin and sulphuric acid it gives a deep-blue coloration. A mixture of benzene and thiophene passed through a red-hot tube does not yield pure dithienyl, but a mixture probably of diphenyl and the bodies $C_6H_5.C_4H_3S$ and $(C_4H_3S)_2$. H. B.

Substances accompanying Toluene from Coal-tar. By V. Meyer and H. Kreis (*Ber.*, **17**, 787—789).—It was previously shown (Abstr., 1883, 1092, and this vol. p. 586) that coal-tar toluene contains the next higher homologue of thiophene, and the substitution-product, C_4HMeBr_2S, was isolated. This body when treated with bromine in excess in the cold yields tribromothiotolene, C_4MeBr_3S, a white crystalline substance melting at 74°.

The separation of the thiotolene from the crude product containing 15 per cent. thiotolene and 85 per cent. toluene, cannot be effected by repeated treatment with strong sulphuric acid. But whereas the benzene hydrocarbons are only acted on by iodine and iodic acid or iodine and mercuric oxide when heated, thiophene and its homologues are readily acted on at the ordinary temperature. The product of the reaction is extracted with ether and the solution fractionated; at 180° there remains an iodothiotolene which cannot be distilled without decomposition; the residue is dissolved in alcohol and treated with sodium; addition of water causes the separation of an oil, which is dried over calcium chloride and rectified. This is pure *thiotolene*, a colourless mobile liquid boiling constantly at 113°, and of sp. gr. 1·0194 at 18°. The authors are now preparing the next homologue—*thioxylene*. H. B.

Isomeric Thiophenesulphonic Acids. By J. LANGER (*Ber.*, **17**, 1566—1570).—This research was undertaken with the view of throwing light on the constitution of thiophene (see also this vol., p. 1131). *Dibromothiophenesulphonic acid*, C_4HSBr_2,SO_3H, was prepared by treating dibromothiophene, boiling at 205—207°, with pyrosulphuric acid ($H_2S_2O_7$). The free acid was not examined. Its *lead salt*, $(C_4SHBr_2.SO_3)_2Pb + 5\frac{1}{2}H_2O$, crystallises from water in small white lustrous crystals, and was debrominated by treating its aqueous solution with sodium amalgam. The sulphonic acid was purified by conversion into its chloride. β-Thiophenesulphonic chloride, $C_4SH_3.SO_2Cl$, forms large colourless crystals melting at 43°, and having an odour similar to that of benzenesulphonic chloride. It appears to distil undecomposed. The chloride of the α-sulphonic acid (obtained directly from thiophene) is liquid. *β-Thiophenesulphonamide*, $C_4SH_3.SO_2NH_2$, was prepared by the action of ammonium carbonate on the chloride. It crystallises in lustrous plates which differ in appearance from those of the amide of the α-acid. It melts at 148°, whereas the α-derivative melts at 142°. It gives a deep-blue solution when heated with isatin and sulphuric acid. It is thus clear that the α- and β-sulphonic acids are isomeric and not identical.

Dibromothiophenedisulphonic acid, $C_4SBr_2(SO_3H)_2$, was obtained by acting on dibromothiophene with a large excess of pyrosulphuric acid. It crystallises in shining white scales which when heated above 150° turn brown, and above 200° are partly decomposed and become liquid. This liquid is undoubtedly the *anhydride* of the disulphonic acid, and is reconverted into the acid by boiling with alkalis or with barium hydroxide.

L. T. T.

Wachendorff's Chloronitrotoluene. By E. LELLMANN (*Ber.*, **17**, 534—537).—Wachendorff (*Annalen*, **185**, 273), by treating paranitrotoluene with antimony pentachloride, obtained a chloronitrotoluene, which he regarded as $C_6H_3MeCl.NO_2$ [1 : 3 : 4], since it yielded a chloronitrobenzoic acid identical with that obtained by Hübner from metachlorobenzoic acid. The author has prepared this chloronitrotoluene and converted it into the corresponding toluidine, which, if Wachendorff's conclusions be correct, should be identical with Wroblewsky's, obtained from para-acetotoluidine (*Annalen*, **168**, 196). A comparison, however, shows it to be distinct; this base boils at 237—238·5°, and solidifies at 10—12°, whilst Wroblewsky's base boils at 222°. Moreover, this compound, when submitted to the diazo-reaction, is converted into chlorotoluene, and the latter by oxidation into orthochlorobenzoic acid melting at 136·5°. From this the author concludes that Wachendorff's chloronitrotoluene contains the chlorine in the ortho-position.

P. P. B.

Action of Copper on Benzotrichloride, Benzal Chloride, and Benzyl Chloride. By A. ONUFROWICZ (*Ber.*, **17**, 833—837).—Benzenyl trichloride, heated with copper at 100°, yields a solid mass, which leaves a white crystalline product when extracted with alcohol or benzene, tolane tetrachloride $(C_6H_5.CCl_2)_2$. Hanhart has previously prepared tolane dichloride by this same method, but it is only a secondary product. as tolane tetrachloride yields the dichloride when heated with copper.

If benzal dichloride is heated with copper, and the mass extracted with benzene, it yields crystals of stilbene chloride, $(C_6H_5.CHCl)_2$, melting at 180°.

Benzyl chloride, when heated with copper, does not act until a temperature of 150—160° is reached. The product contains dibenzyl if the quantity of copper employed is not too large; with excess of copper and access of air, a resinous mass is obtained. H. B.

Derivatives of Benzyl Cyanide. By G. LUCKENBACH (*Ber.*, 17, 1421—1428).—By the action of hydrochloric acid gas on a well-cooled mixture of equal molecular proportions of absolute alcohol and benzyl cyanide, there is first formed the compound $CH_2Ph.CCl(NH_3Cl)\ OEt$, which, on standing in a flat porcelain dish over sodium hydroxide for a few days, is converted into *phenylacetimidoethyl-ether hydrochloride*, $CH_2Ph.C(OEt) : NH,HCl$. This crystallises in concentric groups of flat needles, softens at 60°, and is completely fused at 85°, and then decomposes into phenylacetamide and ethyl chloride, is readily soluble in alcohol and water, nearly insoluble in benzene and ether, and is very deliquescent. The platinochloride crystallises in prisms, and decomposes readily. The free *imido-ether*, $CH_2Ph.C(OEt) : NH$, obtained by the action of concentrated soda on the hydrochloride, forms a colourless liquid of agreeable aromatic odour; on distillation, it decomposes into benzyl cyanide and alcohol. The corresponding methyl ether and its hydrochloride were also prepared; they closely resemble the ethyl compounds, but are still more unstable.

Phenylacetimido acetate, $CH_2Ph.C(O\overline{Ac}) : NH$, prepared by the action of acetic anhydride on phenylacetimido-ether, crystallises in slender white needles, melts at 129°, is sparingly soluble in cold water, more readily soluble in hot water, readily soluble in alcohol.

Phenylacetamidine, $CH_2Ph.C(NH_2) : NH$ (comp. Bernthsen, this Journal, 1870 [ii], 95). On adding a solution of ammonia to phenylacetimido-ether hydrochloride, the free imido-ether is at first formed, whilst ammonium chloride separates; on standing for some days, however, with occasional shaking, the precipitate disappears, and the solution then contains traces of ethyl phenylacetate, together with *phenylacetamidine hydrochloride*. The latter crystallises in long flat needles of the formula $CH_2Ph.C(NH_2) : NH,HCl + H_2O$, and is readily soluble in water and alcohol. The free base, prepared by rubbing the chloride with concentrated caustic soda, drying the resulting paste in a vacuum and extracting with benzene, still somewhat impure, crystallises in lustrous flat needles or plates, melts at 108—112°, is readily soluble in water and alcohol, sparingly soluble in ether and benzene. The platinochloride crystallises in long flat needles. By heating phenylacetamidine with acetic anhydride and sodium acetate, it yields phenylacetimido acetate; with cold acetic anhydride, on the other hand, it gives in addition a diacetyl compound, $CH_2Ph.C(NH\overline{Ac}) : N\overline{Ac}$, crystallising in very brilliant small tetragonal plates, melting at 172—173°, soluble in hot water, sparingly soluble in alcohol and cold water, nearly insoluble in ether.

Symmetrical dimethylphenylacetamidine, $CH_2Ph.C(NHMe):NMe$, separates as hydrochloride after some days' standing from a mixture of phenylacetimido-ether hydrochloride with an alcoholic solution of methylamine. The free base is an oil which crystallises on long standing over sulphuric acid. The hydrochloride crystallises in hexagonal pyramids. The platinochloride,

$$[CH_2Ph.C(NHMe):NMe],H_2PtCl_6,$$

forms small crystals, apparently rhombic; it is more soluble in alcohol than in water.

Unsymmetrical dimethylphenylacetamidine hydrochloride, prepared from dimethylamine and phenylacetimido-ether hydrochloride, is crystalline. The platinochloride, $[CH_2Ph.C(NMe_2):NH]_2,H_2PtCl_6$, crystallises in feathery groups of needles.

Diethylphenylacetamidine hydrochloride, prepared in similar manner by means of ethylamine, is not crystalline; the platinochloride forms a red resinous mass; the free base appears to be less soluble in ether than the methyl compound.

Diphenyl-phenylacetamidine, $CH_2Ph.C(NHPh):NPh$, is prepared by heating a mixture of aniline and phenylacetimido-ether hydrochloride for some time at 60°. It crystallises in flat needles and plates, melts at 107—108°, is readily soluble in alcohol, nearly insoluble in water. The platinochloride crystallises in small plates.

A. J. G.

Oxidation of Mercury Diethyl with Potassium Permanganate. By M. SEIDEL (*J. pr. Chem.* [2], 29, 134—136).—When mercury diethyl is heated with a concentrated aqueous solution of potassium permanganate, it is readily oxidised. On adding hydrochloric acid to the strongly alkaline solution, a white precipitate is obtained, consisting of ethyl mercuric chloride, HgEtCl, crystallising from alcohol in silvery plates melting at 190°. It is probable that in the above reaction mercuric ethyl hydroxide is first formed; but the hydroxyl-group is replaced by chlorine on treatment with hydrochloric acid.

Mercury-dimethyl in like manner yields mercuric methyl chloride, which crystallises in lustrous prisms melting at 170°. J. I. W.

Action of Potassium Permanganate on Mercury-diphenyl: a Correction. By R. OTTO (*J. pr. Chem.* [2], 29, 136—138).—It is stated in a former paper that when the product obtained by oxidising mercury-diphenyl with potassium permanganate is precipitated, by adding hydrochloric acid, the compound $C_6H_5.HgO.OH$, is thrown down in small lustrous crystals melting at 251—252°. The precipitate, however, consists of the *chloride*, HgPhCl. The hydroxide can be isolated by shaking the products of the reaction with benzene before the addition of hydrochloric acid.

Mercury-ditolyl resembles the diphenyl compound in the foregoing properties, the compounds $HgC_7H_7.OH$ and HgC_7H_7Cl being formed.

J. I. W.

Tolylstibine. By A. MICHAELIS and U. GENZKEN (*Ber.*, 17, 924—925).—Antimony tribromide, paramonobromotoluene, and sodium, in presence of benzene, readily react to form *paratolystibine*, $(C_6H_4Me)_3Sb$, a crystalline substance melting at 127·5°.

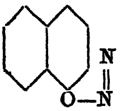
When dissolved in light petroleum and treated with the halogens, the additive compounds, $(C_7H_7)_3SbCl_2$, &c., crystallise out melting at 156·5° (chloride), 233° (bromide), and 182·5° (iodide). The bromide treated with caustic soda yields *paratritolylstibine oxide*, $(C_7H_7)SbO$, melting at 223·5°. If the oxide is dissolved in hot acetic acid, and some water added, it deposits the crystalline *tritolystibine hydroxide*, $(C_7H_7)Sb(OH)_2$, as it cools; this melts at 169·5°. Orthotolylstibine has not yet been obtained in a crystalline state. *Metatritolylstibine* separates from alcohol and ether in crystals melting at 64·5°. The dibromide melts at 113°, and is easily soluble in ether; its isomerides are almost insoluble.
H. B.

Electrolyses and Electrosyntheses. By E. Drechsel (*J. pr. Chem.* [2], **29**, 229—252).—The author has previously (Abstr., 1881, 192) shown that by electrolysing a solution of ammonium carbamate with an alternating current carbamide is formed by the abstraction of the elements of water. It was observed that the platinum electrodes were strongly attacked with formation of platinum bases (Gerdes, Abstr., 1883, 27). By passing the current through a saturated solution of potassium carbonate large quantities of spongy platinum may be prepared. Palladium electrodes with a solution of ammonium carbamate gave no bases, scarcely any of the metal being dissolved. Similar phenomena have been observed by De la Rive (*Pogg. Ann.*, **141**, 152; **145**, 163, 407), who found that gas was disengaged if the electrodes offered only a small surface, whilst with large surfaces but little gas is given off, and the surfaces become covered with a film of the metal (Pt, Pb, Au, Ag, Cu, Pb). Planté (*Jahresb.*, 1866, 98) has also noticed the evolution of oxygen containing ozone from easily oxidisable electrodes. The author, with a view to synthesising phenolsulphuric acid, subjected a mixture of magnesium bicarbonate and sulphate dissolved in water and then saturated with pure commercial phenol, to an alternating current for 30 hours. The electrodes consisted of three large pieces of platinum foil to each pole. A number of products were formed by the action, but mostly in quantities insufficient for analysis. The action of the alternating current may be regarded as inducing alternate oxidation and reduction, the former giving rise to synthetical, and the latter to analytical changes. As products of synthesis there were found γ-diphenol and phenolsulphuric acid, and by oxidation of a single molecule of phenol, quinol, and catechol, were formed, the former in larger quantity than the latter; apparently the catechol suffers further oxidation with formation of acids of the acetic and oxalic series, probably normal valeric and butyric acids, as well as formic acid, whilst the dibasic acids found were succinic, oxalic, and probably also malonic acid. The author points out that some of these substances have not hitherto been obtained directly from phenol, thus neither γ-diphenol, quinol, nor catechol are produced by the action of ordinary oxidising agents, but the author suggests that their formation is in one respect similar to that of catechol by fusing phenol with sodium hydroxide, for in both cases the oxidation takes place in the presence of a strong reducing agent, viz., nascent hydrogen. The acid sulphates of phenol, quinol, and catechol are also formed from phenol in the animal system, but as the whole of the phenol taken into the system is not thus accounted for, a further examination of phenolic urine for some of the other acids, found in the above action, is required, especially for succinic acid. P. F. F.

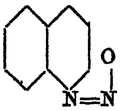
Nitrosophenols. By H. GOLDSCHMIDT (*Ber.*, 17, 801—805).—In a former paper (this vol., 735) it has been shown that the so-called nitrosophenols are formed by the action of hydroxylamine on the quinones, and in all probability therefore they are quinone oximides. It is now shown that α-nitroso-β-naphthol and β-nitroso-α-naphthol are oximido-derivatives.

The β-nitroso-α-naphthol prepared from β-naphthoquinone has already been described (*loc. cit.*), as also the product $C_{10}H_6N_2O$, crystallising in colourless needles melting at 77°, obtained by further heating with hydroxylamine.

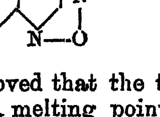
The α-nitroso-β-naphthol was prepared from β-naphthol and amyl nitrite according to Walker's method (*Ber.*, 17, 399); the body, $C_{10}H_6N_2O$, obtained from it by the action of hydroxylamine, melts at 78°. Assuming the usual formulæ for β-nitroso-α-naphthol and α-nitroso-β-naphthol, it follows that by the further action of hydroxylamine two isomeric bodies would be formed—



and



whereas if the bodies have the constitutions here proposed, viz.:—



and

the same body  will be formed in both cases.

Experiment proved that the two products, $C_{10}H_6N_2O$, are identical, their composition, melting point, and crystalline form all being the same, as also their behaviour with different solvents. Liebermann having given the name anthrone to the group $C_{14}H_{10}O$, the name α- or β-naphthone may be given to the group $C_{10}H_8O$, and the "nitrosonaphthols" will then be called β-isonitroso-α-naphthone and α-isonitroso-β-naphthone. Both these bodies yield hydroxylamine when heated with strong hydrochloric acid. The conversion of these "nitrosophenols" into nitrophenols by oxidation may be expressed, assuming two reactions to take place:—

$$C_6H_4\left\{\begin{matrix}O\\NOH\end{matrix}\right. + H_2O = C_6H_4\left\{\begin{matrix}OH\\N(OH)_2\end{matrix}\right.$$

$$C_6H_4\left\{\begin{matrix}OH\\N(OH)_2\end{matrix}\right. + O = C_6H_4\left\{\begin{matrix}OH\\NO_2\end{matrix}\right. + H_2O.$$

H. B.

Carvol. By H. Goldschmidt (*Ber.*, **17**, 1577—1579).—Carvol and hydroxylamine yield *carvoxime*, $C_{10}H_{14}:NOH$, which crystallises in white scales melting at 66·5°. With phenylhydrazine it yields *carvolphenylhydrazine*, $C_{10}H_{14}:N_2HPh$, crystallising in white needles, which soften at 100° and melt at 106°. It is therefore probable that the formula  $CMe\left\langle\begin{matrix}CH.CH\\CO.CH_2\end{matrix}\right\rangle CPr$, first proposed by Fittig, is correct, and not his second and more generally received formula. L. T. T.

Carroway Oil. By F. A. Flückiger (*Arch. Pharm.* [3], **22**, 361—366).—A sample of carvol from H. Haensel, in Pirna, boiled constantly at 224—225°, and a column of 50 mm. rotated polarised light + 29·1°; it was free from carvene, and its sp. gr. is 0·9574 at 23·5°. The formation of terpin from carvene by the action of nitric acid requires the lapse of several months; carvene is a homogeneous body, for it boils constantly at 174°, its sp. gr. is 0·849 at 15°, and the rotation + 53 at 20°; by treatment with sulphuric acid of sp. gr. = 1·55 it is converted into a thick syrup and becomes optically inactive.

Oleum carvi, according to the German Pharmacopœia, gives a violet or red coloration with ferric chloride, but the reaction cannot always be observed. Neither the last fractions nor the pitch-like residue obtained in the distillation of carroway oil contain phenols nor give the above reaction. If, however, the fresh and colourless oil be allowed to stand some months, it becomes yellow and gives the ferric chloride reaction; the substance giving the reaction is soluble in soda solution, but its quantity is very small; this substance is not carvacrol, as this gives a green coloration with ferric chloride (Abstr., 1882, 1065). H. B.

Mixed Ethers of Quinol. By F. Fiala (*Monatsh. Chem.*, **5**, 232—235).—These compounds were prepared from monomethylquinol by the method used by Hlasiwetz and Habermann for the preparation of dimethylquinol (this Journal, 1876, i, 79).

Methylethylquinol, $C_6H_4(OMe).OEt$, forms a colourless crystalline mass, of fatty lustre. It has a penetrating fennel-like odour, and burning taste; it melts at 39° (uncorr.). It is readily soluble in benzene, ether, and chloroform, less soluble in absolute alcohol and glacial acetic acid. Like all other dialkyl ethers of quinol, it readily distils with steam.

Methylpropylquinol, $C_6H_4(OMe).OPr$, crystallises in colourless plates of agreeable odour, somewhat like that of fennel; it has a burning taste and melts at 26° (uncorr.). It is readily soluble in benzene, ether, chloroform, absolute alcohol, and glacial acetic acid; addition of water completely reprecipitates it from its solution in the two last-named solvents.

Methylisobutylquinol, $C_6H_4(OMe).OBu^{\beta}$, forms a colourless liquid, heavier than water, of agreeable aromatic odour and burning taste. It distils between 227—230°. It is readily soluble in benzene, ether, chloroform, absolute alcohol, and glacial acetic acid. A. J. G.

Resorcinol Oxide. By K. Hazura and P. Julius (*Monatsh. Chem.*, 5, 188—192).—*Nitroresorcinol oxide*, $[C_6H_3(NO_2).OH]_2O$, is prepared by shaking 1 gram of mononitroresorcinol with $2\frac{1}{2}$ c.c. of Nordhausen sulphuric acid; after a few seconds the nitroresorcinol dissolves, and the solution is quickly poured into water to prevent further conversion of the oxide into the sulphonic acid; the oxide separates in microscopic needles, whilst nitroresorcinolsulphonic acid remains in solution. Nitroresorcinol oxide can be obtained either in anhydrous pale rose-red needles, or in brownish-red warty crystals of the formula $[C_6H_3(NO_2).OH]_2O + H_2O$. It is sparingly soluble in water and alcohol, insoluble in ether, readily soluble in ammonia, but is not reprecipitated on addition of acetic acid. It dissolves in concentrated sulphuric acid, and is reprecipitated on addition of water. When heated, it turns brown at 170°, and carbonises without fusion at higher temperatures. The normal barium salt, $C_{12}H_6(NO_2)_2O_3Ba + 5\frac{1}{2}H_2O$, crystallises in brownish-yellow needles of nacreous lustre, and is readily soluble in water. The acid barium salt,

$$[OH.C_{12}H_6(NO_2)_2O_2]_2BaO + 2H_2O,$$

crystallises in brownish-yellow needles, and is also readily soluble in water. By the action of concentrated nitric acid, nitroresorcinol oxide is converted into trinitroresorcinol, and another product melting at 104—105°.

By heating resorcinoldisulphonic acid (1 mol.) and resorcinol (2 mols.) at 190°, a substance is obtained which agrees in all respects with Barth and Weidel's diresorcinol oxide (this Journal, 1876, i, 921). The same compound is also formed by heating phenanthrenedisulphonic acid with resorcinol, the phenanthrenesulpheïnresorcinol obtained by Fischer in this reaction (Abstr., 1880, 474) being most probably impure resorcinol oxide. A. J. G.

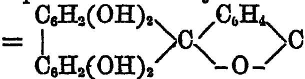
Diresorcinol and Diresorcinolphthaleïn. By R. Benedikt and P. Julius (*Monatsh. Chem.*, 5, 177—187).—On fusing resorcinol with caustic soda, Barth and Schreder obtained about 1·5 per cent. of diresorcinol, together with 60—70 per cent. of phloroglucinol, but by working on a larger scale, as much as 25—35 per cent. of diresorcinol can be obtained. Pure diresorcinol melts at 310°.

Acetyldiresorcinol, $C_{12}H_6(O\overline{Ac})_4$, prepared by boiling diresorcinol with acetic anhydride and sodium acetate, crystallises in lustrous prisms and melts at 152°. It is soluble in cold nitric acid, and is reprecipitated unaltered on addition of water.

Hexanitrodiresorcinol, $C_{12}(NO_2)_6(OH)_4$, is prepared by carefully heating acetyldiresorcinol with fuming nitric acid; it forms lustrous yellow crystals, explodes without previous fusion at about 230°, and is readily soluble in water.

Decabromodiresorcinol, $C_{12}Br_{10}O_4$, prepared by the action of a solution of bromine in concentrated hydrochloric acid on a dilute solution of diresorcinol in potash, forms large crystals; on heating at 185° it loses about 2 mols. of bromine, the residue is insoluble in the usual solvents, and on further heating it again evolves bromine, and blackens at 200—210°. An impure hexabromodiresorcinol is obtained as a yellowish powder by warming the decabromo-compound with sulphurous acid.

Diresorcinolphthaleïn was first prepared by Link (Abstr., 1881, 96), who assigned to it the formula $C_{32}H_{22}O_{10}$; the authors confirm in general his account of the substance, but conclude from the result of their analyses, and from a quantitative study of its formation, that it has the formula $C_{20}H_{12}O_6$ =



$$\begin{array}{l} C_6H_2(OH)_2 \\ | \\ C_6H_2(OH)_2 \end{array} > C < \begin{array}{c} C_6H_4 \\ -O- \end{array} > CO$$

, and that its formation is represented by the equation $C_{12}H_{10}O_4 + C_8H_4O_3 = H_2O + C_{20}H_{12}O_6$. The deep blue ammoniacal solution of diresorcinolphthaleïn is decolorised by alcohol, whilst the solution in potash is unaffected, even on boiling with that reagent. By the action of bromine on diresorcinolphthaleïn, both in solution in glacial acetic acid, a bromo-derivative is obtained in the form of yellow crystals, soluble in alkalis, with a beautiful blue colour. It could not be purified. An acetyl derivative was obtained as an amorphous resinous mass. *Diresorcinolphthalin* was prepared according to Link's directions. On analysis it yields numbers agreeing better with the formula $C_{20}H_{14}O_6$ than with $C_{32}H_{24}O_{10}$, the formula assigned to it by Link. It crystallises with 2 mols. H_2O, and melts at 235°.

Insoluble Diresorcinolphthaleïn, $C_{32}H_{20}O_9$.—In the preparation of diresorcinolphthaleïn, there is always formed in small amount a substance insoluble in water, to which the authors give the name of "insoluble diresorcinolphthaleïn;" the largest yield is obtained when two molecular weights of diresorcinol are heated with one of phthalic anhydride. Its formation is most probably represented by the equation $2C_{12}H_{10}O_4 + C_8H_4O_3 = 2H_2O + C_{32}H_{20}O_9$. It can be in small part converted into the soluble phthaleïn by fusion with phthalic anhydride, whilst the soluble phthaleïn is almost entirely converted into the insoluble compound by heating it with diresorcinol. By recrystallisation from alcohol, it is obtained as a nearly white, heavy, microcrystalline powder. It commences to decompose when heated to 240°.

A. J. G.

Action of Perthiocyanic Acid on some Aromatic Monamines.

By A. Tursini (*Ber.*, **17**, 584—588).—Glutz (*Annalen*, **154**, 44) has shown that aniline and perthiocyanic acid heated together yield a *monophenylthiobiuret*. The author finds that paratoluidine behaves in a similar manner, forming *monotolylthiobiuret*, $C_9H_{11}N_3S_2$. This compound is soluble in alcohol, from which it crystallises in microscopic needles melting at 158°. The thiobiurets possess acid properties, dissolve in alkalis, and are reprecipitated by acids; they are easily converted into ethyl-derivatives by treating their alcoholic solutions with ammonia and ethyl iodide. *Ethylphenylthiobiuret*, $C_8H_8N_3S_2Et$, crystallises from alcohol in rhombic tables melting at 109°, and *ethyltolylthiobiuret* forms large needles melting at 134°. Acetic chloride reacts easily with these compounds, forming acetic derivatives; *acetyltolylthiobiuret* crystallises from alcohol in yellow needles melting at 166°.

Dimethylaniline and perthiocyanic acid react with one another, not, however, to produce substituted thiobiurets, but a base, *tetramethylthioaniline*, similar to the thioaniline described by Merz and Weith (*Ber.*, **4**, 384). *Tetramethylthioaniline*, $(C_6H_4.NMe_2)_2S$, crystallises from alcohol in white needles; it is soluble in ether and melts at 125°. It is easily soluble in hydrochloric acid, and the solution gives a yellow precipitate with platinum chloride. The base is unaltered when heated in sealed tubes with concentrated hydrochloric acid, or by fusion with potash. The picrate is the most stable of its salts; it is insoluble in water, but sparingly soluble in alcohol, and crystallises in yellow needles having the composition $(C_6H_4NMe_2)_2S,C_6H_2(NO_2)_3.OH$.

P. P. B.

Action of Cyanogen on the Toluidines. By J. A. BLADIN (*Bull. Soc. Chim.*, **41**, 125—130).—The author has studied the action of cyanogen on the three toluidines.

Cyanoparatoluidine, $(C_7H_7.NH.CNH)_2$, is obtained by the action of cyanogen on an alcoholic solution of paratoluidine. The crystalline product is purified by solution in sulphuric acid and precipitation with ammonia. When crystallised from alcohol, it forms nacreous scales which decompose before melting. The base combines with acids to form colourless salts, of which the *hydrochloride*, *nitrate*, *sulphate*, and *acid oxalate* are described in the original paper.

Paratolyloxamides.—By evaporating cyanoparatoluidine with an excess of concentrated acetic acid, *monoparatolyloxamide*,

$$C_7H_7.NH.CO.CONH_2,$$

is obtained in white needles, easily soluble in alcohol, and melting at 236—237°. It is decomposed by the action of potash, with formation of ammonia, oxalic acid, and paratoluidine. By the reaction of acetic acid with cyanoparatoluidine, diparatolyloxamide, $(C_7H_7NH.CO)_2$, is also formed. The two bodies are separated by means of boiling water, in which the latter is insoluble. It crystallises from alcohol in colourless scales which melt at 267—268°. These crystals readily sublime when heated, and are only slowly decomposed by boiling potash. This substance has previously been studied by Wilm and Girard, who state that the melting point is 269°.

Dicyanotriparatolylguanidine, $C_{24}H_{23}N_5$.—This body was isolated from the liquid remaining after the crystallisation of cyanoparatoluidine. It crystallises in long yellow needles, which melt at 182°, and are very soluble in alcohol, insoluble in water. The body has been previously obtained by Lavdgrebe by the action of hydrochloric acid on *dicyanodiparatolylguanidine.* It forms red and orange salts with acids. The *hydrochloride*, *platinochloride*, *sulphate*, and *nitrate* are described.

Cyanorthotoluidine is prepared by acting on orthotoluidine with cyanogen. It is more soluble in water than cyanoparatoluidine, and crystallises in nacreous needles. It forms salts which are easily soluble in water. The *hydrochloride*, *nitrate*, *sulphate*, and *oxalate* are described.

Orthotolyloxamides are obtained by methods similar to those employed in the preparation of the para-compounds. The diortho-derivative is more soluble in alcohol than the corresponding para-compound.

Cyanometatoluidine.—Metatoluidine, prepared by the action of zinc on nitrobenzaldehyde, is treated in alcoholic solution with cyanogen. The liquid yields rhombic crystals of cyanometatoluidine, which melt at 200°, and resemble the para- and ortho-compounds. The *hydrochloride*, *nitrate*, and *sulphate* of this base are described. The mother-liquors from the preparation of the above compound deposit small red crystals, but not in quantity sufficient to admit of examination.

Metatolyloxamides may be obtained by the methods described for the preparation of the corresponding para- and ortho-compounds. The mono-derivative crystallises from boiling alcohol in silvery scales melting at 131°.

The author intends to study the action of cyanogen on orthophenylene diamine and on orthamidophenol. W. R. D.

Action of Ethylene Bromide on Nitraniline and on Nitrotoluidine. By L. GATTERMANN and H. HAGER (*Ber.*, 17, 778—780).—Metanitraniline is heated with ethylene bromide at 120—130°, and the resulting mass treated with boiling alcohol; the red residual product, whose formula is $(NO_2.C_6H_4.NH)_2C_2H_4$, is best crystallised from glacial acetic acid; it melts at 206°. It forms salts only with concentrated acids, and even these are easily decomposed by water. When reduced with tin and hydrochloric acid, it is converted into *ethylenediphenylenediamine*, $(NH_2.C_6H_4.NH)_2C_2H_4$, which crystallises from its hot aqueous solution with 1 mol. H_2O; its salts crystallise easily, and, like those of metaphenylenediamine, give a deep-brown coloration with the least trace of nitrous acid. The hydrochloride has the composition $(NH_2.C_6H_4.NH)_2C_2H_4,4HCl$.

By the action of ethylene bromide on metanitroparatoluidine, there is formed *ethyleneditoluylenenitramine*, $(NO_2.C_6H_3Me.NH)_2C_2H_4$, crystallising from chloroform in red plates which melt at 195°. By reduction, it yields *ethyleneditoluylenediamine*, $(NH_2.C_6H_3Me.NH)_2C_2H_4$, melting at 158—159°, and crystallising from alcohol in colourless needles, which afterwards turn violet. H. B.

Derivatives of the Amidoethylbenzenes. By H. PAUCKSCH (*Ber.*, 17, 767—770).—Hofmann and Benz have prepared paramidoethylbenzene, whilst Beilstein and Kuhlberg, by nitration of ethylbenzene and reduction of the isolated products, prepared both the ortho- and para-amido-derivatives. It is, however, preferable to reduce the mixed nitro-substitution products, convert the amides into their acetyl compounds, and separate these by their solubility in water, the para-compound separating first; it melts at 94°, whilst the ortho-compound melts at 110—112°. The free bases may then be prepared, the para-compound boiling at 213—214°, the ortho at 210—211°. Both bases are converted into thiocarbamides, $C_{17}H_{20}N_2S$, by heating them with carbon bisulphide and a little alkali; these are white crystalline solids, melting at 144—145° (para), and 141—142° (ortho). In the preparation of the latter, some thiocarbimide is also formed; this cannot be distilled alone without alteration, but passes over in a current of steam. When heated with aniline, it yields a carbamide melting at 148°.

The paracetyl compound, treated in the cold with strong nitric acid, is converted into a dinitro-substitution product, $C_6H_2Et(NO_2)_2.NH\overline{Ac}$; this, when heated with hydrochloric acid, yields the free base, an almost indifferent body, crystallising from alcohol in orange-yellow prisms which melt at 134—135°. If, however, fuming nitric acid be dropped into a well-cooled solution of the acetyl compound in glacial acetic acid, a mononitro-derivative, $C_6H_3Et(NO_2).NH\overline{Ac}$, is obtained, very soluble in benzene, &c., and melting at 45—47°. Treated with hydrochloric acid, a salt is formed, which however is easily decomposed by water with separation of the free base, $C_6H_3Et(NO_2).NH_2$, in small reddish-yellow crystals melting at 45—47°.

H. B.

Formanhydroisodiamidotoluene (Methenylisotoluylendiamine). By H. HÜBNER and R. SCHÜPPHAUS (*Ber.*, **17**, 775—777).—Reference is given to a former paper (*Annalen.*, **208**, 286).

The compound,  $C_6H_3Me\genfrac{\langle}{\rangle}{0pt}{}{-N=}{NH}CH$ [Me : NH : N = 1 : 3 : 4 or 1 : 4 : 3], is already known, whilst that now described is [Me : NH : N = 1 : 2 : 3 or 1 : 3 : 2].

Acetorthotoluide, when treated with nitric acid, yields a product consisting principally of $C_6H_3Me(NH_2).NO_2$ = [1 : 3 : 4]. If it, however, be first brominated and then nitrated, the body

$$C_6H_2MeBr(NH_2)NO_2 = [1:4:2:3]$$

is obtained, which is reduced and converted into the brominated isoanhydro-base by the action of formic acid; the bromine is finally removed by sodium amalgam and water.

Bromisoortho-diamidotoluene, $C_6H_2MeBr(NH_2)_2$, melts at 59°; its hydrochloride and sulphate are crystalline.

Bromoformanhydroiso-diamidotoluene,  $C_6H_2MeBr\genfrac{\langle}{\rangle}{0pt}{}{-N=}{NH}CH$, crystallises from water in needles melting at 187°. Its salts, hydrochloride, double mercuric chloride, and platinochloride, sulphate, chromate, nitrate, and picrate, are all crystalline.

Formanhydroiso-diamidotoluene,  $C_6H_3Me\genfrac{\langle}{\rangle}{0pt}{}{-N=}{NH}CH$, is easily soluble in water, alcohol, and benzene; it forms colourless needles melting at 143°. The platinochloride and nitrate are both crystalline.

The work is being continued. H. B.

Action of Monochloracetic Acid on Orthamido- and Paramido-phenol and Hydroxyphenylglycines.

By H. VATER (*J. pr. Chem.* [2], **29**, 286—299).—Phenylglycine was first prepared by Michaelsen and Lippmann (*Compt. rend.*, **61**, 739; *Zeitschr. f. Chem.*, 1866, **15**) from monobromacetic acid and aniline, and subsequently by Schultzen, Nencki, P. J. Meyer, and Schwebel (Abstr., 1878, 795), who used monochlor- instead of monobrom-acetic acid. The author has investigated the action of the latter acid on the amidophenols.

Orth-hydroxyphenylglycine, $HO.C_6H_4.NH.CH_2.COOH$, is prepared by boiling monochloracetic acid (1 mol.) with orthamidophenol (2 mols.) and 20 times the weight of water, as long as hydrochloric acid is eliminated. The hydroxyphenylglycine is separated from the more soluble hydrochloride of orthamidophenol by crystallisation. It crystallises with 1 mol. H_2O in colourless plates; it has a neutral reaction, but decomposes carbonates on heating, and forms salts both with alkalis and mineral acids. When heated at 100°, it loses $2H_2O$ and forms an anhydride, which at 143° again loses water, but these anhydrides have not been further examined.

Parahydroxyphenylglycine is prepared in the same manner as the above, paramidophenol being employed in place of the ortho-compound. It crystallises without water in small nodules; even at 200°, it suffers no change. A solution in hydrochloric acid gives a dark violet and then a yellow coloration with chloride of lime. It has a neutral reaction and forms salts with acids and bases, but the hydrogen of the hydroxyphenyl-group is not replaceable by metals.

Orthomethoxyphenylglycine, $MeO.C_6H_4.NH.CH_2.COOH$, is prepared in the same way as the above by heating monochloracetic acid and orthanisidine with water, and then shaking with ether; the glycine dissolves and can be purified by recrystallisation from ether, when it is obtained in rectangular plates, which melt at 141·5°; it forms salts like the above-mentioned compounds.

Paramethoxyphenylglycine was prepared from paranisidine in a similar manner. It decomposes at 200° without melting. The two methoxyphenylglycines are isomeric with tyrosine.

Orthethoxyphenylglycine, $EtO.C_6H_4.NH.CH_2.COOH$, prepared from orthamidophenetoïl, melts at 120°.

Ethylic orthethoxyphenylglycinate, $EtO.C_6H_4.NH.CH_2.COOEt$, is prepared by acting with ethylic monochloracetate on orthamidophenetoïl in alcoholic solution. *Orthethoxyphenylethylglycine*,

$$EtO.C_6H_4.NEt.CH_2.COOH,$$

obtained by acting with monochloracetic acid on orthomonethyl-amidophenetoïl in alcoholic solution, is isomeric with this compound.

Orthethoxyphenyldiethylglycinic chloride,

$$EtO.C_6H_4.NEt_2Cl.CH_2.COOH,$$

is prepared by heating in a sealed tube at 100° a mixture of equal molecular weights of monochloracetic acid and orthodiethylamidophenetoïl dissolved in its own volume of ether. The chloride was only obtained as a syrup, but the platinochloride was prepared. The chloride is decomposed by soda with formation of a neutral oil insoluble in water, but soluble in alcohol and ether; in all probability this was the hydroxide. It is soluble in acids, but not in caustic alkalis, showing that the acid properties of the oxyphenylglycine have disappeared. P. F. F.

Amidocresols. By A. MAARSEN (*Ber.*, **17**, 608—610).—Wallach has shown (Abstr., 1883, 329) that when *metatoluylenediamine* is converted into the acetic compound, the acetoxyl group takes up the para-position, and from this an amidocresol, melting at 159—161°, is obtained, different from that obtained from nitrotoluidine, $C_6H_3Me(NO_2).NH_2$ [1 : 2 : 4]. The amidocresol obtained from this nitrotoluidine has been converted into the acetic derivative by heating it with acetic anhydride. It melts at 178°, whereas the monacetamidocresol obtained by Wallach from metatoluylenediamine melts at 224—225°, so that the two amidocresols are isomeric. A further confirmation of this is to be found in the fact that Nolting and Collin (this vol., p. 1087) have obtained from nitro-orthotoluidine an amidocresol, $C_6H_3Me(OH).NH_2$ [1 : 2 : 4], identical with that prepared by Wallach. P. P. B.

Substitution-products of Azobenzene and an Unsymmetrical Triamidobenzene. By J. V. JANOVSKY (*Monatsh. Chem.* **5**, 155—164).—In the author's paper on the nitro-derivatives of azobenzeneparasulphonic acid (Abstr., 1883, 324), he described two mononitro-acids and a dinitro-acid. The position of the nitro-groups in the mononitro-acids was subsequently determined (Abstr., 1883, 1101), but in the case of the dinitro-acid the possible isomerides are so numerous that a determination of the positions of the nitro-groups seemed impossible, and it appeared best to take one of the mononitro-acids and prepare a dinitro-acid from that. For this purpose paranitroazobenzeneparasulphonic acid was heated with 4½ times the quantity of nitric acid of sp. gr. 1·48—1·5; on addition of water the whole solidifies to a crystalline magma, from which the dinitro-acid is obtained on recrystallisation.

Dinitroazobenzeneparasulphonic acid, $C_{12}H_7(NO_2)_2N_2.SO_3H$, crystallises sometimes in rounded needles, sometimes in rosettes. Most of the salts are very sparingly soluble in water. The potassium salt, $C_{12}H_7(NO_2)_2N_2.SO_3K + aq$, is obtained as a yellow precipitate of microscopic needles; the sodium salt crystallises in microscopic flat needles, is readily soluble in hot water, sparingly soluble in cold water; the barium salt, $[C_{12}H_7(NO_2)_2N_2.SO_3]_2Ba$, is obtained as a yellow microcrystalline precipitate. By moderated reduction, the dinitro-acid yields a deep yellow-coloured product, now under investigation: on complete reduction, it yields sulphanilic acid and unsymmetrical triamidobenzene. With regard to the constitution of the dinitro-acid, its reduction-products show that it must have the constitution

$$\overset{4}{SO_3}H.C_6H_4.\overset{1}{N}:\overset{1}{N}.C_6H_3(N\overset{2}{O}_2)_2.N\overset{4}{O}_2, \text{ or } \overset{4}{SO_3}H.C_6H_4.\overset{1}{N}:\overset{1}{N}.C_6H_3(N\overset{3}{O}_2).N\overset{4}{O}_2,$$

as it appears to be identical with the acid obtained by the direct nitration of azobenzeneparasulphonic acid, which must be regarded as formed by the further nitration of both the para- and metamononitro-acids; the latter formula is the most probable.

Unsymmetrical triamidobenzene, $C_6H_3(NH_2)_3$ [1 : 2 : 4], prepared as above mentioned by the reduction of the dinitro-acid with tin and hydrochloric acid, forms a white crystalline mass which readily becomes discoloured. It melts at 132—133°, and gives an emerald-green coloration with oxidising agents, such as ferric chloride and potassium chromate. The hydrochloride crystallises in long colourless needles, becoming brownish-red on exposure to air. Oxidising agents colour it first violet, then green. The platinochloride forms a crystalline yellow powder. This triamidobenzene must be identical with that obtained from chrysoïdine (this Journal, 1877, ii, 458); it is distinguished from the symmetrical triamidobenzene by its melting point and colour reaction.

Parabromazobenzeneparasulphonic acid, $\overset{4}{SO_3H}.C_6H_4.\overset{1}{N}:\overset{1}{N}.C_6\overset{4}{H_4}Br$, is prepared by treating the parasulphonic acid under water with bromine. It crystallises in fine needles, and is a strong acid, displacing hydrochloric and nitric acid from their alkali salts in the cold. Its salts crystallise well, are readily soluble in hot, sparingly in cold water. The potassium salt, $C_{12}H_8BrN_2.SO_3K$, is obtained as an orange-yellow silky precipitate. On recrystallisation, it yields well-formed plates. The sodium salt crystallises in orange-yellow needles. The barium and calcium salts crystallise in groups of fine needles, very sparingly soluble even in hot water. The zinc salt crystallises in plates. On reduction with tin and hydrochloric acid, the free acid yields sulphanilic acid and parabromamidobenzene.

A. J. G.

Azo-compounds. By C. LIEBERMANN and S. v. KOSTANECKI (*Ber.*, 17, 876—887; see Abstr., 1883, 736, and *Ber.*, 16, 2358).—The same results were obtained in the reduction by tin and hydrochloric acid of phenylazoparacresol and phenylazo-orthocresol as were obtained by Nölting and Kohn (this vol., 900).

By the action of diazobenzene on the phenols, not only are colouring matters soluble in potash formed, but others insoluble in alkalis, and belonging to a different class of compounds. By allowing the aniline hydrochloride and acidified potassium nitrite solutions to react for a sufficient length of time before adding the alkaline solution of the phenol, only those colours soluble in potash are formed. If, however, the phenol solution be quickly added after mixing the amido-salt and the nitrous acid, there are formed nitrosophenols, which afterwards react with the amido-base to form diazo-compounds, which may have a different constitution to those formed by the former method. During the preparation of phenylazoparacresol, azo-orthocresol, and phenylazophenol, these bye-products, insoluble in alkalis, are formed in large quantity. After complete purification, they proved to be diazoamidobenzene in each instance.

By the action of diazobenzene hydrochloride on resorcinol, two colouring matters are obtained, one—phenylazoresorcinol—easily soluble in dilute alkalis; the other only sparingly soluble, and insoluble in alcohol. This last substance has been examined previously, but not with success; it is *phenyldisazoresorcinol*, $(C_6H_5.N_2)_2C_6H_2(OH)_2$, and crystallises in red needles melting at 220—222°. Its acetyl derivative, $(C_6H_5N_2)_2C_6H_2(O\overline{Ac})_2$, forms yellow needles melting at 137—138°. The constitution of phenyldisazoresorcinol is proved by the action of tin and hydrochloric acid, aniline and diamidoresorcinol being formed. There are four possible phenyldisazoresorcinols; two have been described by Wallach; the above is a third; its constitution is partly indicated by the identity of the diamidoresorcinol obtained with that prepared by Fitz from dinitroresorcinol.

Amidopseudocumene (melting at 62°), when heated with potassium nitrite and resorcinol, yields two products, one soluble in alkalis—*cumylazoresorcinol*, $C_6H_2Me_3.N_2.C_6H_3(OH)_2$, melting at 199°—the other insoluble in alkalis—*cumyldisazoresorcinol*, $(C_6H_2Me_3N_2)_2C_6H_2(OH)_2$, forming red needles. Similar bodies obtained from liquid cumidine boiling at 225—231°, have been described.

Employing paramidophenetoil and resorcinol, only one product, that soluble in alkalis, was formed, namely, *paraphenetoïlazoresorcinol*, crystallising in red plates which melt at 165—167°.

The authors had intended to introduce into paracresol a series of different diazo-residues, and afterwards to examine other para-substituted phenols in the same manner. Nölting and Kohn having experimented in the first direction, the authors only describe the action of diazoparaphenetoïl on paracresol. There is formed only *paraphenetoïlazoparacresol*, $EtO\ C_6H_4.N_2.C_6H_3Me.OH$; it is only moderately soluble in alkalis, and forms golden scales which melt at 103—104°; by reduction with tin and hydrochloric acid, it yields paramidophenetoïl and amidoparacresol.

Among the other para-substituted phenols examined were parachlorophenol, parazophenol, and paranitrophenol; the last did not enter into reaction at all with diazocumene, the second did so, but the product could not be purified. On the other hand, the cumenol obtained from the solid cumidine easily enters into reaction; thus with diazocumene, it yields *cumylazocumenol*, $C_6H_2Me_3.N_3.C_6HMe_3.OH$, remarkable for its complete insolubility in alkalis—resembling thus the corresponding compounds of β-naphthol—it is, however, soluble in alcohol and melts at 147—148°. *Phenylazocumenol*,

$$C_6H_5.N_2.C_6HMe_3.OH,$$

crystallises in brown prisms melting at 93—94°; on reduction, it yields aniline and *hydroxycumidine*, $HO.C_6HMe_3.NH_2$, subliming in white needles which melt at 166—167°; this base does not yield any quinone when treated with chromic acid, and when treated with acetic anhydride it does not yield an anhydride, but *acetoxyacetylcumidine*, $\overline{Ac}O.C_6HMe_3.NH\overline{Ac}$. *Potassium-sulphanilazocumenol*, $KSO_3.C_6H_4.N_2.C_6HMe_3.OH + 2H_2O$, forms orange needles, and on reduction yields sulphanilic acid and amidocumenol. H. B.

Metazo- and Hydrazo-phenetoïl. By M. Buchstab (*J. pr. Chem.* [2], **29**, 299—300).—This is a preliminary note on the formation of these bodies by the reduction of metanitrophenetoïl.

By the action of sodium amalgam on this in alcoholic solution, metazophenetoïl is formed; it is soluble in alcohol and ether, but insoluble in water, and crystallises in orange-yellow prisms which melt at 91°. By passing sulphuretted hydrogen through an alcoholic solution of the metazophenetoïl, and adding water, metahydrazophenetoïl separates; it crystallises in colourless needles which melt at 91°. The hydrazophenetoïl is converted into the corresponding diethoxybenzidine by treatment with mineral acids. P. F. F.

Diazo-derivatives. By P. GRIESS (*Ber.*, 17, 603—608).—When Paradiamidobenzoic acid is treated with nitrous acid, it yields a compound isomeric with β- and γ-*azimidobenzoic acids*, which the author styles *paramidodiazobenzoic acid.* It crystallises from hot water in yellow needles or narrow four-sided plates, containing 3 mols. H_2O, which it loses at 100°. This compound does not exhibit the characters of an acid, and to it the author assigns the constitution  $NH_2\,C_6H_3{<}\begin{matrix}\text{-CO-}\\ N:N\end{matrix}{>}O$. It possesses basic properties and forms a hydrochloride, $(C_7H_5N_3O_2)_2,HCl$, which crystallises in white six-sided plates; its *platinochloride*, $(C_7H_5N_3O_2)_2,H_2PtCl_6$, is sparingly soluble in water and crystallises in small yellow rhombic leaflets. The *aurochloride*, $(C_7H_5N_3O_2)_2,HAuCl_4$, forms dark-yellow insoluble needles. It forms a perbromide which has not been analysed. This paramidodiazobenzoic acid is a true diazo-compound, uniting directly with aromatic amines and phenols to form azo-compounds. Thus with *metaphenylenediamine* it forms a compound,

$$COOH.C_6H_3(NH_2).N_2.C_6H_3(NH_2)_2,$$

and with β-*naphthol* the compound $COOH.C_6H_3(NH_2).N_2.C_{10}H_6.OH$. The three phenylenediamines behave with nitrous acid in a similar manner to the three diamidobenzoic acids. Ladenburg has already shown (this vol., 739) that *orthophenylenediamine* yields *azimidobenzene*; *metaphenylenediamine* forms *triamidoazobenzene* (phenylene brown), whilst the para-compound forms a compound similar to the above-mentioned *paramidodiazobenzoic acid*, which the author styles *amidodiazobenzene.* The free base is very unstable, but its salts are stable compounds; the *aurochloride*, which has the composition

$$NH_3Cl.C_6H_4.N_2Cl(AuCl_3)_2,$$

is insoluble in water, and from it the salts are best prepared.

The compound, $C_{12}H_{13}N_2O_3$, obtained by Ladenburg by the action of nitrous acid on paraphenylenediamine, the author considers to be a product of the decomposition of amidoazobenzene. P. P. B.

Derivatives of Amidoazobenzene. By G. BERJU (*Ber.*, 17, 1400—1406).—*Acetylamidoazobenzene*, $PhN_2.C_6H_4.NH\overline{Ac}$, prepared by treatment of amidoazobenzene with acetic anhydride, crystallises in slender yellow needles, melts at 143°, and does not unite with acids to form salts. A. Muller has previously given some account of this substance and of its conversion into acetylhydrazobenzene.

Monomethylamidoazobenzene, $PhN_2.C_6H_4.NHMe$, is prepared by heating amidoazobenzene and methyl iodide for two hours at 50° in a reflux apparatus. It crystallises in brick-red needles, melts at 180°, is soluble in alcohol, and reprecipitated on adding water. The hydrochloride forms violet needles. When treated with acetic anhydride, it yields *acetylmonomethylamidoazobenzene*, $PhN_2 C_6H_4.NMe\overline{Ac}$, crystallising in silky yellow needles melting at 139°.

Dimethylamidoazobenzene, $PhN_2.C_6H_4.NMe_2$, prepared by Griess (this Journal, 1877, ii, 456), by the action of diazobenzene on dimethylaniline, can also be obtained by the action of methyl iodide on monomethylamidoazobenzene.

Trimethylazobenzeneammonium iodide, $PhN_2.C_6H_4NMe_3I$, prepared by the action of methyl iodide on the dimethyl compound in sealed tubes at 100°, crystallises in flesh-coloured plates, melts at 173—174°, and is soluble in alcohol and hot water. It is not decomposed by boiling with alkalis.

Benzylidenamidoazobenzene, $PhN_2.C_6H_4N : CHPh$, is prepared by the action of benzaldehyde on amidoazobenzene in the cold. It crystallises in orange-coloured plates, is soluble in dilute alcohol, and is resolved into benzaldehyde and amidoazobenzene hydrochloride on treatment with hydrochloric acid.

Dibromamidoazobenzene, $C_{12}H_9N_3Br_2$, prepared by the action of an alcoholic solution of bromine on amidoazobenzene, crystallises in bright yellow needles and melts at 152°. By the action of tin and hydrochloric acid, it is converted into aniline and paraphenylenediamine.

Carbamidoazobenzene, $CO(NH.C_6H_4.N_2Ph)_2$, is obtained, together with amidoazobenzene hydrochloride, by the action of carbon oxychloride on amidoazobenzene, both dissolved in benzene. It crystallises in microscopic plates, melts with decomposition at 270°, is sparingly soluble in alcohol, more readily soluble in chloroform and benzene.

By boiling alcoholic solutions of amidoazobenzene and phenyl thiocarbimide, a yellow mass is obtained from which on treatment with alcohol *azobenzenemonophenylthiocarbamide*,

$$PhN_2.C_6H_4.NH.CS.NHPh,$$

can be dissolved out and crystallises on cooling in microscopic plates melting at 179°. The portion insoluble in alcohol consists of *thiocarbamidazobenzene*, $CS(NH.C_6H_4.N_2Ph)_2$; it melts at 199°, and is converted into carbamidazobenzene by treatment with yellow mercuric oxide.

A. J. G.

Helianthin. By R. MÖHLAU (*Ber.*, 17, 1490—1493).—If nitrous acid is passed into a solution of equivalent proportions of the hydrochlorides of aniline and dimethylaniline, diazobenzene chloride and nitrosodimethylaniline are formed. If, however, an alkaline sodium nitrite solution is used in place of nitrous acid, *dimethylamidoazobenzene*, $NMe_2.C_6H_4.N_2Ph$, is formed. It is best to mix a solution of 7·4 grams sodium nitrite and 4 of sodium hydroxide in 54 c.c. water with a solution of 10 grams aniline, 13 of dimethylaniline, and 23 c.c. hydrochloric acid (sp. gr. 1·171 at 15°), in 36 c.c. of water.

The mixture should be kept agitated and the temperature not allowed to exceed 15°. The substance has already been described by Griess (this Journal, 1877, ii, 456). If 1 part of this substance is dissolved in 20 parts of sulphuric acid which contains 30 per cent. anhydride, and allowed to stand for about 24 hours, a very satisfactory yield of its sulphonic acid (also described by Griess, *loc. cit.*) is obtained. This forms a convenient method for the preparation of helianthin (or Orange III) of commerce, which is the sodium or ammonium salt of dimethylamidoazobenzenesulphonic acid.

When orthotoluidine is substituted for aniline in the foregoing reaction, the results are not satisfactory, but if paratoluidine is used, *dimethylamidobenzeneazotoluene*, $NMe_2.C_6H_4.N_2.C_6H_4Me$, is formed. It crystallises in golden-yellow scales, soluble in alcohol and ether; it melts at 168—168·5°, and distils with scarcely any decomposition. The chloride and sulphate crystallise in violet prisms which yield a magenta-coloured solution with alcohol. On reduction, it yields paratoluidine and dimethylparaphenyldiamine. No sulphonic acid could be obtained directly, but *dimethylamidobenzeneazotoluenesulphonic acid*, $NMe_2.C_6H_4.N_2.C_6H_3Me.SO_3H$ [$Me : SO_3H : N = 1 : 3 : 4$], was obtained by Griess's method by acting on diazoparatoluidinesulphonic acid with dimethylaniline. It crystallises in very dark violet prisms, soluble to an orange solution in alcohol and in hot water, but insoluble in ether. The sodium salt crystallises in glittering orange scales. L. T. T.

Phenylhydrazine, a Reagent for Aldehydes and Ketones. By E. Fischer (*Ber.*, **17**, 572—578).—In a former communication (*Ber.*, **16**, 661) the author pointed out the utility of this reagent in detecting the presence of aldehydes, &c.; further investigation shows that it may also be used to identify aldehydes, ketones, and ketonic acids. The method adopted in using this reagent is first to prepare phenylhydrazine hydrochloride by neutralising the base dissolved in 10 parts of alcohol with hydrochloric acid, the crystalline hydrochloride is filtered off, washed with alcohol and ether, and dried. One part by weight of the hydrochloride is added to one and a-half times its weight of sodic acetate dissolved in 8—10 parts by weight of water; the reagent so prepared is added to the aqueous solution of the aldehyde, &c., with which in the majority of cases it reacts directly, in some cases heating on the water-bath is required to bring about the desired reaction. Free mineral acids interfere with the reaction, and require to be neutralised, the presence of nitrous acid is specially injurious, and is most easily removed by treatment with carbamide.

With this reagent, acetic, propionic, butyric, valeric, and œnanthylic aldehydes yield colourless non-crystallisable oils.

Furfuraldehyde in aqueous solutions yields a yellowish oil, which solidifies after a short time; from its ethereal solution, the compound is precipitated by petroleum in colourless plates, melting at 97—98°; the compound has the formula $N_2HPh : C_5H_4O$. One part of furfuraldehyde dissolved in 10,000 parts of water gives a precipitate with a solution of hydrazine in 15 minutes, and 1 part in 1000 produces an immediate precipitate.

With *benzaldehyde*, the reagent yields a precipitate of the compound $N_2HPh : CHPh$, melting at 152·5°. An aqueous solution of benzaldehyde of 1 in 2000 gives first a turbidity, which on shaking forms a white flocculent precipitate, and the reaction takes place even with a solution of 1 in 50,000.

Cinnamic aldehyde suspended in water unites with the phenylhydrazine immediately if the solution is warmed, forming a white crystalline solution of the compound $N_2HPh : CH.C_2H_2Ph$; this crystallises from alcohol in fine yellow needles or plates melting at 168°.

Salicylaldehyde, *cuminaldehyde*, *anisaldehyde*, and *para-hydroxybenzaldehyde*, all form crystalline hydrazine-derivatives. The reagent yields an immediate precipitate with a slightly warmed aqueous solution of *glyoxal;* the compound formed is insoluble in alkalis and dilute acids, and crystallises from alcohol in fine leaflets, melting at 169—170°, having the composition $N_2HPh : CH.CH : N_2HPh$.

The reagent produces insoluble liquid condensation-products with aqueous solutions of the ketones, which on being heated with acids are easily resolved into hydrazine and the ketone.

Acetophenone suspended in water gives a yellow crystalline mass, crystallising from alcohol in fine scales melting at 105°.

Benzylideneacetone, when warmed with an excess of the reagent, gives a solid which crystallises from hot alcohol in yellow prismatic plates, of the formula $CHPh : CH.CMe : N_2HPh$, and melting at 175°.

Benzophenone yields the compound $N_2HPh : CPh_2$, which is insoluble in dilute alcohol, but soluble in hot alcohol, from which it crystallises in colourless needles melting at 137°.

Isatin also unites with phenylhydrazine, 1 part in 2000 parts of water yielding a heavy precipitate of fine yellow needles on boiling; the reaction takes place even with a solution of 1 in 20,000. The compound formed has the composition $C_{14}H_{11}N_3O$, and crystallises from alcohol in fine yellowish-red needles melting at 210—211°.

Phenylhydrazine unites also with ketonic and aldehyde acids, the union taking place in hydrochloric or acetic acid solutions. The compounds are sparingly soluble in water, and separate out as yellow crystalline precipitates.

Phenylhydrazineglyoxylic acid, $N_2HPh : CH.COOH$, crystallises from alcohol or water in fine yellow needles which decompose at 137°. It is soluble in caustic alkalis, and acids precipitate it unaltered from the solutions.

Phenylhydrazinepyroracemic acid, $N_2HPh : CMe.COOH$, crystallises from alcohol in fine prisms which melt at 192°; the reaction will show the presence of 1 part of pyroracemic acid in 1000 of water.

Phenylhydrazinemesoxalic acid, $N_2HPh : C(COOH)_2$, crystallises from hot water or dilute alcohol in fine yellow needles melting at 163—164°.

Phenylglyoxylic acid unites with phenylhydrazine, forming a compound which crystallises from hot acetic acid in fine yellow needles melting at 153°, and having the composition $N_2HPh : CPh.COOH$.

Action of Phenylhydrazine on Cyanhydrins. By A. REISSERT (*Ber.*, **17**, 1451—1462).—In continuation of the researches of Tiemann, Piest, and Stephan (Abstr., 1883, 198, *et seq.*) on the action of aniline on many of the cyanhydrins (hydroxynitriles), the author has investigated the action of hydrazine on the cyanhydrins of benzaldehyde, acetaldehyde, and acetone.

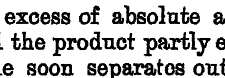
Benzaldehyde cyanhydrin acts on phenylhydrazine in alcoholic solution with development of heat, benzylidenephenylhydrazine, $CHPh:N_2HPh$, being formed. It melts at 152·5°, and has been described by E. Fischer (Abstr., 1878, 309). The same compound is produced if the aldehyde is replaced by phenylchloracetic acid. Neither nitrile nor hydrazido-acid could be obtained.

α-Phenylhydrazidopropionitrile, $PhN_2H_3.CHMe.CN$, is obtained by acting on acetaldehyde cyanhydrin with phenylhydrazine in alcoholic solution. It forms crystals which melt at 58°, and dissolve readily in alcohol and ether, sparingly in benzene and cold light petroleum. When heated with mineral acids or alkalis, it decomposes into hydrocyanic acid and ethylidene-phenylhydrazine, and this latter, by further action of acids, yields acetaldehyde and phenylhydrazine. When it is dissolved in fuming hydrochloric acid and after remaining at rest for several days is neutralised with ammonia, it yields *α-phenylhydrazidopropionamide*, $PhN_2H_3.CHMe.CONH_2$. This substance forms hard white crystals which melt at 124°, are easily soluble in alcohol and boiling water, more sparingly in ether, and almost insoluble in benzene, chloroform, and light petroleum. With acids, it forms salts which decompose Fehling's solution on boiling. When boiled with alkalis for some time, the amide is converted into *α-phenylhydrazidopropionic acid*, which crystallises in glittering white needles, easily soluble in alcohol, benzene, and ether, and melting at 187°. It dissolves in boiling water, the solution having an acid reaction towards litmus-paper. Its barium and zinc salts are crystalline, its calcium salt amorphous. When a solution of the nitrile in excess of alcohol is saturated with hydrochloric acid, the hydrochloride of *ethyl α-phenylhydrazidopropionate* crystallises out, and ammonia precipitates the ether from a solution of its chloride. The ethyl salt crystallises in needles which melt at 116°, and are easily soluble in alcohol, benzene, chloroform, and light petroleum, almost insoluble in water. Both the ether and amide yield α-anilidopropionic acid and ammonia on reduction with tin and hydrochloric acid. These compounds must therefore be unsymmetrical hydrazines, and the formula of the acid be $NH_2.NPh\ CHMe.COOH$. The author believes the α-phenylhydrazidopropionic acid described by E. Fischer and F. Jourdan to be the symmetrical body of the formula $NHPh.NH.CHMe.COOH$.

α-Phenylhydrazidoisobutyronitrile, $PhN_2H_3.CMe_2.CN$, is prepared from acetone in like manner to the propionitrile from acetaldehyde, except that an excess of the acetone cyanhydrin should be used. It crystallises from light petroleum in white needles which melt at 70°, and are easily soluble in alcohol, ether, benzene, and chloroform, insoluble in water. The amide could not be obtained—as in the case of the propionitrile—by saponification with strong hydrochloric or sulphuric acid, but in both cases an internal anhydride of the corresponding butyric-acid was formed. *α-Phenylhydrazido-isobutyric anhydride*, $\mathrm{CMe_2}{<}\genfrac{}{}{0pt}{}{\text{-CO-}}{\text{NPh}}{>}\mathrm{NH}$, thus obtained is easily soluble in alcohol, benzene, ether, and chloroform, sparingly in light petroleum and water, and forms white crystals which melt at 175°. It forms salts with mineral acids—its hydrochloride containing 1 mol. acid to 1 mol. anhydride —and is slowly converted by boiling with sodium hydroxide into *sodium α-phenylhydrazido-isobutyrate*, $\mathrm{PhN_2H_2.CMe_2.COONa}$. On attempting to liberate the acid, the anhydride is at once re-formed. If, in the preparation of the anhydride by the action of strong sulphuric acid on the nitrile, the reaction is stopped *immediately* that a test portion no longer yields hydrocyanic acid on boiling with sodium hydroxide, a small quantity of *α-phenylhydrazido-isobutyrimide*, $\mathrm{(PhN_2H_2.CMe_2.CO)_2NH}$, is formed. This body is easily prepared if a solution of the nitrile in excess of absolute alcohol is saturated with hydrochloric acid gas and the product partly evaporated on the water-bath; ammonium chloride soon separates out, and a solution of the hydrochloride of the imide is left, from which the free imide is precipitated by ammonia. It is a crystalline substance, easily soluble in alcohol, ether, benzene, and chloroform, sparingly in light petroleum and water, and melts at 117°. It is easily soluble in mineral acids, and with hydrochloric acid yields a white crystalline hydrochloride containing 3 mols. of acid to 1 of the base. When heated with alkalis, it yields the internal anhydride described above. Like the propio-compounds, the butyro-compounds proved to be unsymmetric hydrazines.

L. T. T.

Action of Ethyl Acetoacetate on Hydrazine-quinizine Derivatives. By L. Knorr (*Ber.*, **17**, 546—552).—In a former communication, the author described a compound, $\mathrm{C_{10}H_{10}N_2O}$, obtained by the action of phenylhydrazine on ethyl acetoacetate, which is styled *oxymethylquinizine*, having probably the constitution



Its formation takes place in two stages, first *ethylphenylhydrazine acetoacetate*, $\mathrm{N_2HPh:CMe.CH_2.COOEt}$, is produced, which, when heated, is resolved into alcohol and oxymethylquinizine.

With nitrous acid, oxymethylquinizine yields a brown-coloured strongly acid body; with nitric acid, a nitro-compound, and a blue colouring matter, soluble in ether; and colouring matters with benzaldehyde, phthalic anhydride, &c. The hydrogen in it can be replaced by alkyl and acid radicles; for instance, *dimethyloxyquinizine* is formed when it is heated with methyl alcohol and methyl iodide in sealed tubes at 100°; this compound forms beautiful needles melting at 113°. Its dilute aqueous solutions give a characteristic bluish-green coloration with nitrous acid, and in concentrated solutions a green crystalline precipitate, a reaction characteristic for all quinizines.

Orthotolu-oxymethylquinizine, $\mathrm{C_{11}H_{12}N_2O}$, obtained from orthotolylhydrazine, melts at 183°. It forms an *orthotolu-dimethyloxyquinizine* melting at 96—97°.

Ethyl paratolylhydrazine acetoacetate, $C_{12}H_{18}N_2O_2$, the product of the direct action of paratolylhydrazine on ethyl acetoacetate, forms well-defined crystals melting at 91—93°. Heated at 130—140°, it yields *paratolumethyloxyquinizine* melting at 140°; its methyl derivative melts at 137°.

β-Naphtho-oxymethylquinizine, $C_{14}H_{10}N_2O$, is a crystalline compound melting at 190°; its methyl compound, obtained like dimethyloxyquinizine, melts at 129°, and is decomposed by heat. α-Naphthylhydrazine forms similar compounds.

Phenylhydrazine and ethyl succinosuccinate yield a compound resembling methyloxyquinizine. It has the composition $C_{20}H_{16}N_4O_2$, is insoluble in ordinary solvents, dissolves in alkalis, forming a purple solution, from which a blue colouring matter separates out on standing. When heated, a portion carbonises, and at the same time purple vapours are formed, and a blue sublimate. The formation of this compound, which is explained by the following equation, makes it probable that all acids analogous to acetoacetic acid will react with hydrazines:—

$$C_{12}H_{16}O_6 + 2C_6H_8N_2 = 2H_2O + 2Et.OH + C_{20}H_{16}N_4O_2.$$

Aldoximes. By B. LACH (*Ber.*, **17**, 1571—1575).—Gabriel (Abstr., 1883, 188) has shown that nitrobenzaldoxime is decomposed by the action of acetic anhydride, yielding nitrobenzonitrile, whilst according to Westernberger (this vol., 581) terephthalaldoxime forms an acetyl derivative. The author has investigated the action of acetic chloride and anhydride on aldoximes, in order, if possible, to find the characteristics which determine in which of these two ways an aldoxime shall be acted on. Both reagents behave alike, the only difference being that acetic chloride is more violent in its action.

Benzaldoxime yields benzonitrile. *Salicylaldoxime* yields salicylonitrile acetate, $C_6H_4(CN).O\overline{Ac}$ [$\overline{Ac}O : CN = 1 : 2$]. *Parahydroxybenzaldoxime* yields $C_6H_4(CN).O\overline{Ac}$ [$\overline{Ac}O : CN = 1 : 4$], which crystallises in white needles melting at 57°, and boiling at 265—266°. *Œnanthaldoxime* yields œnanthonitrile boiling at 175—177°. *Glyoxime*, $NOH : CH.CH : NOH$, evolves cyanogen, but crystals of diacetylglyoxime, $NO\overline{Ac} : CH.CH : NO\overline{Ac}$, were left in the flask. These crystals decompose on further heating with acetic anhydride, evolving cyanogen gas.

It thus appears that in by far the largest number of cases aldoximes are converted into nitriles by the action of acetic anhydride or chloride, and that the formation of acetyl derivatives is an intermediate stage of the reaction, which would then take place according to the equations—

$$\text{I. } X.CH : N.OH + \overline{Ac}Cl = HCl + X.CH : N.O\overline{Ac}.$$
$$\text{II. } X.CH : N.O\overline{Ac} = \overline{Ac}HO + X.CN.$$

L. T. T.

Trimethylene-derivatives. By W. H. PERKIN, jun. (*Ber.*, **17**, 1440—1444). Acetyltrimethylenecarboxylic acid (this vol., 64) is heated in portions of 5 grams for some time on an oil-bath at 200°; carbonic anhydride is copiously evolved, a colourless liquid distils, and a considerable quantity of a thick dark-coloured oil remains in the retort. On fractioning the distillate, about one-third passes over between 100—125°, and from this, after repeated distillations, *acetyltrimethylene*,  $\left.\begin{array}{l}CH_2\\ |\\ CH_2\end{array}\right>CH\overline{Ac}$, can be isolated as a colourless mobile oil of agreeable acetyltetramethylene-like odour. It boils at 112—113° (at 720 mm.), and is readily polymerised, especially by mineral acids, oils of high boiling point being formed. With hydroxylamine, it yields a small quantity of a derivative crystallising in needles; the greater part is polymerised.

Benzoyltrimethylenoxime,  $\left.\begin{array}{l}CH_2\\ |\\ CH_2\end{array}\right>CH.CPh(NOH)$, is prepared by allowing a mixture of benzoylmethylene with excess of hydroxylamine solution and some alcohol to remain for some days and then extracting the product with ether. It crystallises in peculiarly striated plates, melts at 86—87°, is readily soluble in ether, benzene, chloroform, alcohol, and carbon bisulphide, sparingly in light petroleum.

By heating a mixture of benzoyltrimethylene, hydroxylamine, alcohol, and a few drops of hydrochloric acid, the reaction takes quite a different course, there being formed, according to the amount of hydroxylamine employed, either the hydrochloride of an uncrystallisable base whose isolation could not be effected, or the hydrochlorides of two bases that can be separated by the difference of their solubilities in ether and whose investigation is being continued.

To ascertain if this method of formation of trimethylene-derivatives was general or merely restricted to the action of ethylene bromide on ethyl sodacetoacetates, &c., the action of propylene bromide on ethyl sodacetoacetate was investigated. The product of the reaction is *ethylic acetylmethyltrimethylenecarboxylate*,  $\left.\begin{array}{l}CH_2—\\ |\\ CHMe\end{array}\right>C\overline{Ac}.COOEt$; it is a colourless liquid of feeble odour, boils at 210—215° (720 mm.) and is isomeric with ethyl acetyltetramethylenecarboxylate (b. p. 225°).

Acetylmethyltrimethylenecarboxylic acid,  $\left.\begin{array}{l}CH_2—\\ |\\ CHMe\end{array}\right>C\overline{Ac}.COOH$, is prepared from the ethyl salt, by heating it for four hours on the water-bath with alcoholic potash, neutralising with sulphuric acid, evaporating to dryness, acidulating with sulphuric acid, and extracting with ether. It forms a nearly colourless thick oil, is moderately stable towards alkalis, but is readily decomposed with evolution of carbonic anhydride when heated with acids. Heated alone, it yields carbonic anhydride and a colourless mobile liquid probably acetylmethyltrimethylene. The silver salt, $C_7H_9O_3Ag$, is obtained as an amorphous white powder. A. J. G.

Diphenylacetoxime. By E. SPIEGLER (*Monatsh. Chem.*, 5, 203—207). Diphenylacetoxime was prepared by Janny (Abstr., 1883, 442

580), the present paper deals with some of its derivatives. The methyl, ethyl and benzyl ethers may be prepared by adding to an alcoholic solution of diphenylacetoxime somewhat less than the calculated amount of sodium alcoholate and a slight excess of the halogen-compound of the radical required. The mixture is then heated for several hours in a reflux apparatus, the alcohol evaporated off on the water-bath, water and a few drops of soda added, and the liquid extracted with ether.

Diphenylacetoxime methyl ether, CPh_2NOMe, is obtained in pale yellow crystals melting at 92°.

Diphenylacetoxime ethyl ether, CPh_2NOEt, forms a yellow oil of sharp bitter taste and unpleasant odour; it boils with partial decomposition at 276—279°.

Diphenylacetoxime benzyl ether, $CPh_2NO.CH_2Ph$, is obtained in white crystals melting at 55—56°.

Acetyl-diphenylacetoxime, $CPh_2NO\overline{Ac}$, is prepared by heating diphenylacetoxime with acetic chloride in a reflux apparatus on the water-bath. It forms white crystals, melts at 55°, is sparingly soluble in alcohol, ether, and light petroleum, more readily soluble in chloroform. Its formation is of interest, as Nägeli found that camphoroxime is converted into its anhydride by the action of acetic chloride (this vol., 610).

Diphenylacetoxime hydrochloride, CPh_2NOH,HCl, prepared by passing dry hydrochloric acid gas into a solution of diphenylacetoxime in anhydrous ether, forms a white crystalline powder; it is very unstable, losing hydrochloric acid on exposure to air.

Diphenylsodacetoxime, CPh_2NONa, is prepared by the action of sodium ethylate on an ethereal solution of diphenylacetoxime; it forms a white crystalline powder. A. J. G.

Methylene Blue and Allied Colouring Matters. By A. Bernthsen (*Ber.*, **17**, 611—620). In a former communication (this vol., 595), the author expressed the opinion that *thiodiphenylamine* would prove to be the parent substance to Lauth's violet and methylene blue; a supposition the truth of which is shown by the following results:—

When *thiodiphenylamine* is nitrated carefully by treatment with a nitric acid of sp. gr. 1·44, it yields two isomeric *dinitrodiphenylamine sulphoxides*, which are distinguished as α- and β-compounds, the former is easily separated from the latter by its complete insolubility in boiling alcohol.

Dinitrophenylamine sulphoxide, $NH(C_6H_3NO_2)_2SO$, is soluble in hot aniline, from which it crystallises in yellowish-red needles or prisms. The β-compound separates from its alcoholic solutions as a light yellow powder.

α-Dinitroacetyldiphenylamine sulphoxide, $N\overline{Ac} \colon C_{12}H_6(NO_2)_2 \colon SO$, is formed when acetylthiodiphenylamine is nitrated; it is a light yellow powder consisting of slender, pale-yellow needles.

Methylthiodiphenylamine when nitrated yields compounds similar to the above.

Both the dinitro-compounds form leuco-bases when reduced with tin and hydrochloric acid or with stannous chloride; the α-compound yielding the leuco-base of Lauth's violet, and the β-compound the leuco-base of a violet colouring matter isomeric with Lauth's violet. The colouring matter from the β-compound is a diacid base, whilst Lauth's violet is a monacid base, as shown by the composition of their hydrochlorides. That of the latter has the formula $C_{12}H_9N_3S,HCl$, and that of the former $C_{12}H_9N_3S,2HCl$.

The view, already expressed by the author (*loc. cit.*), that methylene blue is a homologue of Lauth's violet, is supported by the fact that the leuco-bases of these colouring matters when treated with methyl iodide both yield one and the same compound, viz., *pentamethyldiamidothiodiphenylammonium iodide*, which would be formed from compounds having the constitution of these bases, as represented by the following formulæ:—

$NH(C_6H_3.NH_2)_2S$.	$NH(C_6H_3.NMe_2)_2S$.
Lauth's white.	Methylene white.

P. P. B.

Preparation of Phenylcyanamide. By F. Berger (*Monatsh. Chem.*, 5, 217—219). Phenylcyanamide is most cheaply and conveniently prepared by dissolving monophenylthiocarbamide (50 grams) in excess of 30 per cent. potash by aid of heat, and adding a pretty concentrated hot aqueous solution of lead acetate (125 grams) in small portions and with constant shaking. When the liquid is quite cold, it is acidified with acetic acid to precipitate the phenylcyanamide. The yield is 75—80 per cent. of the theoretical. A. J. G.

Derivatives of Isophthalonitrile and Terephthalonitrile. By G. Luckenbach (*Ber.*, 17, 1428—1437).—In order to study the behaviour of a dicyanide of the aromatic series with alcohol and hydrochloric acid, isophthalonitrile was prepared according to Barth and Senhofer's method (this Jour., 1876, i, 585) by distilling potassium metabenzenedisulphonate with potassium cyanide. The product was, however, found to be contaminated with terephthalonitrile and could not be purified by crystallisation. The separation of the two bodies was finally accomplished by conversion into the thioamides and treatment with alcohol in which thioisophthalamide alone is soluble. From the separated thioamides, the nitriles were regenerated by boiling with a solution of lead acetate.

Thioisophthalamide, $C_6H_4(CSNH_2)_2$, prepared by the action of hydrogen sulphide on an alcoholic solution of the nitrile mixed with alcoholic ammonia, forms yellow crystals, melts with decomposition at 199—200°, the greater part decomposing into isophthalonitrile and carbon bisulphide, whilst a yellowish-brown resinous substance is left. It is sparingly soluble in ether and carbon bisulphide, more readily soluble in boiling alcohol.

Isophthalimido ether, $C_6H_4[C(OEt):NH]_2$.—A solution of isophthalonitrile in six parts of benzene is mixed with absolute alcohol and saturated with dry hydrochloric acid gas. After about half an hour the liquid becomes turbid, an oil separates and after a short time solidifies to a crystalline mass of *isophthalimido ether hydrochloride*,

$$C_6H_4[C(OEt):NH],2HCl.$$

This, after purification, crystallises in white needles, softens at 255°, but is only completely fused at above 270°; on further heating it is completely decomposed into ethyl chloride and isophthalamide. It is readily soluble in water, the solution soon decomposing into ammonium chloride and ethyl isophthalate. Better results are obtained in the preparation of the hydrochloride by using ethyl acetate in place of benzene as a solvent of isophthalonitrile. The *free base*, prepared by treating the hydrochloride with soda and ether, is readily soluble in alcohol and ether, melts at 66°, and on heating at 120° is decomposed into ethyl alcohol, isophthalonitrile, and gaseous products.

Isophthalimido methyl ether forms small needles melting at 59—62°. The hydrochloride resembles the corresponding ethyl compound in preparation and properties.

Isophthalamidine, $C_6H_4[C(NH_2):NH]_2$, is obtained as hydrochloride by the action of concentrated alcoholic ammonia on isophthalimido ethyl ether. The free base was only obtained in an impure state as a mass of small needles, insoluble in ether and benzene, soluble in water and alcohol, the solutions rapidly decomposing with evolution of ammonia. The hydrochloride, $C_6H_4[C(NH_2):NH]_2,2HCl$, forms lustrous needles; the platinochloride, $C_6H_4[C(NH_2):NH]_2,H_2PtCl_6$, forms red crystals, sparingly soluble in water and alcohol; the sulphate crystallises in plates and is sparingly soluble in water; the nitrate is readily soluble in water and crystallises in needles. The silver derivative, $C_5H_8N_4Ag_2$, is obtained as an amorphous white precipitate, soluble in nitric acid and in ammonia.

By heating isophthalamidine with acetic anhydride and sodium acetate, it is converted into acetamide and a compound, $C_{16}H_{15}N_5O_2 = NH[C(NH).C_6H_4.CONH_2]_2$. This is insoluble in all ordinary solvents and is decomposed into isophthalic acid and ammonia when heated with potash or with hydrochloric acid.

Isophthalimido thioethyl ether, $C_6H_4[C(SEt):NH]_2$.—The hydrochloride of this base is obtained by the action of hydrochloric acid gas on a solution of isophthalonitrile and mercaptan in ethyl acetate. It crystallises in nodules, and on heating turns yellow at 175°, and melts at 190°, with decomposition into ethyl chloride and thioisophthalamide. It is insoluble in ether, readily soluble in alcohol and water; an oil separates from the aqueous solution, which on being dried in a vacuum solidifies to a mass of small needles of *ethyl thioisophthalate*, $C_6H_4(COSEt)_2$; it is readily fusible. By the action of soda on the hydrochloride, isophthalimido ethyl ether is obtained as an oil soon solidifying to a crystalline mass. It is very unstable.

Thioterephthalamide, $C_6H_4(CS.NH_2)_2$, is obtained as above described in the purification of isophthalonitrile. It forms a yellow powder insoluble in alcohol, and fuses with decomposition at 263°.

Terephthalamidine, $C_6H_4[C(NH_2):NH]_2$.—By the action of hydrochloric acid and alcohol on the crude isophthalonitrile, a mixture of the imidoethers of iso- and tere-phthalic acids is formed, from which on treatment with alcoholic ammonia *terephthalamidine hydrochloride* is obtained as a powder insoluble in absolute alcohol. It crystallises from water in brilliant hard apparently rhombic forms. The platinochloride forms small yellow crystals very sparingly soluble in water. The sulphate crystallises in small prisms and is sparingly soluble in water. The nitrate forms long thin needles. The free base could not be obtained in a pure state. A. J. G.

Action of Ethoxalyl Chloride on Diphenylthiocarbamide and Triphenylguanidine. By M. v. STOJENTIN (*J. pr. Chem.* [2], **29**, 302—303).—By the action of ethoxalyl chloride on diphenylthiocarbamide dissolved in benzene, a crystalline product is obtained of the composition $C_{21}H_{17}N_3S_2O$. On treating this with silver nitrate, the sulphur is removed, and diphenylparabanic acid (diphenyloxalylcarbamide), $CON_2Ph_2(C_2O_2)$, is obtained. By the action of fuming nitric acid on the thio-compound, $C_{21}H_{17}N_3S_2O$, a nitro-derivative, $C_{21}H_{12}N_6S_2O_6$, is formed; this, when heated with water or alkalis yields paranitraniline. A product, $C_{20}H_{16}N_3ClO$, was obtained from triphenylguanidine and ethoxalyl chloride, which, on digestion with alcoholic potash or by means of sodium amalgam, loses chlorine with formation of triphenylguanidine. A crystalline product was also obtained from phenylcarbamide. P. F. F.

Parethoxyphenylurethane and some of its Derivatives. By H. KÖHLER (*J. pr. Chem.* [2], **29**, 257—286).—A number of derivatives have been prepared by the author with a view of ascertaining the influence exerted by the carbamic acid radicle on substitutions of the benzene nucleus.

Parethoxyphenylurethane, $COOEt.NH.C_6H_4.OEt$, is prepared by adding ethylic chlorocarbonate to an alcoholic solution of paramidophenetoïl, precipitating the urethane by water, and recrystallising it from alcohol. It forms pink needles which melt at 94°. Long continued boiling with soda decomposes the urethane thus:—

$$COOEt.NH.C_6H_4.OEt + 2NaOH = NH_2.C_6H_4.OEt + Na_2CO_3 + EtHO.$$

When heated for several hours with strong hydrochloric acid at 130°, in a sealed tube, it is decomposed with formation of paramidophenol hydrochloride, carbonic anhydride, and ethyl chloride. The urethane distils between 250° and 270°, with partial decomposition, *parethoxycarbanil*, $CON.C_6H_4.OEt$, being formed by the elimination of alcohol. Parethoxycarbanil crystallises from glacial acetic acid in white needles melting at 219°; it is exceedingly stable, and unlike ordinary carbanil does not combine with alcohol.

Nitroparethoxyphenylurethane is prepared by acting with concentrated nitric acid (sp. gr. 1·4) on the urethane at 32—35°, precipitating the nitro-compound by water, and crystallising it from alcohol. It forms long golden needles melting at 71°. As shown below, the nitro-group occupies the meta-position to the phenolic hydroxyl, and no isomeric mononitro-compound was found, but a small quantity of dinitroethoxyphenylurethane is formed. The mononitro-compound may be more conveniently prepared than as above by heating 10 grams of the urethane with 150 grams of dilute nitric acid (sp. gr. 1·125) until the reaction becomes violent, after which no further heating is required.

Amidoparethoxyphenylurethane hydrochloride is prepared by reducing the nitro-compound with tin and hydrochloric acid. It crystallises in stellate groups of needles which melt at 155—156°, and dissolve both in water and alcohol; it reduces both silver nitrate and platinum chloride, and gives a blood-red coloration with bleaching powder or ferric chloride. The free amido-compound was obtained from the hydrochloride by neutralising a hot saturated solution of the latter with sodium carbonate; it separates out in small white needles which melt at 88°.

In order to ascertain the position in the benzene nucleus occupied by the nitro- and amido-groups in the above compounds, the diamidophenol was prepared from the amidoparethoxyphenylurethane by heating the hydrochloride with strong hydrochloric acid in a sealed tube for two hours at 130°. The tube was then opened to permit of the carbonic anhydride and ethyl chloride formed to escape, and thus prevent a secondary action by the latter taking place. The tube was then closed, and the heating repeated for periods of two hours at a time, until on opening the tube no further internal pressure was perceptible. The contents were then evaporated down in a current of sulphuretted hydrogen, and the hydrochloride of the diamidophenol obtained in small reddish-brown elongated scales. The diamidophenol was found to differ in several important points from that of Hemilian (this Journal, 1876, i, 918), thus the latter crystallises in small light grey prisms, and is insoluble in strong hydrochloric acid and in alcohol, whilst the diamidophenol from the urethane is soluble in both. Both diamidophenols give a dark-red coloration with chloride of lime or ferric chloride, but whereas that from the orthoparadiamidophenol of Hemilian has a violet tint, the other is of a pure blood-red colour. Since the two diamidophenols are not identical, the one obtained from the urethane must be parametadiamidophenol, and the nitro-group must have entered the urethane in the meta-position to the phenolic hydroxyl, as was to be anticipated.

Diazoimidoethoxyphenylurethane,  $COOEt.N\left\langle\begin{matrix}C_6H_3(OEt)\\ N:N\end{matrix}\right\rangle$, is formed by passing nitrous anhydride through a cold saturated solution of amido-ethoxyphenylurethane hydrochloride in absolute alcohol; the diazo-compound separates out in fine white crystals, which are insoluble in water and melt below 100°. The same compound separates out in white flocks when the hydrochloride of the amido-urethane is treated with an aqueous solution of potassium nitrite. Unlike other diazo-compounds, it neither explodes on heating nor by percussion, nor is it altered on heating with alcohol; on the other hand, when heated with a solution of ammonia or caustic soda, it is dissolved with evolution of nitrogen.

Dinitroparethoxyphenylurethane is prepared by acting with fuming nitric acid on the urethane in the cold, and precipitating with water and recrystallising from alcohol. It forms minute interlaced needles of a yellowish-white colour, melting at 141°. A second dinitro-compound was obtained from the alcoholic mother-liquors of the above, it forms bright yellow needles of considerable length, melting at 121°. The third possible dinitro-urethane was not found.

Diamidoparethoxyphenylurethane hydrochloride was prepared from the first of the above dinitro-urethanes by the action of tin and hydrochloric acid. The diamido-urethane combines with only 1 mol. HCl, and this salt crystallises in dark-coloured hexagonal scales melting at 238°.

Trinitroparethoxyphenylurethane was prepared in the same manner as the dinitro-compounds, only that the reaction was assisted by heat. It crystallises in small bright yellow prismatic needles, melting with decomposition at 211—212°. The trinitro-compound may be more conveniently prepared by heating 10 grams of the urethane with 200 grams of nitric acid (sp. gr. 1·4). All attempts to further nitrate the trinitro-urethane proved abortive. By reduction with tin and hydrochloric acid, the trinitro-compound was converted into *triamidoparethoxyphenylurethane hydrochloride*, which crystallises in small brownish needles, melting with decomposition at 233°.

Trinitroamidophenetoil, $C_6H(NH_2)(NO_2)_3.OEt$, was prepared by heating the trinitro-urethane with 20 times its weight of sulphuric acid (sp. gr. 1·14) for 3—5 hours in a large flask with an inverted condenser; the product was, however, not obtained in a pure state, but mixed with some of the unchanged trinitro-urethane. The crude product was converted by means of tin and hydrochloric acid into *tetramidophenetoil hydrochloride*, $C_6H(NH_2)_4.OEt,2HCl$; this crystallises in long flat prisms, which do not melt at 360°. With chloride of lime or ferric chloride, it gives a dark green coloration, changing to red, reddish-brown, yellow, and finally becomes colourless again.

P. F. F.

Étard's Reaction for the Preparation of Aromatic Aldehydes. By E. BORNEMANN (*Ber.*, 17, 1462—1475).—Étard has shown (Abstr., 1881, 581) that chromyl dichloride unites with aromatic hydrocarbons to form compounds which, when decomposed with water, yield aldehydes if the hydrocarbon contains a methyl-group, and ketones if no methyl-group is present. These compounds are of two kinds, the one class being simply additive products of the hydrocarbon and chromyl chloride, the other containing two hydrogen- and two chlorine-atoms less. The decomposition into aldehyde takes place according to the two equations:—

$$\text{I. } 3R.CH_3(CrO_2Cl_2)_2 + 3H_2O = 3R.COH + 2Cr_2Cl_6 + 2CrO_3 + 6H_2O.$$

$$\text{II. } 3R.CH(CrO_2Cl)_2 + 3H_2O = 3R.COH + Cr_2Cl_6 + Cr_2(OH)_6 + 2CrO_3.$$

Étard states, that with a mixture of the isomeric xylenes, chromyl dichloride forms a product which is decomposed by water, yielding pure metatoluylaldehyde. The author has repeated this reaction, but has always obtained a mixture of the isomeric aldehydes.

Metatoluylaldehyde, $C_6H_4Me.COH$.—35 parts of pure xylene and 100 of chromyl dichloride were each diluted with carbon bisulphide, and then gradually mixed, the red colour of the mixture disappears slowly, and a brown crystalline precipitate of the formula $C_6H_4Me_2,2CrO_2Cl_2$ is deposited. The temperature of the solution must not be allowed to exceed 47°, or dangerous explosions may occur. The brown precipitate is filtered off and dried rapidly by agitation over the water-bath in a flask connected with an air-pump. The heating over the water-bath must not be continued long, or violent explosions may take place. The cause of these explosions could not be ascertained, as small portions of this compound may be heated to 180—200° without change, and only give off hydrochloric acid when heated over 200°. The dried substance is then added to water in small quantities, and the aldehyde separated by distillation with steam or extraction with ether. It is then purified by means of its compound with hydrogen sodium sulphite. Metatoluylaldehyde is a colourless, highly refracting oil which boils at 198—199°, has the odour of bitter almonds and the properties ascribed to it by Gundelach (*Bull. Soc. Chim.*, 1867, **26**, 44) and Étard (*lot. cit.*). It rapidly absorbs oxygen from the air, and is converted into metatoluic acid melting at 109—110°.

Orthotoluylaldehyde was prepared from orthoxylene in a similar manner. It boils at 199—200°, has the odour of bitter almonds, and yields orthotoluic acid melting at 103°.

Paratoluylaldehyde has an odour like pepper, boils at 204—205°, and yields paratoluic acid melting at 180°. The yield of aldehydes in these three cases was about 70—80 per cent. of the theoretical.

Metaxylidenephenylhydrazine, $C_6H_4Me.CH : N_2Ph$, is formed by the action of metatoluylaldehyde on phenylhydrazine, using equal molecular weights. It crystallises in yellow prisms which melt at 91°. It is sparingly soluble in water, but easily so in the other usual solvents. *Metaxylideneaniline*, $C_6H_4Me.CH : NPh$, is obtained by mixing together the aldehyde and aniline. It is a mobile oil of aromatic odour, and boils at 313—314°. It is split up again into its two components by mineral acids and oxalic acid, but is not acted on by acetic or tartaric acid. *Metamethylmandelonitrile*, $C_6H_4Me.CH(OH).CN$, is obtained as a colourless mobile oil when the necessary quantity of hydrochloric acid is added to a mixture of equivalent proportions of metatoluylaldehyde and powdered potassium cyanide. Hydrochloric acid dissolves it at 60—70° with partial decomposition, and the solution yields small quantities of the corresponding amide when neutralised with ammonia. Strong sulphuric acid dissolves it with a red coloration, and water then precipitates a yellow voluminous mass having acid properties. *Metamethylmandelic acid*,

$$C_6H_4Me.CH(OH).COOH,$$

is obtained from the above nitrile by heating it with fuming hydrochloric acid at 60—70°. It crystallises in small glistening white scales which are easily soluble in water, alcohol, ether, chloroform, and boiling benzene, and melt at 84°. Cupric sulphate added to an aqueous solution of the ammonium salt, gives a blue precipitate soluble in ammonia; lead, silver, and zinc salts give white precipitates; the barium salt crystallises from water in small nodules. *Metatoluyl-*

anilidoacetonitrile, $C_6H_4Me.CH(NHPh).CN$, was obtained by heating an ethereal solution of the nitrile described above with aniline in closed tubes at 100°. It crystallises from alcohol in small colourless glittering scales, which melt at 95°, and are sparingly soluble in light petroleum, insoluble in water. Its alcoholic solution decomposes slowly with evolution of hydrocyanic acid. *Metatoluylanilidoacetamide*, $C_6H_4Me.CH(NHPh).CONH_2$, is obtained by dissolving the corresponding nitrile in sulphuric acid, allowing the solution to remain for 24 hours, then pouring it into water, and saturating with ammonia. It crystallises in white lustrous scales or needles which melt at 127—128°, and are easily soluble in alcohol, ether, benzene, and chloroform, insoluble in water. *Metatoluylanilidoacetic acid*,

$$C_6H_4Me.CH(NHPh).COOH,$$

was prepared by digesting the amide with dilute sulphuric acid. It crystallises in small silvery scales which are easily soluble in the usual solvents, and melt at 137—139°. Its salts with mineral acids are unstable, those with metals stable. *Metatoluylamidoacetic acid*, $C_6H_4Me.CH(NH_2).COOH$.—Metamethylmandelonitrile is digested with alcoholic ammonia in closed tubes at 100°, and the resulting dark-red liquid, which contains the amidated nitrile, is decomposed with dilute sulphuric acid. This acid crystallises in microscopic white hexagonal scales which are almost insoluble in the ordinary solvents. If heated with care, it sublimes at about 230°, but decomposes if heated quickly. Its copper, zinc, lead, and silver salts are white, and sparingly soluble in water. By the nitration of metatoluylaldehyde the author has obtained *orthonitrometatoluylaldehyde*—a pale-yellow oil already described (*Ber.*, **16**, 817), and *dinitrometatoluylaldehyde*, crystallising in long silky white needles which melt at 110—112°, and are easily soluble in alcohol, ether, benzene, and chloroform, sparingly so in boiling water. When treated with acetone and dilute alkali, it yields a colouring matter belonging to the indigo-group, so that one nitro-group must be in the para-position to the aldehyde-group. *Metamethylcinnamic acid*, $C_6H_4Me.CH : CH.COOH$, was prepared by heating together 4 parts metatoluylaldehyde, 3 parts dry sodium acetate, and 10 parts acetic anhydride. It crystallises in well-formed thin silky needles melting at 110—111°. It is easily soluble in alcohol, ether, chloroform, benzene, and boiling water, sparingly so in light petroleum. A solution of its ammonium salt yields a characteristic yellow precipitate with ferric chloride: its copper salt is pale blue, its lead salt is white. With a *cold* solution of silver nitrate, it gives a white curdy precipitate which may be recrystallised from boiling water, but the recrystallised salt is not nearly as stable as that precipitated in the cold. L. T. T.

Action of Benzoic Chloride on Benzaldehyde in Presence of Zinc-dust. By C. Paal (*Ber.*, **17**, 909—911).—The action of acetic chloride on benzaldehyde in presence of zinc-dust has been previously studied (Abstr., 1883, 805). In the case of benzoic chloride the product of the reaction is found to consist of two bodies, one sparingly soluble even in hot acetic acid, the other easily soluble. The insoluble body melts at 246°, crystallises in white needles, and has the composition $C_{28}H_{22}O_4$. With alcoholic potash solution, it yields hydrobenzoïn and benzoic acid, and is therefore the hydrobenzoin bibenzoate first prepared by Forst and Zincke.

The soluble body melts at 151°, and has the same composition as the above. On treating it with alcoholic potash and then with water, crystals of isohydrobenzoïn separate, and the solution contains sodium benzoate; the body is therefore isohydrobenzoïn bibenzoate, also prepared by Forst and Zincke. H. B.

Condensation-product from Salicylaldehyde. By H. Schiff (*Ber.*, **17**, 770—771).—Bourguin has recently (next Abstract) described a product obtained by the action of zinc chloride on salicylaldehyde. A similar compound was described by the author in 1872, and the formula $C_{14}H_{10}O_3$ assigned to it. It was obtained by the action of phosphorous oxychloride on helicin, and more slowly by using salicylaldehyde; it cannot again be converted into salicylaldehyde. Bourguin's analyses also confirm the formula $C_{14}H_{10}O_3$, which may perhaps be written $HO.C_6H_4.CO.C_6H_4.COH$; but as the body does not give any aldehyde reactions it probably consists of two such molecules united together by the aldehyde-groups. It possibly belongs to the class of condensation-products obtained by Baeyer (1872) from phenols and aldehydes. H. B.

Action of Zinc Chloride on Salicylaldehyde and Parahydroxybenzaldehyde. By A. Bourquin (*Ber.*, **17**, 502—504).—Both these aldehydes, when heated with glacial acetic acid and zinc chloride, form red amorphous substances, $C_{14}H_{10}O_3$, insoluble in ordinary solvents and slightly soluble in chloroform. They are both soluble in caustic alkalis, the product from salicylaldehyde forming red solutions, whilst that from parahydroxybenzaldehyde gives a violet solution. Further, the former is distinguished from the latter product by its solubility in sodium hydrogen sulphite solution, and by forming an acetyl derivative when heated with acetic anhydride. These compounds, formed by the condensation of 2 mols. of the aldehydes, are isomeric with benzoylsalicylaldehyde ($\overline{Bz}O.C_6H_4.COH$) and Perkin's disalicyl hydride, $(COH.C_6H_4)_2O$; their constitution is most probably represented by the following formula: $(OH.C_6H_4.C)_2O$, which represents them as a species of glycid compound in the formation of which the aldehyde-groups alone take part. P. P. B.

Nitromethylsalicylaldehyde and its Derivatives. By A. Schnell (*Ber.*, **17**, 1381—1358).—These experiments were undertaken (in connection with those of Tiemann and Ludwig—Abstr., 1883, 188—on metahydroxybenzaldehyde) to ascertain if the nitro-group could be replaced by hydroxyl or methoxyl. Metanitromethylsalicylaldehyde was prepared by Voaswinkel (Abstr., 1883, 189); it has the constitution $C_6H_3(COH)(OMe).NO_2$ [= 1 : 2 : 5]. All attempts to convert it into a hydroxylated methylsalicylaldehyde by amidation, conversion into the diazo-compound, &c., were fruitless.

By treatment with ferrous sulphate and ammonia, a crystalline substance, showing the properties both of an amine and an aldehyde, was formed, but was too unstable and obtained in too small quantity to serve as the material for the preparation of a hydroxymethylsalicylaldehyde. This method showing no prospect of success, the substances required were prepared by conversion of the aldehyde into cinnamic acid, and, after substitution, reconversion of this into the substituted aldehyde.

Metanitro-orthomethoxycinnamic acid,

$$C_6H_3(CH:CH.COOH)(OMe).NO_2 \; [= 1:2:5].$$

Metanitromethylsalicylaldehyde is converted into the corresponding cinnamic acid by heating it with acetic anhydride and sodium acetate. The acid crystallises in small white needles, melts at 238°, is readily soluble in ether and alcohol, and sparingly soluble in cold water. A neutral solution of the ammonium salt gives the following precipitates with metallic solutions:—With barium chloride white, soluble in hot water; with calcium chloride white, readily soluble; with lead acetate white, voluminous, dissolves on heating, then resinifies; with copper sulphate, greenish-blue, nearly insoluble; and with silver nitrate a white, very sparingly soluble salt.

Metamido-orthomethoxycinnamic acid,

$$C_6H_3(C_2H_2.COOH)(OMe).NH_2 \; [1:2:5],$$

prepared by reduction of the nitro-acid with ammonia and ferrous sulphate, crystallises in pale-red needles, melts at 189°, is nearly insoluble in cold water, somewhat more readily in hot water, readily soluble in alcohol and ether. The ammonium salt gives a voluminous white precipitate with silver salts which resinifies on heating; a yellow precipitate with lead salts; a dark-green precipitate with copper sulphate, nearly insoluble in hot water; a white precipitate with zinc salts.

Orthomethoxycinnamic acid metadiazo chloride,

$$C_6H_3(C_2H_2.COOH)(OMe)(N:NCl) \; [= 1:2:5].$$

1 part of the amido-acid is rubbed to a paste with 3 parts of concentrated aqueous hydrochloric acid and a solution of half part of sodium nitrite in 10 parts of water added in portions with constant stirring; the dark red-brown solution obtained deposited yellow crystals of the diazo-chloride on long standing. It is decomposed by heating at 102°. The corresponding *nitrate,*

$$C_6H_3(C_2H_2.COOH)(OMe)(N_2.NO_3) \; [= 1:2:5],$$

prepared by the action of nitric acid on the chloride, crystallises in yellow needles, explodes on heating to 151—152°, is nearly insoluble in cold water, alcohol, and ether, somewhat soluble in hot water.

Metahydroxyorthomethoxycinnamic acid,

$$C_6H_3(C_2H_2.COOH)(OMe).OH \; [= 1:2:5],$$

prepared by boiling the diazo-nitrate or chloride with water, forms small yellow crystals, melts at 179—180°, is nearly insoluble in cold water, readily soluble in alcohol, ether, benzene, and hot water. Solutions of the ammonium salt give a yellow precipitate with barium salts; a yellow precipitate with silver nitrate; a reddish-white precipitate with lead acetate; a clear green precipitate with copper sulphate; insoluble in hot water; soluble in ammonia, with yellowish-red colour. Fusion with potash converts the acid into a mixture of dihydroxybenzoic acid and other products.

Metaorthodimethoxycinnamic acid,

$$C_6H_3(C_2H_2.COOH)(OMe)_2\ [= 1 : 2 : 5],$$

is obtained by the action of methyl iodide and methyl alcohol on the dipotassium salt of the preceding acid, the product being treated with potash to decompose the methyl salt first formed. It crystallises in clear yellow needles, and melts at 143°. The ethereal solution shows a green fluorescence. A solution of the ammonium salt gives a white precipitate with lead acetate; with cupric sulphate a bluish-green precipitate insoluble on boiling; and a white precipitate with silver nitrate.

By oxidation with potassium permanganate, the dimethyl acid is readily converted into dimethylgentisic aldehyde,

$$C_6H_3(COH)(OMe)_2\ [= 1 : 2 : 5],$$

the constitution of which has been worked out by Tiemann and Max-Müller (Abstr., 1882, 52).

A. J. G.

Condensation of Acetone with Aromatic Aldehydes. By L. CLAISEN and A. C. PONDER (*Annalen*, **223**, 137—148).—The *Benzalacetone*, COMe.CH∶CHPh, which Claisen and Claparède (Abstr., 1882, 511) obtained by the action of zinc chloride on a mixture of benzaldehyde, acetone, and acetic anhydride, is identical with the acetocinnamone described by Engler and Leist (this Journal, 1873, 901). It is best prepared by adding 20 parts of a 10 per cent. solution of sodium hydroxide to 1800 parts of water containing 20 parts of benzaldehyde and 40 of acetone. After an interval of three or four days the mixture is extracted with ether. The ethereal solution is dried over calcium chloride and distilled in a vacuum, when a small quantity of dibenzalacetone is left in the retort. Benzalacetone boils at 152° under a pressure of 25 mm., and at 261° under the ordinary atmospheric pressure. Many of the properties of this compound have been previously described (*loc. cit.*).

Dibenzalacetone or *cinnamone*, $CO(CH∶CHPh)_2$ (Abstr., 1882, 511), can also be prepared by acting on an alcoholic solution of benzaldehyde and acetone with caustic soda. The crystalline mass, which is slowly deposited, is washed with alcohol and recrystallised. A better yield is obtained by mixing together 7 parts of monobenzalacetone, 5 of benzaldehyde, 200 of water, 150 of alcohol, and 20 parts of a 10 per cent solution of soda. Dibenzalacetone crystallises in monoclinic plates, $a : b : c = 4·886 : 1 : 1·378$. $\beta = 78° 43'$. The crystals melt at 112° with decomposition.

Traces of acetone may be detected in alcoholic solution by the addition of a few drops of benzaldehyde and sodium hydroxide. After a few hours the characteristic crystalline plates of dibenzalacetone are deposited.

The preparation and properties of *monofurfuralacetone* have been previously described by the authors (Abstr., 1882, 513). *Difurfuralacetone*, $CO(CH:CH.C_4H_3O)_2$, is prepared by adding 30 grams of a 10 per cent. solution of caustic soda to a mixture of 20 grams of furfuraldehyde, and 6 of acetone, dissolved in 400 c.c. of water and 500 of alcohol. After an interval of several days, the liquid is poured into water. The crude product is recrystallised from light petroleum, and is then obtained in brown prisms, which melt at 60° and dissolve freely in alcohol, ether, and chloroform

Benzalfurfuralacetone, $CHPh:CH.CO.CH:CH.C_4H_3O$, formed by the action of dilute caustic soda on an alcoholic solution of furfuralacetone and benzaldehyde, or of benzalacetone and furfuraldehyde, crystallises in straw-coloured plates or flat prisms melting at 56°. The crystals are soluble in alcohol, ether, benzene, chloroform, and give a dark red coloration with sulphuric acid.

Cuminol forms two compounds with acetone, viz., *cuminalacetone*, $C_3H_4(C_{10}H_{12})O$, a strongly refractive oily liquid boiling at 180° under a pressure of 23 mm., and *dicuminalacetone*, $C_3H_2(C_{10}H_{12})_2O$, crystallising in long prisms melting at 106°.

Benzalacetophenone can also be prepared by adding soda to acetophenone and benzaldehyde dissolved in a mixture of alcohol and water. W. C. W.

Action of Acetic Chloride on Benzophenone in Presence of Zinc-dust. By C. PAAL (*Ber.*, 17, 911—913).—The reaction in ethereal solution is energetic, a white crystalline compound of the composition $C_{26}H_{20}O$ being deposited, it melts at 178—179°; with alcoholic potash, it yields triphenylmethane and benzoic acid; it is β-benzopinacoline (Abstr., 1881, 813). The yield is excellent if an excess of acetic chloride—viz., about four times the theoretical quantity—be employed. If the theoretical quantity of acetic chloride is used, the product consists mainly of α-benzopinacoline, forming long needles and melting at 196°. By employing about twice or two and a-half times the theoretical amount of acetic chloride, a body is obtained melting constantly at 158—159°; it is, however, a mixture of the α- and β-benzopinacoline.

In this reaction benzopinacone biacetate seems to be formed, but at once decomposes into acetic anhydride and α-benzopinacoline, which is converted into β-benzopinacoline by the excess of acetic acid.

H. P.

Benzoylacetone and Isonitrosobenzoylacetone. By M. CERESOLE (*Ber.*, 17, 812—817).—By the action of hydroxylamine hydrochloride on benzoylacetone, $COPh.CH_2.COMe$, a crystalline substance melting at 65·5—66° is formed; it does not contain the isonitroso-group twice, but only once, and unlike all such compounds (this vol., 599) it is quite insoluble in acids and in alkalis. The action of alkalis should decide which of the two possible isomerides the body is, viz., $COPh.CH_2.CMe:NOH$, or $CPh(NOH).CH_2.COMe$, the reaction, however, was not very sharp, but pointed rather to the second formula. Attempts to act on the second carbonyl-group were quite unsuccessful; this is remarkable, the more so since by the action of phenylhydrazine on orthonitrobenzoylacetone both carbonyl-groups are attacked.

In order to ascertain if hydroxylamine would act on both carbonyl-groups in certain derivatives of benzoylacetone, use was made of isonitrosobenzoylacetone, COPh.C(NOH).COMe, since this also promised to give the first of a new class of bodies, the trioximides.

Isonitrosobenzoylacetone is not formed by the action of alkalis and nitrous acid on ethylic benzoylacetoacetate; but it is easily prepared by adding sodium alcoholate, and then nitrous acid, to an alcoholic solution of benzoylacetone. It crystallises from hot water in needles melting at 123·5—124° It yields hydroxylamine hydrochloride when heated with strong hydrochloric acid. Heated with hydroxylamine and hydroxylamine hydrochloride a body is obtained, which, after purification, melts at 178°, and contains the isonitroso-group, not thrice, but only twice. Another substance melting about 115°, formed at the same time, was also found not to be the desired

$$CPh(NOH).C(NOH).CMe:NOH,$$

since it contains the isonitroso-group twice; it is probably one or other of the two possible isomerides, CPh(NOH).C(NOH).COMe, and COPh.C(NOH).CMe : NOH. H. B.

Phenyl Thienyl Ketone. By A. Comey (*Ber.*, 17, 790—791).—The author has been unable to complete his investigation to ascertain whether thiophene undergoes the Friedel-Crafts reaction, but communicates the following. Crude thiophene (Abstr., 1883, 1091) heated with benzoic chloride and aluminium chloride yields phenyl thienyl ketone, $C_6H_5.CO.C_4H_3S$, which is separated by distillation with steam and extraction of the distillate with ether; it melts at 55°, and boils at about 300°. When heated in alcoholic solution with hydroxylamide hydrochloride and caustic soda, *phenylthienylacetoxime*,

$$C_6H_5.C(NOH).C_4H_3S,$$

is obtained in colourless crystals melting at 91—92°. The ketone, when heated with soda-lime, yields calcium benzoate, free from sulphur; the oily distillate is not pure thiophene, but contains benzene. Phenyl thienyl ketone gives a blue coloration with isatin and sulphuric acid; the acetoxime, a violet coloration. H. B.

Substances accompanying Benzoic Acid prepared from Gum Benzoin. By O. Jacobsen (*Arch. Pharm.* [3], 22, 366—374).—On treating benzoic acid from gum benzoin with sodium carbonate solution, an oil is left undissolved, smelling of vanillin and also of phenol. By fractionation, it may be separated into three principal portions, boiling at 200—210°, 235—245°, and 280—330°, and a pitch-like residue not further examined. The first fraction consists of methyl benzoate and guaiacol, which can be separated by treatment with cold dilute caustic soda. The second and smaller fraction, when shaken with water, gives up catechol in the aqueous solution; the portion insoluble in water and dilute alkalis is acetylguaiacol (Abstr., 1882, 54). The third and largest portion consists of an oil, insoluble in dilute alkalis, which by saponification with alcoholic potash, and subsequent treatment with water and ether, yields benzyl alcohol, and benzophenone, whilst the aqueous solution contains guaiacol and benzoic acid; this fraction therefore contains benzyl benzoate, benzophenone, and benzoylguaiacol. The oil also contains vanillin, but in minute quantity only. The medicinal value of sublimed benzoic acid is attributed to the catechol and guaiacol; it is believed that of the above bodies only vanillin and benzyl benzoate exist ready formed in the gum. Benzaldehyde may be formed by the oxidation of the contained benzyl benzoate, so that the production of the former cannot be considered as a proof of adulteration with cinnamic acid. Schiickum and Schneider (Abstr., 1882, 1138) have tested the genuine nature of natural benzoic acid by its reducing boiling ammoniacal silver solution; but catechol will reduce the solution in the cold, and the author therefore suggests the following method of testing:—Convert the benzoic acid into the sodium salt, and, after drying, shake with ether; after removal of the ether, the residue may be dissolved in water, and the above or any other tests for catechol applied. H. B.

Aromatic Acids as Dye-forming Substances. By C. ZULKOWSKY (*Monatsh. Chem.*, 5, 221--227).—A mixture of benzoic acid (1 mol.) and resorcinol (2 mols.) is heated for 6 to 8 hours at 170—180° with an amount of zinc chloride equal in weight to the resorcinol employed. After washing several times with water, the residue is dissolved by boiling it with 50 per cent. alcohol. On cooling, crystals separate; these are much less soluble in alcohol than the crude product, and their solution has a golden-yellow colour, with a bright green fluorescence, which becomes much stronger on addition of ammonia or potash. Sulphuric acid can be used instead of zinc chloride as the dehydrating agent. From its method of preparation this substance should be identical with Doebner's resorcinolbenzeïn (Abstr., 1880, 644). Benzoic anhydride can be substituted for the acid when zinc chloride is employed.

By heating benzoic acid (1 mol.), orcinol (2 mols.), and sulphuric acid for about four hours at 130—135°, there is obtained, after washing with hot water, a steel-green brittle mass, of metallic lustre. This, after purification by boiling with an amount of dilute soda, insufficient for complete solution, and precipitation with acetic acid, forms a golden-yellow precipitate, whose alcoholic solution has a golden-yellow colour and a feeble dark green fluorescence, increased by ammonia. The substance can be crystallised from glacial acetic acid.

The product obtained by heating benzoic acid (1 mol.) with pyrogallol (2 mols.) and sulphuric acid for 2½ hours at 120—130° is soluble in hot water, from which it separates in large crystals on cooling. The crystals appear to be really colourless, but are covered by a brown layer, apparently formed by an oxidation-product. The alcoholic solution has a brownish-red colour; it turns violet with ammonia, whilst potash produces discoloration.

Salicylic acid and resorcinol heated with zinc chloride or sulphuric acid at 130—140° give a substance forming dark reddish-brown crystals. The alcoholic solution has a red-yellow colour, and shows a green fluorescence which becomes extraordinarily intense on adding ammonia. A. J. G.

Action of Reducing Agents on Ortho-nitrophenoxyacetic Acid. By A. Thate (*J. pr. Chem.* [2], **29**, 145—191).—This subject was first investigated by Fritzsche (Abstr., 1880, 318), who employed stannous chloride as the reducing agent, and obtained a product which he named orthamidophenoxyacetic acid. The author finds that the product obtained according to Fritzsche's instructions is never a pure orthamidophenoxyacetic anhydride, but always contains more or less chlorine not separable by recrystallisation.

Orthonitrophenoxyacetic acid, $NO_2.C_6H_4O.CH_2.COOH$.—Fritzsche's method of evaporating a solution of sodium monochloracetate with sodium orthonitrophenylate gives but a very small yield, owing to most of the nitrophenol becoming liberated and volatilised. A much better process is to heat equivalent weights of sodium orthonitrophenylate in saturated solution with sodium monochloracetate for 10 hours at 100° in a flask provided with a reflux condenser. The reaction is complete when the wine-red colour of the liquid is changed to yellow or yellowish-red. The filtered liquid is acidulated with hydrochloric acid, and the precipitated acid is purified by recrystallisation from water. The acid is yellowish-white, melts at 156·5°, and crystallises in irregular pyramids, which exhibit double refraction, and therefore do not belong to the regular system, as stated by Fritzsche.

Azoxyorthophenoxyacetic acid, $(C_6H_4O.CH_2.COOH)_2N_2O$.—Prepared by the action of sodium amalgam on a solution of sodium orthonitrophenoxyacetate. The solution is poured off from the separated mercury, and solidifies to a yellow mass on cooling, which is collected, is decomposed by acid, and recrystallised from dilute alcohol. The substance so obtained is a mixture of azoxy- and azo-orthophenoxyacetic acid. If the reduction has taken place satisfactorily, the melting point of the substance should not be below 170°. In order to purify the azoxy-acid, it is etherified by means of alcohol and hydrochloric acid gas; the ether crystallises out on cooling, and is separated from the corresponding ether of the azo-acid by washing with dilute acid. The ether is then saponified, the potassium salt decomposed with hydrochloric acid and the azoxyorthophenoxyacetic acid recrystallised from water. The acid crystallises with 1 mol. H_2O in forms which resemble those of calcspar; it is insoluble in anhydrous ether and benzene, and melts at 186—187°. The acid forms a normal and an acid silver salt, both of which are anhydrous, whilst the barium salt contains 2 mols. H_2O. The ethylic ether crystallises in long white silky needles melting at 113—114°.

Azo-orthophenoxyacetic acid, $C_6H_4(O.CH_2.COOH)_2N_2$.—The preparation is similar to that of the azoxy-acid, excepting that more sodium-amalgam has to be employed. The acid can generally be obtained in a pure state by three or four recrystallisations from dilute alcohol, but it cannot be separated from the azoxy-acid by means of its ethylate, as the latter is very difficult to obtain in a pure state; the two acids may, however, be approximately separated by means of their silver salts, that of the azo-acid being precipitated from a hot aqueous solution, whilst the silver salt of the azoxy-acid only falls out on cooling. The azo-acid crystallises with 2 mols. H_2O in beautiful silky orange needles melting at 162°. It is soluble in water, alcohol, ether, alkalis, and strong acids. The salts are of a bright yellow or red colour; the potassium, sodium, and silver salts each crystallise with 3 mols. H_2O, the barium salt with $2H_2O$, and the calcium salt with $8H_2O$. The diethylate melts at 110—111°.

Hydrazo-orthophenoxyacetic acid, $(NH.C_6H_4O.CH_2.COOH)_2$, is prepared by saturating a solution of azo-orthophenoxyacetic acid with sulphuretted hydrogen, and allowing the mixture to remain for some time in a closed flask; the ammonium salt of the hydrazo-acid then separates out mixed with sulphur, and is purified by recrystallisation from alcohol. The ammonium salt is only partially converted into the free acid by acidulation with acetic acid, an acid salt being the chief product. The potassium salt crystallises with 3 mols. H_2O; on drying in contact with air, it partially passes into the potassium salt of the azo-acid, acquiring thereby a vermillion colour. Mineral acids, on the other hand, precipitate the azoxy-acid from the aqueous solutions of salts of the hydrazo-acid.

Orthamidophenoxyacetic acid, $NH_2.C_6H_4O.CH_2.COOH$.—The acid itself is as yet unknown, for it decomposes into 1 mol. H_2O and a body which, from its mode of formation, may be termed orthamidophenoxyacetic anhydride, $C_8H_7NO_2$. This substance is obtained as a bye-product in the preparation of azo-orthophenoxyacetic acid. The filtrate from the sodium salt of this acid, which separates after the reduction is complete as described above, is acidulated with hydrochloric acid and evaporated to dryness, the residue then consists of sodium chloride together with the azo-acid and the amido-anhydride. The amido-anhydride is extracted by absolute alcohol, and is separated from the azo-acid by crystallisation from water, and afterwards from dilute alcohol. The anhydride crystallises in short white prisms melting at 166—167°. It is also formed when orthonitrophenyoxyacetic acid is reduced with iron filings and acetic acid. It was not found possible to convert the anhydride into monochlororthamidophenoxyacetic acid by continued boiling with hydrochloric acid; this compound, $C_8H_6ClNO_2$, is however formed, and crystallises out when an aqueous solution of orthonitrophenoxyacetic acid is reduced with stannous chloride; it is purified by repeated crystallisation from water, and has a melting point of 196—197°. Several salts of the two acids from which these anhydrides are respectively derived are then described.

The author points out that the substance previously obtained by Fritzsche, and melting at 143—144°, may possibly consist of 1 mol. of orthamidophenoxyacetic anhydride, and 1 mol. of monochlororthoamidophenoxyacetic anhydride ($C_8H_7NO_2 + C_8H_6ClNO_2$), and that if this be the case it is not improbable that pairs of molecules of one and the same anhydride may be similarly linked together, thus: $(C_8H_7NO_2)_2$ and $(C_8H_6ClNO_2)_2$. Owing to the instability of these compounds it was not found possible to test this hypothesis by means of vapour-density determinations. Assuming, however, this proposition to be true, the so-called "inner anhydrides" can be readily derived from the hydrazo-compounds, a step which is apparently justified on the one hand by the intermediate position which they occupy between the hydrazo- and the amido-compounds, and on the other by the instability which the hydrazo compounds exhibit. P. F. F.

Constitution of Dibromanisic Acid. By L. BALBIANO (*Gazzetta*, 14, 9—12).—From the results obtained by the destructive distillation of calcium dibromanisate and of a mixture of sodium dibromanisate with lime (Abstr., 1883, 1125), the author inferred that the bromine-atom occupied the ortho-position relatively to the methyl-group or to the carboxyl-group. A study of the action of nitric acid on dibromanisic acid has now enabled him to definitely determine the constitution of the latter.

On adding dibromanisic acid (5 grams) to nitric acid of sp. gr. 1·52 (35 to 40 grams), at a temperature of 30° to 40°, it dissolves with effervescence, due to evolution of carbonic anhydride, and the solution becomes red; on pouring this into a large quantity of water, a white crystalline substance is precipitated about equal in weight to the dibromanisic acid originally employed. The product when purified by crystallisation from a mixture of ether and alcohol melts at 122—123°, and has all the properties of the anisoïl derivative obtained by Koerner (*Gazzetta*, 4, 390) from Brunck's dibromonitrophenol, and which has the constitution [$OMe : Br : NO_2 : Br = 1 : 2 : 4 : 6$]. In order to remove all doubt as to its identity, it was converted into nitrodibromaniline by the action of alcoholic ammonia at 180°; the product melted at 202° to 203°, and agreed in all its properties with Koerner's derivative [$NH_2 \cdot Br : NO_2 : Br = 1 : 2 : 4 : 6$] (*Gazzetta*, 4, 369, *et seq.*). From these results it is certain that the dibromanisic acid, $C_6Br_2(OMe).COOH$, has the constitution [$OMe : Br : COOH : Br = 1 : 2 : 4 : 6$], and it follows also that the dibromhydroxybenzoic acid mentioned in the former paper (*loc. cit.*) has a similar constitution. C. E. G.

Substituted Aromatic β-Lactones and Derivatives of Cinnamic Acid. By A. BASLER (*Ber.*, 17, 1494—1503).—This paper forms a continuation of the author's previous communication on this subject (this vol., 603).

When ammonia in excess is allowed to act on paranitrophenyl-β-bromopropionic acid or its lactone in the presence of water, *paranitrophenyl-β-alanine*, $C_9H_{10}N_2O_4$, is formed. This body crystallises in small white scales or prisms which melt at 166—167°. It is *very* sparingly soluble in the usual solvents in the cold, more easily in boiling alcohol and water, and in glacial acetic acid. It dissolves in a hot solution of sodium carbonate, but crystallises out unchanged on cooling. A hot aqueous solution dissolves mercuric oxide yielding long colourless needles, from which the alanine is regenerated by acids. When diazotised, it yields nitrophenyllactic acid. It does not form metallic salts, but yields a hydrochloride crystallising in small needles, and a hydrobromide forming colourless plates or cubes melting at 132—135°; both these salts are decomposed by water. Acids and alkalis decompose it into ammonia and paranitrophenyllactic acid: but if dissolved in concentrated sulphuric acid, it yields a body crystallising in white needles which melt at 180°. When heated with acetic anhydride, it yields a monacetyl-derivative, which crystallises in small colourless scales, fuses at 140—150°; and is soluble in alcohol, ether, and glacial acetic acid, but insoluble in a solution of sodium carbonate.

When paranitrophenyl-β-bromopropionic acid is acted on by aniline in the cold, an aniline salt of the acid is obtained, from which the acid is regenerated by acetic or other acid. When aniline is used in large excess, and the mixture is digested at 100°, *paranitrophenyl-β-anilidopropionic acid*, $NO_2.C_6H_4.CH(NH_2).CH_2.COOH$, is obtained. It is also formed when the aniline salt described above is dissolved in an alkali. It crystallises in yellow prisms which melt at 120—122°, and are soluble in alcohol and benzene, sparingly so in boiling water or acetic acid. It forms yellow metallic salts—of which the *ammonium salt* is the most characteristic and crystallises in yellow silky needles melting at 150—156°—whilst with mineral acids it yields crystallisable salts which are decomposed by water. By etherifying the yellow acid, the same ethyl salt is obtained as is formed by the action of aniline on the ether of the brominated acid; it crystallises in cubes which are sparingly soluble in the usual solvents. It forms no salts with acids. With paranitrophenyl-β-propiolactone, aniline yields paranitrophenyl-β-lactanilide which melts at 176—178°, and in its general characteristics very much resembles the β-alanine described above.

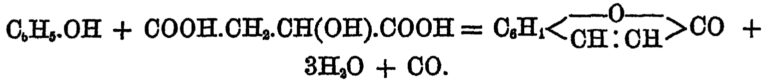
Taking all these data into consideration, the author believes this β-alanine to be paranitrophenyl-β-lactamide,

$$NO_2.C_6H_4.CH(OH).CH_2.CONH_2,$$

and the β-alanine described by Einhorn (this vol., 304) to be the corresponding ortho-compound, and not, as that investigator supposed, an internal anhydride. The author believes that its formation from the brominated acid is probably preceded by that of the lactone.

L. T. T.

New Mode of Formation of the Coumarins; Synthesis of Daphnetin. By H. v. PECHMANN (*Ber.*, **17**, 929—936).—The only known method of preparing the coumarins synthetically is to apply Perkin's reaction to the hydroxyaldehydes; this method has been successfully employed by Perkin, Tiemann, and Kauffmann, but the preparation of the hydroxyaldehydes often offers very great difficulties. The synthesis of these compounds is of special interest, as probably very many vegetable products belong to this class—among others, æsculetin and daphnetin. By allowing concentrated sulphuric acid, zinc chloride, or other similar dehydrating agents to act at high temperatures on a mixture of a phenol and malic acid, water and carbonic oxide are eliminated, and a coumarin is formed more or less easily according to the nature of the phenol employed. Thus in the case of coumarin,



$$C_6H_5.OH + COOH.CH_2.CH(OH).COOH = C_6H_4<\overset{O}{\overline{CH:CH}}>CO + 3H_2O + CO.$$

This reaction really takes place in three stages :—(1.) The conversion of the malic acid into the hypothetical half-aldehyde of malonic acid and formic acid, which is decomposed into water and carbon monoxide, $COOH.CH(OH).CH_2.COOH = CH_2O_2 + CHO.CH_2.COOH$. This reaction resembles the conversion of lactic acid into formic acid and acetaldehyde, and is proved by the formation of a condensation-product, $C_6H_4O_4$, of the half-aldehyde of malonic acid (see p. 1124). (2.) The union of the nascent aldehyde with the phenol to form an ortho-hydroxyphenyl-lactic acid, $C_6H_5.OH + CHO.CH_2.COOH = OH.C_6H_4 CH(OH) CH_2.COOH$. (3.) The elimination of 2 mols. of water,  $OH.C_6H_4.CH(OH).CH_2.COOH = C_6H_4<\overset{O}{\overline{C_2H_2}}>CO + 2H_2O$. The second stage quite corresponds with the method of v. Pechmann and C. Duisberg (this vol., 66) for the preparation of coumarins, and the author considers these two methods of synthesis as sufficient proof against the objections of Wittenberg and of Michael (this vol., 736). This reaction also explains Schmid's synthesis of methylumbelliferone, and is capable of great extension, since other hydroxy-acids of the fatty series may be employed, and the phenols may be replaced by aromatic amido-compounds.

Thus far, the actions of phenol, resorcinol, and pyrogallol on malic acid have been examined. Phenol acts with difficulty, forming coumarin in small quantity; the other two yield umbelliferone and daphnetin respectively.

Umbelliferone,  $OH.C_6H_3<\overset{O}{\overline{CH:CH}}>CO$ [OH : O : CH = 1 : 3 : 4]. —Resorcinol and malic acid in molecular proportion are heated with twice their weight of strong sulphuric acid, then poured into iced water, and after a time the crystalline mass is collected and recrystallised.

Daphnetin,

$$(OH).C_6H_2<\overset{O}{\overline{CH:CH}}>CO \ [OH : OH : O : CH = [1 : 2 : 3 : 4].$$

—The preparation is carried out as in the preceding case; it gives all the reactions of natural daphnetin, whose constitution was first made out by Stunkel, but he failed to prove the presence of more than one hydroxyl-group, that is, he could only prepare a monacetyl-derivative and a monobenzoyl-derivative. The author has, however, prepared *diacetyldaphnetin* from both natural and artificial daphnetin; it melts at 129; and also *dibenzoyldaphnetin* which crystallises in needles and melts at 152°.

H. B.

β-Lactone of Metanitrophenyl-lactic Acid. By G. Prausnitz (*Ber.*, 17, 595—599).—The starting point in the preparation of this compound was metanitrocinnamic acid, prepared from metanitrobenzaldehyde by Perkin's reaction; this acid was next heated at 100° in sealed tubes with glacial acetic acid, saturated with hydrobromic acid. In this way *metanitrophenylbromopropionic acid* is prepared, which is sparingly soluble in boiling toluene and light petroleum, more easily in benzene, and very soluble in glacial acetic acid, chloroform, ether, and absolute alcohol. When boiled with water, it yields *metanitrostyrolene*, *nitrocinnamic* and *nitrophenyl-lactic acids*, these compounds are also formed by boiling it with solution of sodium carbonate sufficient for neutralisation; when treated with an excess of caustic alkali *metanitrocinnamic acid* is obtained.

β-Lactone of metanitrophenyl-lactic acid, $NO_2.C_6H_4.CH<\substack{CH_2\\-O-}>CO$, is obtained by neutralising the above acid carefully with a solution of sodium carbonate in the cold, and allowing the solution to remain some hours, when a crystalline mass separates out which, after solution in benzene and precipitation with light petroleum, is obtained in small white crystals melting at 98°; when heated above its melting point, it is resolved into carbonic anhydride and nitrostyrolene.

Metanitrostyrolene, $C_8H_7.NO_2$, is best obtained by boiling the nitrobromopropionic acid with sodium carbonate, when it passes over with the steam; it may be extracted from the distillate by ether. On evaporation, the ethereal solution leaves an oil which solidifies at − 15°. It is easily soluble in ether, alcohol, light petroleum, chloroform, and glacial acetic acid.

Metanitrostyrolene dibromide, $NO_2.C_6H_4.CHBr.CH_2Br$, is obtained by adding bromine to a solution of nitrostyrolene in glacial acetic acid; it crystallises from alcohol in well-formed crystals melting at 78—79°.

Metanitrophenyl-β-lactic acid, $NO_2.C_6H_4.CH(OH).CH_2.COOH$, is formed, together with nitrocinnamic acid and nitrostyrolene, as described above. It is separated from the nitrocinnamic acid by its solubility in water, the mother-liquors from this acid yielding the phenyl-lactic acid on extraction with ether. Nitrophenyl-lactic acid crystallises from water in white lustrous leaflets which melt at 105°. When it is heated at 140° in sealed tubes with glacial acetic acid, which has been saturated with hydrobromic acid, nitrophenylbromopropionic acid is reproduced. P. P. B.

Hydroxyphenylacetic Acids. By H. SALKOWSKI (*Ber.*, **17**, 504—510).—In the preparation of these compounds, the author first obtains the three isomeric nitrobenzyl cyanides by nitrating benzyl cyanide and separating these by systematic crystallisation from glacial acetic acid. Besides the para-, ortho-, and meta-nitrobenzyl cyanides, a fourth body is formed, identical with that described by Perkin (Trans., 1883, 112), but which is not the ortho-derivative as was supposed by Perkin.

Parahydroxybenzyl cyanide, $OH.C_6H_4.CH_2.CN$, is obtained by treating an acid solution of the amido-derivative with sodium nitrite; it crystallises from hot aqueous solutions in large shining tables, which melt at 69—70°. Its aqueous solution yields a violet coloration with ferric chloride. On saponification with hydrochloric acid, it yields *parahydroxyphenylacetic acid*, melting at 148°. The cyanide, when heated with potassium hydroxide and methyl iodide, yields a methyl ether, which, by saponification with hydrochloric acid, is converted into *paramethoxyphenylacetic acid*, an acid homologous with anisic acid.

Metanitrobenzyl cyanide forms large well-defined monoclinic crystals melting at 61°. The author finds that the corresponding phenylacetic acid melts at 120°, somewhat higher than the melting point given by Gabriel and Borgmann (Abstr., 1883, 1121). *Metamidobenzyl cyanide* is an oily liquid, which was converted into the hydroxy-derivative, a substance easily soluble in alcohol, ether, and water, and crystallising on slow evaporation of its aqueous solution in rhombic tables melting at 52—58°. *Metahydroxyphenylacetic acid* was obtained by saponification of the cyanide, it crystallises from hot benzene or light petroleum in slender needles, which melt at 129°. Ferric chloride gives with its aqueous solutions at first a violet coloration, but it rapidly fades.

Orthonitrobenzyl cyanide crystallises in large well-defined rhombic prisms melting at 84°; it yields the nitrophenylacetic acid melting at 141° (Bedson, Trans., 1880, 90). The author has not succeeded in isolating in a state of purity the corresponding amidobenzyl cyanide, the crude amido-derivative treated with sodium nitrite, &c., does not yield an hydroxy-derivative, but a compound crystallising in slender colourless needles, melting at 139°, and apparently of the composition $C_8H_6N_2O$. This, when heated with hydrochloric acid, does not yield hydroxyphenylacetic acid, but a compound, $C_{14}H_{11}N_3O_4$, melting at 254°.

P. P. B.

Condensation-products from Phthalic Anhydride. By S. Gabriel (*Ber.*, 17, 1389—1396).—The author has previously shown (Abstr., 1881, 733) that by heating phthalic anhydride with ethyl acetate and sodium acetate there was obtained orthotribenzoylene benzene and a crystalline substance, to which he provisionally assigned the formula $C_{12}H_8O_2$. This formula should be doubled. On nitration, the substance yields a nitro-derivative, $C_{24}H_{14}(NO_2)_2$, crystallising in groups of slender needles, melting at over 280°, soluble in boiling nitrobenzene, sparingly soluble in boiling glacial acetic acid. By heating it with hydriodic acid and phosphorus for three hours at 170—175°, it is converted into a new hydrocarbon, phthalacene, $C_{21}H_{16}$, ethyl iodide, and carbonic anhydride. *Phthalacene* forms long colourless crystals, and melts at 173°. Its derivatives are described in the Abstract, p. 1189. From these results, it seemed highly probable that the compound, $C_{24}H_{16}O_4$, was the ethyl salt of an acid, $C_{21}H_{11}O_2.COOH$, phthalaconecarboxylic acid, and further investigation has completely confirmed this view.

By heating the compound, $C_{24}H_{16}O_4$, with concentrated sulphuric acid for half an hour, and pouring the blood-red liquid into water, a citron-yellow precipitate is obtained, which may be purified by crystallisation, first from boiling alcohol, then from boiling glacial acetic acid, and again several times from boiling alcohol; on mixing the hot alcoholic solution with hot alcoholic potash, *potassium* *phthalaconecarboxylate*, $C_{21}H_{11}O_2.COOK + H_2O$, separates in slender yellow needles. The sodium salt, $C_{21}H_{11}O_2.COONa + H_2O$, crystallises in slender golden-yellow needles.

Phthalaconecarboxylic acid, $C_{21}H_{11}O_2.COOH$, obtained by decomposing the alkali salts with hydrochloric acid, crystallises in yellow microscopic needles, melts at 280—281·5°, is moderately soluble in hot alcohol, less soluble in hot glacial acetic acid.

Ethyl hydrophthalaconecarboxylate, $C_{21}H_{13}(OH)_2.COOEt$, prepared by the action of zinc-dust on a solution of ethyl phthalaconecarboxylate in boiling glacial acetic acid, forms a very pale-yellow crystalline powder, which melts at 211—213°. When heated with potash, it is converted into a dark resin, which on digestion with hot water, gives an indigo-blue solution, whilst yellow crystals remain undissolved.

Hydrophthalaconecarboxylic acid, $C_{21}H_{13}(OH)_2 COOH$, obtained by the action of zinc in alkaline solution of phthalaconecarboxylic acid, crystallises in colourless microscopic needles, and melts at over 280°. It was not obtained in a state of purity.

Ethyl dioximidophthalacenecarboxylate, $C_{21}H_{11}(NOH)_2.COOEt$, prepared by the action of hydroxylamine hydrochloride on ethyl phthalaconecarboxylate, crystallises in yellow needles, and melts at 263—264°.

Dioximidophthalacenecarboxylic acid, $C_{21}H_{11}(NOH)_2.COOH$, forms brownish-yellow needles, melts with decomposition at 271—273°, is readily soluble in alcohol, sparingly soluble in glacial acetic acid.

On repeating his experiments with phthalic anhydride and ethyl malonate, the author has not been able to obtain again the substance crystallising in needles melting at 217—219·5°. A. J. G.

α-Hydroxyphthalic Acid. By O. MILLER (*Ber.*, **17**, 552).—The author claims priority in the discovery of the acid described by Jacobsen as β-hydroxyorthophthalic acid (Abstr., 1883, 1224), which had been already obtained by him and described with other derivatives of phthalic acid (Abstr., 1882, 404). P. P. B.

Derivatives of the Ethereal Salts of Acetophenoneacetoacetic Acid. By C. PAAL (*Ber.*, **17**, 913—918).—(Comp. this vol, 598 and 746.) By the action of dilute hydrochloric acid on ethyl acetophenoneacetoacetate, Weltner (this vol., 746) obtained a body having the same composition as acetophenoneacetone, but it differs essentially from acetophenoneacetone, as described by the author. By the action of excess of phenylhydrazine, it yields a crystalline mass which, after purification by crystallisation from benzene and alcohol, melts at 154—155°, and has the composition $C_{17}H_{16}N_2$:—

$$C_{11}H_{12}O_2 + C_6H_8N_2 = C_{17}H_{16}N_2 + 2H_2O.$$

When acetophenoneacetone is heated with dehydrating agents, such as acetic anhydride, then neutralised with potash and distilled with steam, it yields a crystalline body, $C_{11}H_{10}O$, insoluble in water and alkalis; this melts at 41—42°, and boils at 235—240°. Its constitution is not determined. It does not form additive-products with bromine, and on oxidation it yields benzoic acid. Another body, isomeric with the preceding, is formed at the same time, it is less volatile and cannot be distilled without decomposition, it melts at 82—83°, combines directly with bromine, and is converted into the above-described body, $C_{17}H_{16}N_2$, by the action of phenylhydrazine.

The formation of the acid, $C_{12}H_{10}O_3$, has been previously described. When treated with potassium permanganate, it yields benzoic, acetic, and carbonic acids; hydriodic acid and phosphorus convert it into a hydrocarbon, probably $C_{11}H_{14}$. The potassium salt of the acid crystallises from alcohol anhydrous, and from water, with water of crystallisation; the ammonium salt is anhydrous, and scarcely soluble in aqueous ammonia. Hydrochloric acid passed into the alcoholic solution of the acid gives rise to the formation of an oil, $C_{12}H_9O_3Et$. The author, in continuing the work, hopes to show some connection between these compounds and naphthalene. H. B.

Acetylisation of Gallic Acid and Tannin. By C. Böttinger (*Ber.*, **17**, 1503—1507).—When hydrated gallic acid is gently warmed with excess of acetic anhydride, it yields *triacetogallic acid*, but if the gallic acid is first dehydrated, the triaceto-compound is mixed with a *pentacetyl-compound* melting at 151°, and somewhat resembling pentacetotannic acid in properties. Crystallised tannic acid, when treated with cold acetic anhydride, yields *pentacetotannic acid*.

The author has investigated the action of acetic anhydride on the aqueous extracts of *divi-divi*, *algarrobilla*, *valonia*, and *nutgall*. The principal constituent of the acetyl-derivatives appeared in each case to be a substance of the composition of triacetogallic acid, but isomeric and not identical with this latter. L. T. T.

Digallic Acid. By C. Böttinger (*Ber.*, **17**, 1475—1479).—The author finds that the derivatives of gallic acid previously described by him (this vol., 55) do not contain the pyruvic nucleus, and that the pyruvic acid used in the reaction may be replaced by glyoxylic acid without change of products. If, however, it is replaced by acetic acid, the gallic acid undergoes scarcely any change (only a trace of rufigallic acid being formed), whereas if no foreign acid be employed, the whole of the gallic acid will be converted into rufigallic acid.

Gallic acid or ether is moistened with pyruvic or glyoxylic acid, concentrated sulphuric acid added, and the whole heated for half an hour in the water-oven. A substance is thus formed which is easily soluble in water, and somewhat resembles in properties the body described by Schiff (this Journal, 1874, 267). If the heating with sulphuric acid is continued for several hours, a substance is obtained which is insoluble in water, but soluble in acetic anhydride with formation of an acetyl-derivative. The soluble substance is very hygroscopic, has a strong odour, and melts below 100°, giving off water, but undergoing little further change until about 148°, when it is converted into an insoluble substance. Its formula is $C_{14}H_{14}O_{11}$, but when dried at a little above 100°, it loses 2 mols. H_2O, but at the same time is slightly decomposed. The dried body, when digested with acetic anhydride at 100°, yields a pentacetyl-derivative of the formula $C_{14}H_5Ac_5O_9$, so that the acid must be $C_{14}H_{10}O_9 + 2H_2O$. The author calls the substance *digallic acid*, and believes the insoluble substance to be its anhydride. Digallic acid is isomeric but probably not identical with tannin. L. T. T.

Morin. Part I. By R. Benedikt and K. Hazura (*Monatsh. Chem.*, 5, 165—176).—A short notice of these results has already appeared (this vol., 846). The dyeing properties of fustic (*Morus tinctoria*) are usually attributed to the presence of two substances, morin and maclurin. This would appear, however, to be in part erroneous, as from many of the commercial extracts not even a trace of these substances can be obtained, although yielding good results in dyeing. Experiments of Klaye show that maclurin is not a dye, as it only gives a very pale, dirty yellowish-brown colour on goods mordanted with alumina; pure morin, on the contrary, gives intense pure yellows.

Morin is best prepared as follows:—20 kilos. of fustic extract of 20° Baume is well mixed with an equal volume of water and a little hydrochloric acid, the clear liquid decanted, and the residue repeatedly treated with acidulated water in similar manner, until the washings are no longer yellow. The residue is then pressed, powdered, and air-dried. The crude morin so obtained is dissolved in alcohol by aid of heat, and one-tenth of the volume of hot water added; on cooling, pure morin separates. The filtrate is again heated to boiling and a small quantity of hot water added, when more morin separates. This is repeated on the filtrate until the last addition of hot water causes no separation. The various crystallisations are then mixed together and recrystallised in a similar manner.

By fusing morin with potash, Hlasiwetz and Pfaundler (*J. pr. Chem.*, **94**, 65) obtained phloroglucinol alone, and, in some experiments, a little oxalic acid. The authors find that resorcinol is also formed in large quantity.

By reducing morin with sodium amalgam, phloroglucinol is obtained, and also an acid which yields resorcinol on distillation, and therefore must stand in some simple relation to it. According to Hlasiwetz and Pfaundler (*loc cit.*) phloroglucinol alone is formed. The yield of phloroglucinol obtained by the authors was less than one-ninth of that required on the theory of its being the only product. The authors have failed to obtain the isomorin of Hlasiwetz and Pfaundler; they can at present assign no reason for their want of success.

The oxidation of morin with nitric acid yields styphnic acid (trinitroresorcinol), according to Wagner (*J. pr. Chem.*, **51**, 82). Hlasiwetz and Pfaundler found oxalic acid to be the usual product of the action of oxidising agents on morin. By the careful oxidation of morin dissolved in glacial acetic acid with nitric acid, the authors have obtained β-resorcylic acid, and another substance separating, on addition of baryta to the reaction-product, as a voluminous greyish-brown precipitate; small quantities of oxalic acid and of a nitro-product were also observed.

From a consideration of all the analyses yet published, the authors arrive at the conclusion that morin is best represented by the formula $C_{12}H_8O_6$ for the dried substance. It crystallises with 1 mol. H_2O.

From the foregoing results, it follows that morin must have a constitution analogous to that of maclurin, as they are both resolved by simple reactions into phloroglucinol and an acid of the formula $C_7H_6O_4$; protocatechuic acid in the case of maclurin, and β-resorcylic acid in that of morin. A. J. G.

Derivatives of Benzenesulphonic Acid. By R. HÜBNER (*Annalen*, **223**, 234—246).—The ethereal salts of benzenesulphonic acid are obtained by the action of benzenesulphonic chloride on dry sodium methylate, ethylate, &c., suspended in absolute ether. The ethylic salt which has been previously described by Schiller and Otto (*Ber.*, **9**, 1638) has the sp. gr. 1·22 at 17°. The methyl and propyl salts resemble this substance in their properties. Their specific gravities at 17° are 1·272 and 1·1785 respectively. Negative results were obtained in attempts to prepare the anhydride of benzenesulphonic acid by the action of benzenesulphonic chloride on benzenesulphonic acid or on the sodium, ethyl, or silver salt of the acid. W. C. W.

Nitro- and Amido-triphenylphosphine Oxide. By A. MICHAELIS and H. v. SODEN (*Ber.*, **17**, 921—924).—Fuming nitric acid dissolves triphenylphosphine, and on pouring the solution into water, a mixture of triphenylphosphine nitrate, $Ph_3P(NO_3)_2$, and triphenylphosphine hydroxide, $Ph_3P(OH)_2$, is deposited as an oil; on exposure to the air, it is entirely converted into the latter. By evaporating the nitric acid solution to dryness, the nitrate is obtained purer; but by long standing over slaked lime and sulphuric acid, it leaves a basic nitrate, $Ph_3P(NO_3)(OH)$. By employing a mixture of nitric and sulphuric acids, substitution and oxidation take place. The hydroxide is best prepared by treating triphenylphosphine first with water and bromine, then with caustic soda; when heated, it loses water and leaves the oxide, Ph_3PO, boiling above 360°. When the hydroxide is dissolved in cold nitric and sulphuric acids and the solution poured into water, it yields a precipitate of *trinitrotriphenylphosphine oxide*; it melts at 243°.

Triamidotriphenylphosphine oxide is obtained by reduction of the preceding body with tin and hydrochloric acid. It is only slightly soluble in cold water, melts at 259°, and its salts are very soluble. Dissolved in acetic anhydride and precipitated with ether, it yields the acetyl-derivative, $(NH\overline{Ac}.C_6H_4)_3PO + H_2O$, melting at 187·5°. The benzoyl-derivative, $(NH\overline{Bz}.C_6H_4)_3PO$, melts at 180°. Bromine added to the solution of the hydrochloride produces a precipitate, probably $(NH_2.C_6H_2Br_2)_3PO$. The base is isomeric with Schiff's anilide of orthophosphoric acid, $PO(NHPh)_3$. H. B.

Synthesis of Indole-derivatives. By E. FISCHER and O. HESS (*Ber.*, **17**, 559—568).—One of the authors has already shown (this vol., 52) that methylphenylhydrazine and pyroracemic acid unite directly to form an acid, which when treated with hydrochloric acid, is resolved into ammonia, and an acid, $C_{10}H_9NO_2$. The further investigation of this compound shows that it is related to indole, into a methylated derivative of which it is converted by heat, and therefore the authors style this acid *methylindolecarboxylic acid*.

Methylindole, C_9H_9N, obtained by heating the above acid at 205°, is a yellow oil, volatile in steam, and boils at 239°; it is insoluble in water, but easily miscible with alcohol, ether, and benzene. In physical and chemical properties, it exhibits a great resemblance to indole; with pine wood moistened with hydrochloric acid, it gives a violet coloration. Methylindole and picric acid unite to form a *picrate*, $C_9H_9N,C_6H_2(NO_2)_3.OH$, crystallising from ether in dark red prisms, melting at 150°.

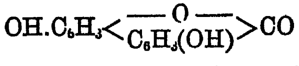
Methylpseudisatin, $C_9H_7NO_2$.—If methylindole is treated with solutions of sodic hypobromite or hypochlorite, a halogen-derivative is formed, the bromine or chlorine of which is easily substituted, and when the compound is treated with alcoholic soda *methylpseudisatin* is produced. This crystallises from water in beautiful red needles, melting at 134°; its properties are similar to those of Baeyer's ethylpseudisatin (*Ber.*, **16**, 2193); it yields an indophenine with coal-tar benzene and sulphuric acid, and like isatin unites directly with phenylhydrazine.

Ethylphenylhydrazine unites directly with pyroracemic acid, forming ethylphenylhydrazine-pyroracemic acid, which when heated with hydrochloric acid yields *ethylindolecarboxylic acid*, $C_{11}H_{11}NO_2$, crystallising in colourless needles which melt at 183°. Like the methyl-derivative, it is resolved by heat into carbonic anhydride and *ethylindole*, $C_{10}H_{11}N$, a liquid boiling 8° higher than methylindole, to which it has the closest resemblance. Ethylindole is oxidised by sodic hypochlorite, and converted into *ethylpseudisatin*, identical with that described by Baeyer (*loc. cit.*).

Diphenylhydrazine and pyroracemic acid unite to form *diphenylhydrazinepyroracemic acid*, $NPh_2.N : CMe.COOH$, which crystallises from hot alcohol in white needles, melting at 145°; when heated with hydrochloric acid, it is converted into *phenylindolecarboxylic acid*, crystallising from alcohol in white needles, melting at 173—176°; this when heated at 200—210° loses carbonic anhydride, and yields a heavy oil, apparently phenylindole. P. P. B.

New Reaction of Benzidine. By P. JULIUS (*Monatsh. Chem.*, 5, 193 194).—In aqueous solutions of benzidine, potassium dichromate produces a voluminous precipitate of interlaced blue needles of benzidine chromate, $C_{12}H_8(NH_2)_2,H_2CrO_4$. It is insoluble in the ordinary solvents, and is partially decomposed on boiling with water; when boiled with dilute ammonia, it is converted into benzidine, ammonium dichromate, and a brownish amorphous substance, containing much chromium. The reaction is sensitive, as a solution containing 1 part of benzidine in 5000 parts water gives a distinct precipitate on heating. The isomeric diphenylene gives a similarly delicate reaction with potassium dichromate. A. J. G.

The Euxanthone Group. By E. SPIEGLER (*Monatsh. Chem.*, **5**, 195—202; and *Ber.*, **17**, 807—810).—Diphenylene ketone when treated with hydroxylamine hydrochloride and alcohol, yields *diphenyleneacetoxime*, $<\begin{smallmatrix}C_6H_4\\C_6H_4\end{smallmatrix}>C:NOH$, forming pale yellow crystals, and melting at 192°. All attempts to convert diphenylene ketone oxide and euxanthone into the corresponding oximes, either by treatment with free hydroxylamine or its hydrochloride, were unavailing. These negative results appear to throw considerable doubt on the accuracy of the formulæ $O<\begin{smallmatrix}C_6H_4\\C_6H_4\end{smallmatrix}>CO$ and $O<\begin{smallmatrix}C_6H_3(OH)\\C_6H_3(OH)\end{smallmatrix}>CO$, usually assigned to these bodies. The absence of the ketone-group is further confirmed by their not reacting with phenylhydrazine. The author considers it probable that they may be lactones, and suggests the formulæ $C_6H_4<\begin{smallmatrix}-O-\\C_6H_4\end{smallmatrix}>CO$ for diphenylene ketone oxide, and



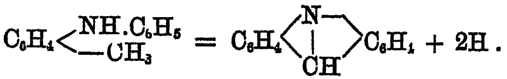
$$OH.C_6H_3<\begin{smallmatrix}—O—\\C_6H_3(OH)\end{smallmatrix}>CO$$

for euxanthone. It has been already shown that α- and γ-lactones do not react with hydroxylamine, and the author now shows that coumarine, a Δ-lactone, $C_6H_4<\begin{smallmatrix}—O—\\CH_2.CH_2\end{smallmatrix}>CO$, is also without action.

Paradioxybenzophenone, treated with hydroxylamine and alcohol, readily yields the corresponding *oxime*, $C(C_6H_4.OH)_2 : NOH$, as a yellow oil, crystallising on long standing. This result shows that the presence of other oxygen-atoms in the molecule does not prevent the ketone-group reacting with hydrogen. That a high molecular weight does not prevent the reaction is shown by the formation of *phenyl-α-naphthylacetoxime*, by the action of phenyl-α-naphthyl ketone on hydroxylamine. It forms a yellow oil of the formula $C_{10}H_7.CPh : NOH$.

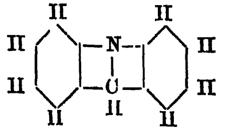
A. J. G.

Formation of Acridine. By C. GRAEBE (*Ber.*, **17**, 1370—1371).—The synthesis of acridine from diphenylamine leads to the view that its constitution is analogous to that of anthracene, and not to that of phenanthrene. A still further confirmation of this assumption is now brought forward by the author, who shows that a large yield of acridine is obtained by passing orthotolylaniline through a red-hot tube, the reaction being expressed by the equation



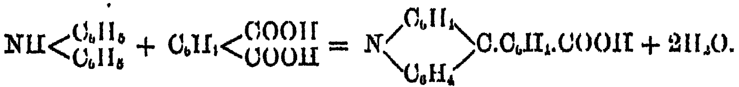
$$C_6H_4<\begin{smallmatrix}NH.C_6H_5\\—CH_3\end{smallmatrix} = C_6H_4<\begin{smallmatrix}N\\|\\CH\end{smallmatrix}>C_6H_4 + 2H.$$

Benzylidene-aniline does not yield acridine when passed through a red-hot tube, whilst it should do so if acridine had a constitution similar to that of phenanthrene. Orthoditolylamine yields acridine, and a methylated acridine. Paratolylaniline does not yield acridine at a red heat. These experiments give further proof that the nitrogen and CH-group are in the ortho-position in both benzene-groups, the constitution of acridine being expressed by the formula



A. J. G.

Butylacridine and Acridylbenzoic Acid. By A. BERNTHSEN and J. TRAUBE (*Ber.*, **17**, 1508—1512).—*Butylacridine*, $C_{17}H_{17}N$, was obtained by heating a mixture of valeric acid and diphenylamine with zinc chloride for 20 hours at 200—220°. It forms a white amorphous substance, which rapidly turns brown when exposed to the air. It distils without much decomposition. Its *hydrochloride* crystallises in brownish-yellow rhombohedric prisms which melt at 191°; in dilute alcoholic solution, it exhibits a strong bluish-green fluorescence. The *nitrate* forms long, pale yellow, silky needles, melting at 139°; the chromate $C_{17}H_{17}N,H_2CrO_4$, crystallises in orange needles, which melt at a little above 100°, with evolution of acridine. Reduced with zinc, the hydrochloride yields *hydrobutylacridine*, $C_{17}H_{19}N$, which forms glittering white scales melting at 90—92°. *Acridylbenzoic acid*, $C_{13}H_8N.C_6H_4.COOH$, is obtained by heating phthalic anhydride and diphenylamine with zinc chloride at 180—200° for about 12 hours. It crystallises in yellow prisms or needles, easily soluble in dilute acids or alkalis, almost insoluble in boiling water. Its dilute solutions in acids have a green, and in alkaline solution, a blue fluorescence. It may be heated to 300° without change, but above that temperature it is decomposed with evolution of phenylacridine. Its *hydrochloride* crystallises in small yellow needles or tables, which melt at 163°. Its *sodium salt* crystallises in mother-of-pearl-like scales or needles, which are very soluble in water, and contain water of crystallisation (probably 1½ mols.). The *silver salt* is yellowish-white and amorphous; the *copper-salt* bluish-green. By reduction, *hydroacridylbenzoic acid*, $C_{20}H_{15}NO_2$, is obtained in the form of colourless needles, which readily become reoxidised to acridylbenzoic acid. Like other hydroacridines it has no basic properties. The formation of acridylbenzoic acid is probably explained by the equation—



$$NH{<}{\substack{C_6H_5\\C_6H_5}} + C_6H_4{<}{\substack{COOH\\COOH}} = N{<}{\substack{C_6H_4\\C_6H_4}}{>}C.C_6H_4.COOH + 2H_2O.$$

L. T. T.

New Method of Preparing Carbostyril. By J. RÖTHEIT (*J. pr. Chem.* [2], **29**, 300—302).—This is a preliminary note on the formation of carbostyril by heating trichloroxyquinoline with fuming hydriodic acid in a sealed tube at 250°. The trichloroxyquinoline was prepared by acting with chlorine on a solution of quinoline in dilute acetic acid, first in the cold, and then with the aid of heat. P. F. F.

α- and β-Methylnaphthalene. By K. E. SCHULZE (*Ber.*, **17**, 842—846).—Fittig prepared α-methylnaphthalene from α-bromonaphthalene and methyl iodide; Reingruber (Abstr., 1881, 436) isolated a substance from coal-tar which he believed to be different from Fittig's product, and called β-methylnaphthalene.

A sample of coal-tar oil purified by sulphuric acid and caustic soda and boiling at 200—300° was examined. By fractionation an oil boiling at 139—142° and solidifying at 2°, was isolated; this after repeated melting and recrystallisation and pressing, followed by crystallisation from alcohol, melted constantly at 32·5°. Analysis showed it to be a methylnaphthalene; it boils at 241—242°. The author considers this to be β-methylnaphthalene, and Reingruber's and Fittig's products to have been essentially the same. The following compounds have been obtained pure: the *picrate*, crystallising from alcohol and melting at 115°: *α-nitro-β-methylnaphthalene*, melting at 81°, is formed together with a small quantity of a dinitro-derivative melting at 206° by the action of a mixture of nitric and sulphuric acids on β-methylnaphthalene.

The oil pressed from the β-methylnaphthalene, and which did not crystallise at −15°, was purified and found to be a methylnaphthalene: it boils at 240—243°; according to Fittig the boiling point of α-methylnaphthalene is 231—232°, the author, however, has made a preparation according to Fittig's directions, and found the boiling point to be also 240—242°. The mononitro-substitution product is an oil not crystallising at −15°; the picrate melts at 116°. Reingruber could prepare neither a crystalline nitro-derivative nor a picrate; his product was neither β- nor pure α-methylnaphthalene. H. B.

α- and β-Methylnaphthalene. By K. E. SCHULZE (*Ber.*, **17**, 1527—1530).—*Esobromo-α-methylnaphthalene* (for nomenclature see this vol., 998) was obtained by exposing a mixture of molecular proportions of α-methylnaphthalene and bromine dissolved in carbon bisulphide to the action of sunlight. It was purified by the help of its picric acid compound. It is a colourless liquid with a slight odour resembling that of bromotoluene, and boiling with slight decomposition at 298°, corr. It forms a compound with picric acid which crystallises in deep yellow needles melting at 105°. *Esobromo-β-methylnaphthalene*, prepared in a similar manner, boils at 296°, corr. Its picric acid compound crystallises in yellow needles melting at 113°. *β-Naphthomethyl chloride*, $C_{10}H_7.CH_2Cl$, was obtained by passing a current of chlorine into β-methylnaphthalene at 240—250°. It distils at 168° under 20 mm. pressure, and solidifies to a mass of small micaceous scales. It melts at 47°, but if allowed to resolidify and *immediately* reheated it melts at 41°; if allowed to remain 15 or 20 minutes after solidification, it recovers its normal melting point of 47°. *β-Naphthomethyl bromide* was prepared in a similar manner. If the temperature during the reaction is allowed to reach 280°, total decomposition takes place. Crystallised from alcohol, it forms white fatty scales melting at 56°. It boils at 213° under 100 mm. pressure. Both the chloride and bromide resemble the corresponding benzyl-derivatives in odour. They do not form compounds with picric acid. *β-Naphthaldehyde*, $C_{10}H_7.COH$, was prepared by oxidising the chloride or bromide with lead nitrate; it forms white scales melting at 59°, and is identical with that obtained by Battershall by the distillation of a mixture of calcium α-naphthoate and formate. *β-Naphthoic acid* is only obtained in very small quantity by the oxidation of the aldehyde, but may be prepared almost quantitatively if the chloride or bromide be oxidised by shaking with a cold solution of potassium permanganate. It melts at 185°, and is identical with Vieth's acid, for which he found the melting point 182°. L. T. T.

Isobutylnaphthalene. By R. Wegscheider (*Monatsh. Chem.*, 5, 236—240).—Isobutylnaphthalene is obtained by mixing 1 part of isobutyl chloride with 2 parts of fused naphthalene, and then adding aluminium chloride in small portions, the mixture being heated just sufficiently to prevent crystallisation. Excess of aluminium chloride should be avoided, about one-twelfth of the weight of the naphthalene being sufficient. In addition to isobutylnaphthalene there are formed α-α-dinaphthyl, α-β-dinaphthyl, and isodinaphthyl: their separation can be effected by distillation with steam.

Isobutylnaphthalene forms a colourless oil; it boils at 280°, volatilises with difficulty in a current of steam, and is readily soluble in ether. The picric acid compound crystallises in aggregates of slender needles, melts at 96°, and is readily soluble in alcohol. Isobutylnaphthalene is not obtained by heating a mixture of naphthalene, isobutyl alcohol, and zinc chloride. A. J. G.

Condensation-product of β-Naphthol with Benzaldehyde. By W. Trzcinski (*Ber.*, 17, 499—501).—This condensation-product having the composition $C_{68}H_{46}O_3$, is obtained by treating β-naphthol and benzaldehyde dissolved in alcohol with concentrated sulphuric acid: by crystallisation from benzene or chloroform it is obtained in microscopic rhombic tablets melting at 190—191°. It is insoluble in alcohol, ether, and alcoholic potash, and apparently does not contain hydroxyl-groups. It forms bromo- and chloro-substitution-products, and is converted into *melinontrisulphonic acid* by concentrated sulphuric acid (this vol., 590). When nitrated, it gives a compound of the composition $C_{31}H_{17}(NO_2)_7O_2$.

Probably the formation of this takes place in two phases: (1) a compound $C_{31}H_{21}O_2$ is formed, thus:—

$$2C_{10}H_8O + 2C_7H_6O - 2H_2O = C_{31}H_{21}O_2;$$

(2) 2 mols. of this condense and give $C_{68}H_{46}O_3$, thus:—

$$2C_{31}H_{24}O_2 - H_2O = C_{68}H_{46}O_3.$$

P. P. B.

Naphthalene Derivatives. By R. Flessa (*Ber.* 17, 1479—1486).—A. J. Smith (Trans., 1879, 789) showed that by the direct bromination of β-naphthol in acetic solution the end-product was tetra-bromonaphthol. By the use of Gustavson's method (this Journal, 1877, ii, 599), the author has obtained *pentabromo-β-naphthol*: 2—3 grams of aluminium-foil are gradually added to a *well-cooled* solution of bromine in carbon bisulphide and then 10 grams of β-naphthol, the whole being finally heated to complete the reaction. When purified, pentabromo-β-naphthol crystallises in colourless needles which melt at 237°. It dissolves sparingly in boiling alkali, and the solution deposits the alkaline salt on cooling. When oxidised with dilute nitric acid at 100°, this substance yields *tetrabromo-β-naphthaquinone*, $C_{10}H_2Br_4O_2$, which is of a red colour, crystallises in nodules, is moderately soluble in the usual solvents, and melts at 164°. Alkalis dissolve it, but not without change, as acids reprecipitate from the solution a pale-yellow substance, and the filtrate contains bromine. When heated with nitric acid of sp. gr. 1·15 in closed tubes at 150°, this quinone is converted into *tribromophthalic acid.* This substance crystallises in silky needles or scales easily soluble in ether, alcohol, acetic acid, and alkalis, moderately so in boiling water, and melts at 190—191°. It forms soluble salts with alkalis: the barium salt and the calcium salt both crystallise with 2 mols. H_2O: the silver salt is precipitated as a white flocculent substance. When heated a little above its melting point, the acid is converted into *tribromophthalic anhydride,* which sublimes without decomposition in beautiful white scales melting at 157°. It is almost insoluble in cold water, and is reconverted into the acid by boiling water. It is easily soluble in the usual solvents. When fused with resorcinol, it yields a compound having properties similar to those of fluoresceïn.

When pentabromo-β-naphthol is treated at 100° with bromine containing aluminium bromide, a more highly brominated derivative (probably hexabromo-β-naphthol) is obtained; this crystallises in colourless needles, and also yields a brominated phthalic acid on oxidation. These compounds are still under investigation.

Attempts at the direct bromination of phthalic anhydride proved fruitless, even in the presence of aluminium bromide, mere traces of brominated acids being obtained. L. T. T.

Derivatives of Nitro-β-naphthaquinone. By O KORN (*Ber.*, 17, 906—909).—Phenylazo-β-naphthol (see this vol., 610) was converted into nitro-β-naphthaquinone according to Stenhouse and Groves' method. Reduced with tin and hydrochloric acid the hydrochloride of *amidodihydroxynaphthalene*, $C_{10}H_5(\alpha OH)(\beta OH)(NH_2,HCl)$, is obtianed. This base differs in several respects from the amidodihydroxynaphthol prepared by Graebe and Ludwig from biimidonaphthol; and since nitro-β-naphthaquinone is oxidised to phthalic acid, its constitution is probably $C_{10}H_5(OH)(OH)(NH_2)$ [$\alpha : \beta : \beta$].

By the action of aniline on a boiling alcoholic solution of nitro-β-naphthaquinone, red needles of *nitro-β-naphthaquinoneanilide*,  $C_{10}H_4(OH)(NO_2)<\genfrac{}{}{0pt}{}{-O-}{NPh}>$ are formed; it melts at 253°, and is insoluble in most reagents. By the continued action of aniline and alcohol, a compound is formed melting at 183—185°; alcohol alone, however, decomposes nitro-β-naphthaquinone with the formation of a crystalline body, probably nitro-β-naphthaquinol. H. B.

Note on the Chemical Constitution of Anthraquinone, Anthracene, and Analogous Compounds. By E. v. MEYER (*J. pr. Chem.* [2], 29, 139—144).

Constitution of Phthalic Chloride and Anthraquinone. By V MEYER (*Ber*, **17**, 817—819).—The question whether phthalic chloride has the constitution $C_6H_4(COCl)_2$ or  $C_6H_4<\substack{CO\\CCl_2}>O$, is not decided by the formation of phthalophenone,  $C_6H_4<\substack{-CO-\\CPh_2}>O$, but a proof that the second formula is the correct one is the fact that the so-called phthalyl ether—formed by the action of zinc ethyl on the chloride—is not a ketone, for under no conditions does it combine with hydroxylamine; it is probably a lactone, $C_6H_4<\substack{-CO-\\CEt_2}>O$.

E. v. Meyer (*J. pr. Chem.* [2], **29**, 139) has supposed that anthraquinone is a lactone, viz., phenylenephthalide, but it has been shown that when treated with hydroxylamine it yields a body, $C_{14}H_9O_2N$, and that lactones are incapable of uniting with hydroxylamine (Abstr., 1883, 1104). It would appear that only one carbonyl-group is acted on in those double ketones in which the two carbonyl-groups are not directly united. H. B.

Diethyl Alizarin Ether. By J. HABERMANN (*Monatsh. Chem.*, **5**, 228—231).—Schutzenberger described this body as a bright-yellow substance, insoluble in water, soluble in alcohol; his analytical results are very unsatisfactory.

The author prepares the ether by heating a mixture of alizarin, potassium ethyl sulphate, and potash for some hours at 160—170°. The contents of the tubes are acidulated with sulphuric acid, diluted with water and repeatedly extracted with ether. The ethereal solution is then repeatedly shaken with water rendered slightly alkaline as long as it acquires a violet hue, so as to remove alizarin and any monethyl ether, the ethereal solution is then evaporated and the residue dissolved in chloroform; this solution is then largely diluted with ether, and after being repeatedly shaken with slightly alkaline water, is allowed to evaporate spontaneously. *Diethyl alizarin ether*, $C_{14}H_6O_2(OEt)_2$, so obtained, forms aggregates of golden or brownish-yellow needles; it is nearly insoluble in cold, somewhat soluble in hot water, it is more soluble in alcohol and ether, the solutions having a yellow colour. Its best solvent is chloroform. It appears to volatilise unaltered in a current of steam. It dissolves in concentrated nitric acid with golden-yellow colour, but on dilution with water only a few flocks separate. Water added to the dark yellowish-brown solution in concentrated sulphuric acid, precipitates pale-yellow flocks which are not coloured by potash. A. J. G.

Action of Concentrated Sulphuric Acid on Nitroanthraquinone. By J. LIPSCHÜTZ (*Ber.*, **17**, 891—899).—This reaction has been studied by several chemists, Liebermann (Abstr., 1883, 597) first showing that the nitro-group suffers reduction whilst some of the hydrogen-atoms are oxidised to hydroxyl-groups. Liebermann's experiments have now been repeated, using a pure nitro-product as starting point, the diorthonitroanthraquinone prepared according to Römer's directions (Abstr., 1883, 737). When this is heated with concentrated sulphuric acid and the product poured into water, it yields a red-brown precipitate containing four colouring matters, (α) red, and (β) reddish-violet, both soluble in cold alkalis, (γ) blue and (δ) red, both insoluble in cold alkalis. Cold alcohol dissolves (α) not (β) and (δ) more than (γ).

α dissolves in alcohol with red, and in alkalis with deep bluish-violet colour; analyses point to the formula $C_{28}H_{17}N_3O_9$. A solution of β in benzene or ether or in strong sulphuric acid shows very characteristic and sharp absorption-bands; its alkaline solution is deep blue; its composition is $C_{28}H_{17}N_3O_{12}$. γ crystallises from benzene and alcohol in lustrous brown needles; and its solutions also show characteristic absorption-bands, it is $C_{28}H_{14}N_4O_7$. δ separates from alcohol as a brownish-red crystalline powder; it has the same composition as α, namely, $C_{28}H_{17}N_3O_9$.

Each of these compounds was dissolved in sulphuric acid, and potassium nitrite gradually added, then boiled with absolute alcohol, and precipitated with water; in each case, dihydroxyanthraquinones were obtained. γ yielded anthrarufin, and since it was prepared from diorthonitroanthraquinone, all the hydroxyl- and amido-groups must occupy the α-position. α yielded metabenzodihydroxyanthraquinone and a new dihydroxyanthraquinone, insoluble in baryta-water, crystallising from alcohol and ether in deep-red needles melting at 175—180° and volatilising easily; it does not colour mordants; it is probably the last possible and still unknown isomeric dihydroxyanthraquinone. The formula $C_{28}H_{17}N_3O_9$, given for α would, however, yield a dihydroxy- and a trihydroxy-anthraquinone on decomposition; the non-formation of the latter is explained by the reducing action of the nitrous acid. The product β yielded only the last-named dihydroxy-anthraquinone, and here again reduction must have taken place; its formula is $NH_2.C_{14}HO_2(OH)_4\ O.C_{14}H_3O_2(OH)_3\ NH_2$.

δ gave a substance not completely investigated, but in all probability chrysazin. H. B.

Anthraquinonecarboxylic Acid. C. Liebermann and G. Glock (*Ber.*, **17**, 888—891).—Liebermann replies to E. v. Meyer's arguments in favour for the new formulæ proposed for anthracene and anthraquinone (*J. pr. Chem.* [2], **29**, 138). The unusual stability of the chloride of anthracenecarboxylic acid has been already pointed out (this vol., 329). The chloride and other derivatives of *anthraquinonecarboxylic acid* have been now prepared, to ascertain whether they were also unusually stable. This turns out to be the case, and it is therefore to be remarked that although the corresponding benzene and naphthalene-derivatives behave with reagents like other similar compounds, the anthracene- and anthraquinone-carboxylic acids yield derivatives very much more stable. The compounds examined are:—

Anthraquinonecarboxylic chloride, obtained from the carboxylic acid by the action of phosphorous pentachloride. It crystallises well from benzene and melts at 147°. The powdered substance left in contact with 100 times its weight of water for 120 hours was only decomposed to the extent of 7·5 per cent. Benzoic chloride is completely decomposed in six hours, and the chlorides of α-and β-naphthoic acids are very easily decomposed.

Ethyl anthraquinonecarboxylate, obtained by decomposing the chloride with alcohol; 18 hours are requisite when cold. It is easily soluble in alcohol, from which it separates in crystals melting at 147°.

Anthraquinonecarboxylamide is formed by the action of ammonia gas on a solution of the chloride in benzene. It is also remarkably stable; it is not acted on when boiled with weak potash solution, and it is also unaffected by strong sulphuric acid.

Anthraquinonecarboxylanilide is formed comparatively easily by the action of aniline on the chloride.

Anthraquinonecarboxylic acid also yields substitution-products with difficulty, the action of bromine is very slight at over 200°; strong nitric acid has no effect, but in presence of strong sulphuric acid there is formed *mononitroanthraquinonecarboxylic acid*. H. B.

Action of Concentrated Sulphuric Acid on α-Nitro-anthraquinonesulphonic Acid, and the Constitution of the Latter. J. Lifschütz (*Ber.*, **17**, 899—902).—α-Nitroanthraquinonesulphonic acid was prepared from sodium meta-anthraquinonesulphonate by Claus' method (Abstr., 1882, 1105). The position of the nitro-group was determined by converting the body into the corresponding dihydroxyanthraquinone as follows: the amido-acid, prepared by reduction of the nitro-derivative with tin and hydrochloric acid, was dissolved in boiling acetic acid and treated with dilute solution of potassium nitrite, when *erythrohydroxyanthraquinonesulphonic anhydride*,

$$C_6H_4(CO)_2C_6H_2\left\langle\begin{matrix}\text{-O-}\\ SO_2\end{matrix}\right\rangle,$$

is deposited in grey needles; it decomposes below 100°, is a very insoluble body; cold caustic soda solution does not dissolve it, but when hot it does; from this solution concentrated hydrochloric acid precipitates *erythrohydroxyanthraquinonesulphonic acid*,

$$C_6H_4(CO)_2C_6H_2(OH).SO_3H,$$

as a yellow powder. The free acid is easily soluble and yields soluble salts, their solutions being red; the silver salt crystallises in golden needles. When the free acid or the anhydride is fused with alkalis, it easily yields alizarin; it is not identical with any of the four acids so far known.

When nitro-anthraquinonesulphonic acid is heated with concentrated sulphuric acid at 211° and the product treated with water, it yields a red compound which crystallises from its alcoholic solution on addition of ether; it is a *dihydroxyamidoanthraquinonesulphonic acid*, $C_{14}H_4O_2(OH)_2(NH_2).SO_3H$. As this is the formula originally given by Liebermann (Abstr., 1883, 597), it is in favour of the arguments against the formulæ proposed by Claus. H. B.

Phthalacene-derivatives. By S. Gabriel (*Ber.*, **17**, 1397-1400).—*Phthalacene oxide*, $C_{21}H_{14}O$, is obtained by oxidation of phthalacene (p. 1176) with chromic acid; it forms compact citron-yellow crystals, and melts at 211—214°.

Bromphthalacene, $C_{21}H_{15}Br$, is obtained by the action of bromine on a solution of phthalacene in hot glacial acetic acid: it forms colourless lustrous crystals, melts at 184—184·5°, and is less soluble than phthalacene in boiling acetic acid. On oxidation, it is converted into *bromophthalacene oxide*, $C_{21}H_{13}BrO$, crystallising in glittering, flat, yellow needles, which melt at 200°.

Dinitrophthalacene, $C_{21}H_{14}(NO_2)_2$, obtained by nitration of phthalacene in the cold with a mixture of acetic and nitric acids, crystallises in small brownish-yellow needles, sinters together at 270—280°, and is completely decomposed on further heating.

Oximidophthalacene, $C_{21}H_{14} : NOH$, is obtained by heating a mixture of hydroxylamine hydrochloride and phthalacene oxide with alcohol and a few drops of hydrochloric acid for two hours at 150—160°. It crystallises in lustrous yellow needles, and melts at 265—266°. The formation of this substance shows that phthalacene oxide contains a CO-group.

By heating phthalacene oxide with finely powdered soda lime for 6 to 7 hours at 350°, there is obtained, in small quantity, the calcium salt of a new acid. *Phthalacenic acid*, $C_{20}H_{15}.COOH$, forms pale yellow compact crystals, and melts at 245—247°. A. J. G.

Synthesis of a Terpene. By R. RADZISZEWSKI and J. SCHRAMM (*Ber.*, **17**, 838—840).—Amylene from fusel oil, boiling at 35—37° (mostly trimethylethylene), was converted into the hydrochloride, and this was heated with dilute ammonia at 110—120°. On adding potash to the product and purifying the oily layer which separated, two bases were isolated, namely, *oxyisoamylamine*, $C_5H_{11}O.NH_2$, and *dioxyisoamylamine*, $(C_5H_{11}O)_2NH$; the base $C_5H_9.NH_2$, observed by Wurtz, was not formed. The first base boils at 157—159°, and has a strongly alkaline reaction; its platinochloride is easily soluble in water. The second base is viscous, and boils at 249—251°; its platinochloride and aurochloride are very soluble and not crystallisable.

The action of phosphorous pentoxide on oxyisoamylamine is very energetic; the bulk of the product consists of a liquid smelling of turpentine oil, and distilling at 155—156°. The composition of the oil is very nearly expressed by $C_{10}H_{16}$, and it absorbs oxygen from the air and becomes very viscous. H. B.

Camphoroxime. By E. NÄGELI (*Ber.*, **17**, 805—807).—In previous papers (Abstr., 1883, 728, and this vol., 610) camphoroxime,

$$C_9H_{16} : C : N.OH,$$

and the so-called anhydride, $\underbrace{C_9H_{15} : C : N}$, have been described. By heating the anhydride with alcoholic potash, there are obtained an oil, not fully examined, and a white crystalline substance of the same composition as camphoroxime, but it melts at 125° (camphoroxime at 115°), and does not yield an ether when treated with sodium methylate and methyl iodide, moreover it is quite odourless; the body may therefore be called *isocamphoroxime*. Since the anhydride does not yield an acid on saponification, it cannot be a nitrile, $C_9H_{15}.CN$, but is probably $\underbrace{C_9H_{15} : C : N}$; in this case isocamphoroxime will be either $C_9H_{16} : C : N.OH$ or $HO.C_9H_{15} : C : NH$. H. B.

The Quinovin Group. By C. LIEBERMANN (*Ber.*, **17**, 868—875).—The previous work of Liebermann and Giesel (*Ber.*, **16**, 926) has been confirmed by Oudemans; the following are further observations. Quinovic acid, like pyroquinovic acid, gives a red coloration with strong sulphuric acid. *Ethyl quinovate*, $C_{32}H_{46}EtO_6$, when freshly prepared from potassium quinovate and ethyl iodide, is an oil which crystallises after very long standing; it melts at 127—130°. Pyroquinovic acid, when crystallised from glacial acetic acid, seems to combine with it, for the acid is only removed by long heating at 130°. Novic acid and its salts have almost the same composition as those of pyroquinovic acid, but the alkaline solution of the latter acid is lævorotatory acid, and that of novic acid strongly dextrorotatory. Novic, quinovic, and pyroquinovic acids when distilled yield a resinous distillate; this contains oxygen compounds which may be removed by heating with strong hydriodic acid and phosphorus. On redistillation, *quinoterpene*, $(C_{10}H_{16})_3$, a dextrorotatory terpene, is obtained; it can also be prepared by treating pyroquinovic acid with hydriodic acid and phosphorus. The resinous body obtained during the preparation of quinochromin is essentially the same substance. Assuming quinoterpene to be $C_{30}H_{48}$, from its high boiling point, quinovic acid is $C_{30}H_{46}O_2(COOH)_2$ and pyroquinovic acid $C_{30}H_{47}O_2.COOH$, whilst quinochromin is $C_{30}H_{46}O_2$. Giesel has obtained from quinovaresin a crystalline indifferent substance, $C_{30}H_{46}O_2$; it melts at 139°, and distils at over 360°; with hydriodic acid, it yields a viscous mass, $C_{10}H_{16}$, hence the name *oxyquinoterpene* is proposed for this body. When quinochromin is treated with reducing agents, coloured products are obtained, but they are not identical with oxyquinoterpene. In small quantities, quinovite, $C_6H_{12}O_5$, may be distilled without decomposition at 297—305°. *Acetylquinovite*, $C_6H_9O(O\overline{Ac})_3$, forms white needles melting at 46—47°, and boiling at about 303°; when heated with dilute acids, it is resolved into quinovite and acetic acid. Quinovite has the same composition as a body prepared by Bourchardt from dulcite and the mannide prepared by Berthelot from mannite. The author failed to prepare an acetyl-derivative of mannide, which also differs from quinovite in not reducing Fehling's solution. The quantity of quinovin occurring in the various barks is very different; from 7 to 16 grams pure quinovin being obtainable from 12 kilos. of the bark. H. B.

Viola-quercitrin, a new Glucoside. By K. MANDELIN (*Bied. Centr.*, 1884, 285).—Viola-quercitrin, $C_{42}H_{42}O_{24}$, obtained from *Viola tricolor, var. arvensis*, is yellow, soluble in alkalis and boiling water and is crystalline. When treated with acids, it is decomposed into 3 mols. of a fermentable sugar and 1 mol. quercetin, which is identical with that obtained from quercitrin. E. W. P.

Asarone and the Ethereal Oil of Asarum Europæum, L. By T. POLECK (*Ber.*, 17, 1415—1416).—The paper by Rizza and Butlerow on asarone (this vol., 1042) has caused the author to publish the results he has obtained along with Staats on this subject, although their investigations are still far from complete. Pure asarone is markedly phosphorescent, melts at 61°, can be distilled in small quantities, is readily soluble in light petroleum, alcohol, ether, and chloroform, slightly soluble in boiling water. It is without odour. By reduction with zinc-dust, it yields a small quantity of a liquid product and a not inconsiderable amount of a mixture of gases, containing CO about 30 per cent., CH_4 36 per cent., H_2 26 per cent., hydrocarbons absorbed by sulphuric acid 2 per cent., CO_2 none. By oxidation, best with potassium permanganate, there were obtained carbonic anhydride, formic, acetic, and oxalic acids, a solid acid crystallising from ether in needles, and melting at 144°, and a substance of neutral reaction crystallising in slender silky needles melting at 117°, and soluble in water. Analysis led to the empirical formula $C_8H_8O_3$. The authors continue their work on this subject.

A. J. G.

Quassin and its Constitution. By V. Oliveri and A. Denaro (*Gazzetta*, **14**, 1—9).—In order to prepare quassin from quassia, 10 kilos. of the finely divided wood are twice extracted with 45 litres of boiling water, and the solution evaporated to 10 litres *at a gentle heat;* when cold, the quassin is precipitated by tannin, collected, washed, and after being mixed with a sufficient quantity of lead carbonate, it is thoroughly dried at 100°. The product is then extracted with boiling alcohol, the alcohol distilled off, and the residue set aside until it deposits the quassin in a crystalline state: it is, however, always contaminated with resinous matters, from which it is purified by repeated crystallisations from dilute alcohol: 30 kilos. of the wood gave 10 grams of pure quassin. It crystallises in very slender, colourless, iridescent needles, which belong to the monoclinic system, the predominating form being the oblique prism with rhombic base. It melts at 210—211° (Christensen 205°), and is very soluble in alcohol, chloroform, and acetic acid, but only sparingly in ether: 100 parts of water at 22° dissolve 0·2529; the aqueous solution becomes yellow on exposure to the air, is dextrorotatory, excessively bitter, and reduces Fehling's solution. The results of the analyses agree nearly with the numbers required by the formula $C_{32}H_{44}O_{10}$, and differ considerably from those given by Wiggers and by Christensen, who proposed the formulæ $C_{10}H_{12}O_3$ and $C_{31}H_{42}O_9$ respectively.

When quassin is heated at 90° for some hours with dilute sulphuric acid (4 per cent.), it yields *quasside*, $C_{32}H_{42}O_9$, a white, amorphous, bitter substance, formed from quassia by the removal of the elements of 1 mol. H_2O; no glucose could be detected in the mother-liquors. It melts at 192—194°, and when boiled with dilute alcohol is reconverted into quassin, which crystallises out as the solution cools. Quasside is also formed when quassin is boiled with acetic anhydride, but if sodium acetate is present there is a powerful reaction, and several substances seem to be produced; these have not as yet been submitted to examination.

Bromine diluted with acetic acid acts on a solution of quassin in the same solvent, and on adding water an amorphous resinous substance is obtained, but it does not crystallise: this melts with decomposition at 155°, and the results of the analyses suggest the formula $C_{32}H_{41}Br_3O_9$. Nitric acid added to an acetic solution of quassin seems to give rise to a nitro-derivative, which is precipitated on the addition of water. It dissolves in boiling alcohol, and, as the solution cools, is deposited again as a yellowish powder which melts at 130°.

If quassin is heated with concentrated hydrochloric acid in sealed tubes for four hours at 100°, methyl chloride is formed and escapes on opening the tubes; whilst the hydrochloric solution, when diluted with water, deposits first a resinous matter, which should be removed, and then, after a time, a colourless substance in small nodules. This new compound, which the author calls *quassic acid*, $C_{14}H_{19}O_3.COOH$, or $C_{28}H_{34}O_6(COOH)_2$, is far less soluble in alcohol than quassin, and crystallises in silky needles which melt at 245°, and reduce Fehling's solution and ammoniacal silver nitrate in the cold. It seems to be formed thus: $C_{32}H_{44}O_{10} + 2HCl = C_{28}H_{38}O_6(COOH)_2 + 2CH_3Cl$, so that quassin would be the ethereal salt of quassic acid. The author has also tried the action of nascent hydrogen, and of boiling dilute nitric acid on quassin, but the products are resinous. Fusion with potash and oxidation with chromic anhydride also gave unsatisfactory results.

The resinous matter obtained in the preparation of crystallised quassin, and in all probability produced from the latter, was submitted to distillation with zinc-dust. The brown oily product was treated with sodium and fractionally distilled; the portion passing over at 170—190° when again distilled gave an oil boiling at 173—178° of the formula $C_{11}H_{16}$, whilst crystals melting at 76—78° were obtained from the residue in the retort. C. E. G.

New Methods for the Formation of α-Carbopyrrolic Acid from Pyrroline. By G. CIAMICIAN and P. SILBER (*Ber.*, **17**, 1437—1439).—α-Carbopyrrolic acid can be prepared from pyrroline by heating it with carbon tetrachloride and alcoholic potash. It is also formed, together with another acid, by the action of carbonic anhydride on the fused potassium-derivative of pyrroline. Attempts to prepare the aldehyde of carbopyrrolic acid by the action of chloroform on pyrroline in presence of potash were unsuccessful, nothing but resinous products being obtained. A. J. G.

Constitution of Pyridine. By A. HANTZSCH (*Ber.*, **17**, 1512-1522).—With the hope of throwing light on the constitution of the pyridine nucleus, the author has investigated the constitution of the pyridine-derivatives obtained by the condensation of ammonio-aldehydes with ethyl acetoacetate. Ethyl phenyl-lutidinedicarboxylate, $C_5NPhMe_2(COOEt)_2$, already described by Schiff and Puliti (Abstr., 1883, 1151) was saponified with alcoholic potash. The neutral potassium salt, which is easily soluble in alcohol, was then oxidised by means of potassium permanganate. The oxidation takes place more regularly than with ethyl collidinedicarboxylate. The solution is filtered from precipitated manganic oxide and treated with excess of concentrated nitric acid, when *trihydrogen potassium phenylpyridinetetracarboxylate*, $C_{15}H_8NO_8K + H_2O$, crystallises out in small prisms or pyramids, sparingly soluble in cold water, and having a strongly acid reaction and taste. *Paraphenylpyridinetetracarboxylic acid*,

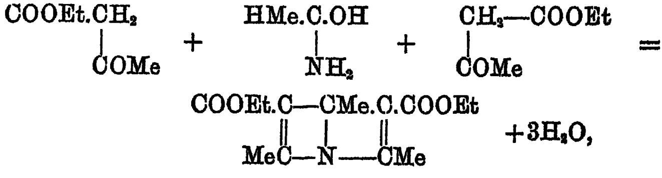
$C_5NPh(COOH)_4$, forms small glittering crystals containing $3H_2O$, which it loses at 120°. It melts at 205—207° with evolution of carbonic anhydride. It is easily soluble in water, rather sparingly in ether. It is best obtained pure from the trihydrogen potassium salt; this salt is covered with a little water, excess of concentrated sulphuric acid added, and the whole warmed until the crystals of the salt are completely dissolved: as the solution cools, the acid crystallises out in a pure state. Its neutral ammonium salt is precipitated by *mercurous, lead,* and *silver salts:* on heating with ferric chloride a flocculent precipitate, and with cadmium sulphate a crystalline precipitate is produced. The *copper salt,* $C_5NPh(COO)_4Cu_2 + 7H_2O$, crystallises in small blue rhombohedrons, which when once formed are quite insoluble in water. Barium chloride, even in presence of excess of ammonia, precipitates a double salt of the formula

$$(C_5NPh)_2(C_2O_4Ba)_3(COONH_4)_2 + 6H_2O,$$

in the form of microscopic plates. It loses its water of crystallisation at 130°.

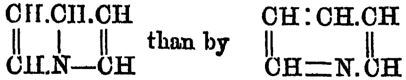
Paraphenylpyridine, C_5NPhH_4, is obtained by the dry distillation of trihydrogen potassium phenylpyridinetetracarboxylate, but the yield is much better if the salt is first intimately mixed with its own weight of lime. It distils at 274—275° (uncorr.), and solidifies to a glistening white mass which melts at 77—78°. It is thus different from the α- and β-phenylpyridines described by Skraup (*Wiener Monatsh.*, 1884, 436), which are liquid and both boil at 269—270°. It has the odour of diphenylamine, and volatilises slowly in a current of steam. It dissolves in warm hydrochloric acid, and yields a *hydrochloride* crystallising in needles. The *platinochloride,* $(C_5NPhH_4)_2,H_2PtCl_6$, is anhydrous, and crystallises in microscopic nodules. The *picrate* crystallises in yellow needles, which soften at 190° and melt at 195—196°. The *dichromate,* $(C_5NPhH_4)_2,H_2Cr_2O_7$, crystallises in long orange-coloured needles which melt at 155° with partial decomposition.

When oxidised with potassium permanganate, γ-phenylpyridine yields isonicotinic (or γ-pyridinecarboxylic) acid. This acid has been proved by Skraup to be the para-acid, so that the phenyl-group, in all the above-mentioned substances, must be in the para-position to the N-atom. It is thus clear that in the formation of ethyl phenyllutidinedicarboxylate the phenyl of the ammoniobenzaldehyde takes the para-position to the N-atom, and it is therefore probable that in the formation of ethyl collidinedicarboxylate the methyl of the ammonioaldehyde takes the same position. The author thinks that the formation of the latter body would be as follows:—



$$\begin{array}{l}COOEt.CH_2\\ \;|\\ COMe\end{array} + \begin{array}{l}HMe.C.OH\\ \quad\;|\\ \quad NH_2\end{array} + \begin{array}{l}CH_2—COOEt\\ |\\ COMe\end{array} = \begin{array}{c}COOEt.C—CMe.C.COOEt\\ \|\qquad|\qquad\|\\ MeC—N——CMe\end{array} + 3H_2O,$$

and that the constitution of pyridine would be more correctly explained by the formula



$$\begin{array}{l} CH.CH.CH \\ \| \quad | \quad \| \\ CH.N{-}CH \end{array} \text{ than by } \begin{array}{l} CH:CH.CH \\ \| \qquad\quad \| \\ CH{=}N.CH \end{array}$$

L. T. T.

Pyridine-derivatives. By W. Konigs and R. Geigy (*Ber.*, **17**, 589—595).—Konigs and Korner (this vol., 85) have shown that when quinolinic acid is fused with potash it forms a hydroxyquinolinic acid, which differs from Lieben and Haitinger's ammonio-chelidonic acid (Abstr., 1883, 871), inasmuch as when heated with water at 195° it is resolved into carbonic anhydride and a *hydroxypyridinemonocarboxylic acid*, $C_6H_5NO_3$; this acid crystallises from hot water in colourless crystals melting at 301—302°; with ferric chloride it yields a yellow coloration. The solutions of its sodium salt give immediate precipitates with copper, lead, and silver salts, and with barium and calcium salts after boiling. The lead salt, $(C_6H_4NO_3)_2Pb + \frac{1}{2}H_2O$, crystallises from hot water in white needles.

The formation of hydroxypyridine by the distillation of hydrogen silver hydroxyquinolate, observed by Konigs and Körner, has been confirmed by the authors, who have subjected this compound to further investigation. Its aqueous solution gives a red coloration with ferric chloride, and with silver nitrate and ammonia a precipitate soluble in excess of ammonia. Its hydrochloride separates in white needles when hydrochloric acid gas is passed into an ethereal solution of hydroxypyridine. Its aqueous solution, treated with bromine-water, yields a *dibromohydroxypyridine*, $C_5H_3Br_2NO$, which crystallises from water in white needles melting at 206—207°. It is different from the dibromohydroxypyridine described by Hofmann (Abstr., 1879, 733), also from that obtained by Lieben and Haitinger (*loc. cit.*), and that prepared by Ost from comenamic acid (*J. pr. Chem.* [2], **29**, 65). The formation of this hydroxypyridine is similar to the production of carbostyril, and it therefore probably has the constitution [N : OH = 1 : 2].

Pyridinedisulphonic Acid.—The production of this acid by the treatment of piperidine with concentrated sulphuric acid has already been described by Konigs and Hofmann (Abstr., 1883, 1143). It is very soluble in water, but almost insoluble in ether, alcohol, and glacial acetic acid; it crystallises from water in white needles. The potassium, lead, and sodium salts are all well-defined crystalline compounds, the latter containing 4 mols. of H_2O, and the lead salt 4½ mols. The disulphonic acid, when treated with bromine, is converted into a *dibromopyridine* melting at 164°. *Barium pyridinedisulphonate* is scarcely acted on by phosphorous pentachloride at 130—150°, but at 200° a reaction takes place with formation of a mixture of a *dichloro-* and *trichloro-pyridine*, from which, by repeated crystallisations from alcohol, the latter compound may be obtained in lustrous plates melting at 48°.

P. P. B.

Synthesis of Pyridine and Piperidine Bases. By A. Ladenburg (*Ber.*, **17**, 772—774).—The action of heat on pyridine ethiodide has been already noticed (*Ber.*, **16**, 2059), the action on pyridine propiodide is now described. Pyridine and propyl iodide are heated at 290°, and the product distilled with potash, by which means it is separated into three portions, namely, pyridine, a portion boiling at 160—164°, and a third fraction boiling at 173—175°.

The second portion is *propylpyridine*, $C_8H_{11}N$, as is shown by its analysis and vapour-density; it boils at 162°, and its sp. gr. at 0° is 0·9393. The aurochloride and platinochloride, $(C_8H_{11}N)_2,H_2PtCl_6$, are moderately soluble. Potassium permanganate converts it into γ-pyridinecarboxylic acid, melting at 305°; the base is therefore γ-propylpyridine.

The third portion resembles greatly in odour and specific gravity, &c., the second portion, but the aurochloride and platinochloride are more sparingly soluble; it is also a propylpyridine, but whether of the α or β series, cannot be decided, an acid being obtained on oxidation which does not appear to be a pyridinecarboxylic acid at all.

If these two propylpyridines are treated with sodium and alcohol, they yield propylpiperidines, $C_8H_{17}N$. The γ-compound boils at 157—161°, and its sp. gr. at 0° is 0·870; its aqueous solution is rendered turbid by heat, but not very readily. The other base boils at 165—168°, and also smells very much like conine, the aqueous solution is at once rendered turbid on warming, but it is optically inactive. It has many properties in common with conine, and like it is poisonous, acting in the same manner and to the same degree; the γ-base and its salts are not so active. It is possible that the higher boiling base contains some α-propylpiperidine (*i.e.*, conine), although in two optical modifications. The researches are being continued.

H. B.

Nitrogenous Derivatives of Chelidonic Acid. By A. LIEBEN and L. HAITINGER (*Ber.*, **17**, 1507—1508).—Ost has found (*J. pr. Chem.*, [2], **29**, 57 and 378) that his hypothetical pyridine is the hydroxypyridine obtained by the authors from chelidonic and ammonio-chelidonic acids. The authors have now obtained a *hydroxymethylpyridine*, C_6H_7ON, in the following ways:—1, action of methyl iodide and potash on hydroxypyridine; 2, action of methyl iodide on hydroxypyridine, and treatment of the product with silver oxide; and 3, by heating methylammoniochelidonic acid. This body is a crystalline but very deliquescent substance, which yields a crystalline platinochloride. With bromine, it yields the same dibromo-derivative, $C_6H_5Br_2ON$, melting at 192°, as is obtained by the action of methyl iodide and potash on hydroxydibromopyridine. *Methylammoniochelidonic acid* is a crystalline substance prepared by the action of methylamine on chelidonic acid. Aniline, in like manner, yields *phenylammoniochelidonic acid*. Dimethylamine, like the mineral alkalis, decomposes chelidonic acid into oxalic acid and acetone. It seems to act like a primary amine with phenylhydrazine.

L. T. T.

Metachloroquinoline. By W. LA COSTE and J. BODEWIG (*Ber.*, **17**, 926—928).—The parachloroquinoline has been previously described (Abstr., 1882, 979). Metachloroquinoline was prepared by Skraup's reaction, using metachloraniline and nitrobenzene. By mixing a solution of the sulphate with a sufficient quantity of potassium dichromate, and allowing it to stand, crystals of *metachloroquinoline* *chromate*, $(C_9H_6ClN)_2,H_2Cr_2O_7$, separate. The crystals require more than 400 parts of cold water for solution. *Metachloroquinoline* is an oil boiling at 264—266°, and scarcely soluble in water. The hydrochloride, C_9H_6ClN,HCl, is deliquescent; the platinochloride, $(C_9H_6ClN)_2,H_2PtCl_6 + 2H_2O$, is a brownish-yellow precipitate, which may be crystallised from dilute hydrochloric acid. Metachloroquinoline unites with methyl iodide to form metachloroquinoline methiodide, C_9H_6ClN,MeI, in yellow needles melting at 231—232°, and having an intensely bitter taste. When metachloroquinoline is heated with nitric and sulphuric acids, it yields two isomeric nitro-derivatives. *α-Nitrometaquinoline* melts at 185—186°, and crystallises from the alcoholic solution first, it is sparingly soluble even in warm alcohol. *β-Nitrometachloroquinoline* melts at 120—123°, and is easily soluble in hot alcohol. Both compounds yield crystalline platinochlorides, and by tin and hydrochloric acid they are reduced to amido-derivatives.

H. B.

Dimethylquinoline. By L. Berend (*Ber.*, **17**, 1489—1490).—This was prepared by Skraup's reaction from orthoxylidine, nitrobenzene, glycerol, and concentrated sulphuric acid. *Dimethylquinoline*, $C_{11}H_{11}N$, is a yellowish liquid boiling at 273—274°. Its platinochloride, $(C_{11}H_{11}N)_2,H_2PtCl_6 + H_2O$, crystallises in pale yellow microscopic needles. The acid sulphate crystallises in prisms which effloresce on exposure to the air, and appear to contain water of crystallisation. The chromate yields small orange needles, sparingly soluble in boiling water. Fuming sulphuric acid at 115—120° yields a crystalline sulphonic acid which melts at 265—266°. This acid, on fusion with potash, gives a dimethylquinophenol, which is volatile in steam, and yields a platinochloride, crystallising in pale yellow needles. As the amido-group is in the para-position in orthoxylidine, the two methyl groups in dimethylquinoline must be contiguous.

L. T. T.

Some Derivatives of Quinolinemetacarboxylic Acid. By O. Fischer and G. Körner (*Ber.*, **17**, 765—766).—In a previous paper, (Abstr., 1882, 412 and 869) the preparation of the ortho- and meta-cyanoquinolines is described, and also (Abstr., 1882, 71) the quinolinecarboxylic acids. During the preparation of orthocyanoquinoline, a large quantity of the meta-compound is always formed.

Tetrahydroquinolinemetacarboxylic acid, $C_{10}H_{11}NO_2$, is prepared by treating the quinolinemetacarboxylic acid with zinc and hydrochloric acid at 100°; a portion of the product separates as zinc salt, the rest is extracted with ether. It crystallises from alcohol in long colourless needles or plates, which melt at 146—147°. Treated with a nitrite in acid solution, it yields a nitroso-body, $C_{10}H_{10}N_2O_3$, crystallising in fine yellow prisms from alcohol.

Kairolinmetacarboxylic acid, $C_{10}H_{10}MeNO_2$.—The preceding acid is heated with the necessary amount of ethyl iodide at 140—150°; the product is dissolved in water, and the solution mixed with sodium acetate, when the new acid separates out; it crystallises from alcohol in needles which melt at 164°; on allowing the mother-liquor to remain for a time, the methyl iodide additive-compound separates in large crystals. This acid receives the above name, as König and Hoffmann have given the name kairolin to tetrahydromethylquinoline.

H. B.

Synthesis of Quinoline-derivatives. By L. Knorr (*Ber.*, **17**, 540—546).—The continuation of the investigation of the method of preparing quinoline-derivatives by the action of primary amines on ethyl acetoacetate has yielded the following results:—

Phenyl-β-imidobutyric acid, PhN : CMe.CH_2.COOH, is formed when aniline and ethyl acetoacetate are heated in sealed tubes at 150—160°, it is soluble in water, ether, &c., and has both acid and basic properties. Ferric chloride imparts to its solutions a dark violet coloration, destroyed by hydrochloric acid. Sulphuric acid in the cold, and hydrochloric acid after continued heating, convert it into *γ-hydroxyquinaldine*, an oily liquid.

Orthotolyl-β-imidibutyric acid is obtained from orthotoluidine and ethyl acetoacetate, it crystallises in flat needles, and by concentrated sulphuric acid is converted into *orthotoluene-γ-hydroxyquinaldine*, $C_{11}H_{11}ON$, a solid melting at 185°.

Paratolyl-β-imidobutyric acid, $C_{11}H_{13}NO_2$, is obtained from paratoluidine; sulphuric acid converts it into the corresponding γ-hydroxyquinaldine, melting at 245°.

β-Naphthyl-β-amidobutyric acid, $C_{14}H_{13}NO_2$, is formed by the action of β-naphthylamine on ethyl acetoacetate, it crystallises from water in needles which melt at 92°. At the same time, a considerable quantity of the naphthalide of this acid is formed, a compound crystallising from benzene in needles melting at 200°; this, when heated with hydrochloric acid, yields a further quantity of β-naphthyl-β-imidobutyric acid. When the acid is heated with concentrated hydrochloric acid it yields *β-naphtha-γ-hydroxyquinaldine*, which crystallises from alcohol in flat shining needles, melting at 286°. It exhibits marked resemblance to γ-hydroxyquinaldine, and is volatile without decomposition. Distilled with zinc-dust, it yields a volatile base melting at 91—92°, having all the properties of naphthoquinaldine; its solutions in strong acids have a green fluorescence and an intense blue in dilute acids. Its *platinochloride*, $(C_{14}H_{11}N)_2,H_2PtCl_6$, is sparingly soluble in hot dilute hydrochloric acid. This base differs from the quinaldine prepared by Döbner and Miller's method.

α-Naphthylamine yields condensation-products with ethyl acetoacetate, the α-naphtho-γ-hydroxyquinaldine melts at 292°.

Phenylenedi-imidobutyric acid, $C_{14}H_{16}N_2O_4$, is obtained by heating orthophenylenediamine with ethyl acetoacetate at 170°; it crystallises in plates which melt at 176°.

Ethyl succinosuccinate behaves with the aromatic primary amines as ethyl acetoacetate does; when heated with paratoluidine at 200° it yields a compound, $C_{31}H_{13}N_3O_3$, crystallising from alcohol in needles which melt at 263°. It is insoluble in ordinary solvents, acids, and alkalis. Aniline yields a similar compound, melting at 210°.

P. P. B.

Derivatives of Toluquinoline. By J. Herzfeld (*Ber.*, **17**, 903—906; comp. this vol., 1051, and next Abstract).—*α-Methyl-γ-quinolinemonosulphonic acid*, [N : CH_3 : SO_3H, 1′ : 1 : 3], orthamidometatoluenesulphonic acid, prepared from orthotoluidine, was heated with nitrobenzene, glycerol, and sulphuric acid, and the product poured into water. It forms colourless prisms, only slightly soluble in water. *γ-Hydroxy-α-methyl-quinoline* is formed by fusing the above with caustic soda. It is not volatile with steam, crystallises from ether, and melts at 200°.

α-Methyl-δ-quinolinemonosulphonic Acid.—Orthonitrotolueneparasulphonic acid is reduced by sulphuretted hydrogen, and the amido-acid converted into the substituted quinoline by Skraup's method as before. It crystallises well from water. *Hydroxy-α-methylquinoline* is obtained from the preceding by fusion with potash; it melts above 260°.

The author has endeavoured to obtain the same bodies directly from toluquinoline. Orthotoluquinoline, boiling at 246—248°, was heated at 135—140° with fuming sulphuric acid, and precipitated with water; two acids are formed, one sparingly soluble in water, the other easily soluble. The first, *orthotoluquinoline-(a)-monosulphonic acid*, yields a sparingly soluble barium salt; fused with alkalis, it yields *(a)-hydroxyorthotoluquinoline*, melting at 94—96°, and volatile with steam. The second, *orthotoluquinoline-(b)-monosulphonic acid*, forms an easily soluble barium salt. The corresponding *(b)-hydroxyorthotoluquinoline* is not volatile with steam; it melts at 92—93°.

H. B.

Derivatives of Toluquinoline. By J. HERZFELD (*Ber.*, **17**, 1550—1553).—The author previously described two toluquinolinesulphonic acids, *a* and *b* (preceding Abstract), which he had prepared from a commercial sample of toluquinoline of constant boiling point, 246—248°, and which he believed to be the ortho-compound. He has now for comparison prepared the sulphonic acids from pure bodies.

Orthotoluquinolinemonosulphonic acid was obtained by the action of fuming sulphuric acid (sp. gr. 1·89) on *pure* orthotoluquinoline, boiling at 248°. It crystallises in brilliant colourless prismatic needles. The acid and its barium and potassium salts are easily soluble in water. The *barium salt* forms anhydrous rhombic needles; the *potassium salt*, large plates. *Orthohydroxyquinoline*, obtained by fusing the sulphonic acid with sodium hydroxide, melts at 245—248° with partial decomposition. It is not volatile in steam, but may be sublimed with care, and yields tufts of needles. It gives a reddish-brown coloration with ferric chloride. It dissolves in soda and potash, and an alcoholic solution of these compounds, when digested with methyl iodide, yields *orthomethoxytoluquinoline*. This is a dark-red oil, boiling at 225—230°. Its platinochloride crystallises in yellow needles. The above sulphonic acid and other derivatives are therefore identical with the *b* acid and its derivatives before described.

Paratoluquinolinemonosulphonic acid, prepared from *pure* paratoluquinoline boiling at 259—261° (corr.), crystallises in scales. Its *alkali salts* are easily soluble; the *barium*, *calcium*, and *copper salts* sparingly so. *Parahydroxytoluquinoline* is volatile in steam, crystallises in colourless needles, and melts at 95—96°. Its *platinochloride* forms orange needles. *Paramethoxytoluquinoline* is a yellowish-brown oily mass, which may be distilled. The crystalline *platinochloride* is brown. The parasulphonic acid and its derivatives are therefore identical with the α acid and derivatives previously described. It is thus clear that the commercial toluquinoline used in the previous experiments must have been a mixture of the ortho- and para-compounds, notwithstanding that it boiled constantly within less than two degrees of the boiling point of orthotoluquinoline. L. T. T.

Quinaldinecarboxylic Acids. By O. DOEBNER and W. v. MILLER (*Ber.*, **17**, 938—944).—The action of the three amidobenzoic acids on aldehyde, in presence of hydrochloric acid, has been examined to ascertain whether the carboxyl-group had any modifying action. The reaction, however, proceeds quite normally (this vol., p. 183), quinaldinecarboxylic acid, $COOH.C_6H_3<\begin{smallmatrix}N:CMe-\\CH:CH\end{smallmatrix}>$, being formed.

Paraquinaldinecarboxylic Acid.—The reagents, hydrochloride of paramidobenzoic acid, paraldehyde, and hydrochloric acid, react with development of heat and the hydrochloride of paraquinaldinecarboxylic acid separates out; it is purified by recrystallisation from dilute hydrochloric acid. On adding the requisite quantity of sodium carbonate to a solution of the hydrochloride, the free acid is deposited as a sandy powder, only slightly soluble even in hot water. It forms salts with both acids and bases. The hydrochloride, $C_{11}H_9NO_2,HCl + H_2O$, is soluble in water, but not in dilute acid; the platinochloride, $(C_{11}H_9NO_2)_2,H_2PtCl_6 + 4H_2O$, is only slightly soluble; the chromate, $(C_{11}H_9NO_2)_2,H_2Cr_2O_7$, is also only slightly soluble in cold water. The calcium salt, $(C_{11}H_8NO_2)_2Ca + 2H_2O$, the silver salt, $C_{11}H_8NO_2Ag$, and the copper salt, $(C_{11}H_8NO_2)_2Cu + 6H_2O$, are obtained from the ammonium salt by precipitation; they are crystalline.

Metaquinaldinecarboxylic Acid.—It is necessary to use a larger excess of paraldehyde and of hydrochloric acid, and the mixture requires heating. The free acid is prepared from the crystalline hydrochloride as above. The following salts are described: $C_{11}H_9NO_2,HCl + H_2O$; the abnormal platinum salt, $4(C_{11}H_9NO_2,HCl),PtCl_4$, also $(C_{11}H_9NO_2)_2,H_2Cr_2O_7$; $(C_{11}H_8NO_2)_2Ca + 2H_2O$; $(C_{11}H_8NO_2)Ag$; and $(C_{11}H_8NO_2)_2Cu + 3H_2O$.

Orthoquinaldinecarboxylic Acid.—Here an excess of paraldehyde must be avoided. The free acid melts at 151°, and is decidedly soluble in cold water; it crystallises from hot water with ½ mol. H_2O, which it loses at 100°. The hydrochloride is very soluble in water, and is not reprecipitated by strong hydrochloric acid; the platinochloride, $(C_{11}H_9NO_2)_2,H_2PtCl_6 + 2H_2O$, is easily soluble in hot water; the chromate is also soluble in hot water. The silver, calcium, and copper salts, $(C_{11}H_8NO_2)_2Cu\frac{1}{2}H_2O$, are described. H. B.

Conine. By A. W. HOFMANN (*Ber.*, **17**, 825—833).—Conine hydrochloride, distilled with zinc-dust, does not yield an amine, viz., octylamine, but one of the pyridine bases, $C_8H_{11}N$, *conyrine*, having nearly the same boiling point (166—168°) as conine, from which it is separated by conversion into the hydrochloride; all its salts, with the exception of the platinochloride, are very soluble in water. Methyl iodide combines at ordinary temperatures with conyrine to form the iodide of an ammonium base. By the action of silver chloride, the chloride and thence the platinochloride were prepared; it is $(C_8H_{11}N,MeCl)_2,PtCl_4$. Conyrine boils lower than other known bases of the same formula; moreover, it is distinguished by a blue fluorescence and the absence of any tendency to polymerise; with potassium permanganate, it yields a pyridinecarboxylic acid, viz., picolinic acid. Conine also yields conyrine when distilled with zinc chloride. According to Skraup and Cobenzl, picolinic acid contains the nitrogen and carboxyl groups in the ortho-position; conyrine will then be orthopropylpyridine, and conine itself hexahydrated propylpyridine or orthopropylpiperidine.

The reconversion of conyrine into conine is easily effected by heating it with hydriodic acid at 280—300°. Natural conine, and conine regenerated from conyrine have exactly the same physiological action. Conyrine is not so poisonous and acts more like a narcotic.

The synthesis of conine is thus simplified. Ladenburg has prepared ethylpyridine by methods used for obtaining the substituted anilines, and it is probable that conyrine or conine will be formed by the action of isopropyl iodide on pyridine or piperidine at a high temperature.
H. B.

Thebaïne. By W. C. Howard (*Ber.*, 17, 527—533).—*Bromothebaine tetrabromide*, $C_{19}H_{20}Br,NO_3,Br_4$, is obtained as a yellowish-red precipitate by adding an excess of bromine-water to a dilute solution of thebaine in hydrobromic acid.

Bromothebaine, $C_{19}H_{20}BrNO_3$, is prepared by adding bromine-water to the hydrobromic acid solution of thebaine as long as a precipitate is formed, filtering, and adding ammonia to the filtrate, when it forms a precipitate, which is at first reddish, but finally becomes blue.

Morphothebaine, $C_{17}H_{17}NO_3$.—The acid hydrochloride or hydrobromide of this base is obtained by heating thebaine with concentrated hydrochloric or hydrobromic acid in sealed tubes at 80—90°. The base is thrown down from solutions of its salts by caustic alkalis, carbonates of the alkali metals, or ammonia, as a greyish-blue precipitate, soluble in excess of caustic alkalis. It is soluble in alcohol and ether, also in benzene, from which it crystallises in well-defined crystals melting at 190—191°. *Morphothebaine hydrochloride*,

$$C_{17}H_{17}NO_3,HCl,$$

obtained by treating the acid hydrochloride with alcohol, forms small shining crystals, insoluble in alcohol, but soluble in water. The *hydrobromide* resembles the hydrochloride. The *nitrate*,

$$C_{17}H_{17}NO_3.HNO_3 + 2H_2O,$$

obtained by treating the solution of the hydrochloride with silver nitrate; it forms white small crystals. The *sulphate*,

$$(C_{17}H_{17}NO_3)_2,H_2SO_4 + 7H_2O,$$

prepared in a similar manner, crystallises from its aqueous solutions in monoclinic crystals. *Acetomorphothebaine*, $C_{17}H_{16}NO_3\overline{Ac}$, prepared by heating morphothebaine hydrobromide with acetic anhydride and sodium acetate, crystallises from alcohol in shining scales which melt at 183°. The solutions of morphothebaine hydrochloride are precipitated by platinic and auric chlorides, by potassium ferrocyanide, potassic bismuthic iodide, ammonium molybdate, potassic mercuric iodide, and potassic chromate.

Phosphorus pentachloride reacts with thebaïne, yielding a compound containing no chlorine, proving the absence of a hydroxyl-group in the same. *Thebaïne methiodide* is obtained by heating a solution of thebaine in methyl alcohol with methyl iodide; crystallised from alcohol, it gives crystals having the composition $C_{19}H_{21}NO_3$,MeI,EtHO. *Thebaïne ethiodide*, $C_{19}H_{21}NO_3$,EtI, obtained like the above, crystallises from alcohol in fine needles. *Thebaïne ethyl chloride*, formed by decomposing the iodide with silver chloride, crystallises from a mixture of alcohol and benzene in slender white needles.

Thebaïne benzyl chloride crystallises in small nodules.

P. P. B.

Synthetical Piperidine. By A. LADENBURG and C. F. ROTH (*Ber.*, **17**, 513—515).—One of the authors has already shown that by the action of sodium on an alcoholic solution of pyridine it is converted into a hexahydro-base, very nearly resembling piperidine. The authors have compared these two bases carefully with one another, and have established their identity. P. P. B.

Putrefactive Alkaloïds. By L. BRIEGER (*Ber.*, **17**, 516—517).—The author proposes the name *neuridine* for the alkaloid $C_5H_{14}N_2$, described by him (Abstr., 1883, 1159), since it yields trimethylamine when boiled with potassium hydroxide. Atropine stops the poisonous action of the alkaloid $C_5H_{11}N$, which contracts the pupil when introduced into the eye. The author is of opinion that this poisonous alkaloïd is *trimethylvinylammonium hydroxide*, and this is supported by the analysis and chemical and physical characters of its platinochlorides, also by the physiological action of the trimethylvinylammonium hydroxide.

Commercial neurine appears to contain two bases, one having the formula $C_5H_{11}N$, and forming sparingly soluble platino- and aurochlorides, and another $C_5H_{11}NO = Me_3N(OH).C_2H_4.OH$, *trimethylhydroxethylammonium hydroxide*, forming an easily soluble platinochloride. P. P. B.

Physiological Chemistry.

Researches on the Development and Nourishment of the Silkworm. By O. KELLNER, T. SAKO, and J. SAWANO (*Bied. Centr.*, 1884, 235—240).—Silkworms were fed with weighed quantities of mulberry leaves, which were given during all periods of growth, those periods being (1) a week from the hatching of the egg; (2) May 6—12; (3) May 12—19; (4) 19—26; (5) May 26—June 3, when the chrysalis state was assumed; (6) June 6, when the cocoon was completed; (7) June 22, when the butterfly emerged. It was during the 4th period that the excrement of 1000 worms was examined, and found to contain 2·49 per cent. of uric acid, which fell to 1·31 per cent. in the 6th; but little ammonia was found, and no urea. Of the food given the worms only consumed about $\frac{1}{6}$—$\frac{1}{5}$, and of the digested matter the nutrient ratio was as follows:—

Period...	1	2	3	4	5
N.R......	1:1·85	1:2·13	1:1·94	1:2·14	1:1·45

But little of the fibrous matter could be digested, but the albumin and fat were digested to an extent surpassed only by ruminants. The following table shows the composition of the worm, &c., at different ages:—

	Newly hatched.	Period 1.	Period 2.	Period 3.	Period 4.
Water	75·94	84·10	85·68	86·92	87·81
In 100 dry matter.					
Protein less chitin	75·58	75·42	73·26	72·52	72·23
Chitin			5·32	5·46	5·40
Fat	16·20	8 72	10·73	12·35	11·47
Ash	6·10	9·05	8·98	9·48	9·32
Undetermined	1·82	6·81	1·79	—	1·58
Total nitrogen	12·09	12·07	12·04	11·93	11·88
Albuminoid and peptin nitrogen	11·39	11·06	10·42	9·81	9·94
Chitin nitrogen			0·32	0·33	0·32
Nitrogen in undetermined compounds*	0·71	1·01	1·30	1·79	1·62
Ditto in per cent. of total N.	5·80	8·30	10·80	15·00	13·30

	Period 5.	Empty cocoon.	Pupa.	Butterfly.
Water	80·33	12·50	78·89	71·77
For 100 dry matter.				
Protein less chitin	59·16	98·82	55·81	56·58
Chitin	4·77	—	3·89	7·38
Fat	16·31	0·01	28·17	32·01
Ash	6·06	1·18	5·62	3·04
Undetermined	13·70	—	6·51	0·10
Total nitrogen	9·75	17 97	9·16	9·49
Albuminoid and peptin nitrogen	8·11	—	5·68	8·18
Chitin nitrogen	0·29	—	0·23	0·44
Nitrogen in undetermined compounds*	1·35	—	3·25	0·87
Ditto in per cent. of total N.	13·80	—	35·50	9·20

* Precipitated by phosphotungstic acid.

The remarkably rapid growth of the worm is exemplified by the figures in the subjoined table:—

	Ratio of live weight.	Ratio of dry weight.
	Weight of new-hatched worm = 1.	
Period 1............	11·40	7·70
„ 2............	61·80	37·40
„ 3............	275·50	152·20
„ 4............	1241·90	639·70
„ 5............	5364·70	4457·70
Cocoon and pupa....	2826·10	3468·50
Butterfly...........	1215·00	1450·70

From this it is evident that much of the increase in live weight is due to water, and from the previous table we learn that nearly one-half of the albuminoïds in the worm are employed in the formation of the silk of the cocoon.

Passing on to the amount of the food constituents digested, the following will show all that is necessary on this point:—

Periods............	1	2	3	4	5	Average.
Dry matter...........	29·4	28·9	27·2	37·8	63·3	56·6
Organic matter.........	27·5	27·0	25·3	35·7	61·9	55·0
Crude protein.........	45·0	58·1	51·5	79·7	87·1	83·8
Albumin..............	68·8	70·0	45·6	71·4	75·6	73·5
Fat..................	20·0	23·4	31·6	42·3	—	—
Potash...............	—	—	—	2·1	3·5	—
Lime.................	—	—	—	23·7	18·7	—
Magnesia.............	—	—	—	34·5	33·8	—
Phosphoric acid........	—	—	—	63·2	25·0	—

In the 5th period there was an addition to the fat, which was in excess of that contained in the food, and this excess could not have been produced by the decomposition of albumin, by reason of insufficiency, consequently we must suppose that some non-nitrogenous matter other than fat had been converted into this compound.

E. W. P.

Urine of Cows and Sheep. By E. ZACHARLWICZ (*Ann. Agronomiques*, **10**, 177—183).—The author has estimated the urea in the urine of cattle and sheep under varying conditions of food and treatment. Esbach's ureometer-tube was employed, with Kraup's solution of sodium hypobromite.

The mean proportion of urea found in sheeps' urine was 20 grams per litre, and supposing a sheep to void 1 litre of urine per day, the urea excreted per annum would be 7·3 kilos. A very fat sheep excretes an unusually large quantity of urea, and a sheep in poor condition and bad health less than the average.

The urine of four cows receiving food of known composition was examined on June 15, July 13, and August 24, the mean proportions of urea being 21·14, 26·35, 14·80 grams per litre respectively for the three dates mentioned. The great falling off in August is due to the change of food, for whilst in August the cows received maize and cotton-cake only, in June and July they had cotton-cake, hay, straw, lucerne, and trifolium. The mean results give about 20 grams urea per litre, and reckoning with Boussingault 9 litres of urine per day, the total quantity of nitrogen excreted in the form of urea will be 28—30 kilos. per annum per cow. The nutrient ratio of the three foods given was in June, 1 : 3·9; July, 1 : 5; and August, 1 : 8·8. By analysis of the milk, the author shows that the highly nitrogenous diet of July did not cause any corresponding increase of caseïn in the milk, but that the excess of nitrogen was excreted as urea in the urine. J. M. H. M.

Influence of Movement on the Secretion of Milk. By H. Munk (*Bied. Centr.*, 1884, 232).—Most of the writers on the subject have stated that movement is detrimental to the secretion of milk. Fleischmann, however, found that the reduction in quantity is but slight, and is fully compensated for by the increased yield of solids. To settle this question, the author experimented with 30 cows, and finds that when the cows had half an hour's exercise during the day, the total quantity of milk as well as the fat and caseïn increased, but much exercise was detrimental to the yield; when the cows are on grass, their increased appetite and the abundance of food fully compensates for any loss incurred by the motion required to obtain that food. It is therefore advisable that milch-cows when being stall-fed, should have daily exercise. E. W. P.

Chemistry of Vegetable Physiology and Agriculture.

A Concentrated Nutritive Fluid for Plants. By W. Knop (*Landw. Versuchs-Stat.*, 30, 292—294).—The author who is engaged in experiments on the absorption of various acids and bases by the roots of plants, recommends in this paper the use of a liquid fertiliser of his own invention, which, being of known composition and concentration, can be readily diluted to suit the requirements of the experimentalist.

There are two solutions, viz., No. 1—

205 grams of magnesium sulphate = 100 grams of the anhydrous salt = 33·33 MgO + 66·67 SO_3 in 3·5 litres of water.

No. 2 solution—

400 grams calcium nitrate = 136·58 CaO + 263·42 N_2O_5.
100 „ potassium nitrate = 46·58 K_2O + 43·52 N_2O_5.

100 grams potassium phosphate $= 34 \cdot 63\ K_2O + 52 \cdot 22\ P_2O_5 + 13 \cdot 15\ H_2O$ dissolved in the same quantity of water, 3·5 litres.

For use, he suggests mixing 100 c.c. of each, and making up to 10 litres, each litre would then contain—

Water of combination......	0·0377
Potash	0·2320
Lime.....................	0·3903
Magnesia	0·0952
Combined phosphoric acid..	0·1491
Sulphuric acid...........	0·1905
Nitric acid	0·9052
Free phosphoric acid	0·0746

J. F.

Influence of Light and Heat on Plants. By HELLRIEGEL (*Bied. Centr.*, 1884, 240—253).—A continuation of the author's researches (this vol., 855). As it was thought impossible that plants growing in glass-houses could obtain light of an intensity equal to that which they would receive outside, the results of experiments conducted under cover would not be perfectly trustworthy; the author therefore arranged that the plants experimented on should be exposed to the free air in fine weather, but removed under shelter when bad weather occurred; as a proof that the new arrangements made considerable differences to those obtained under the old method, the results of experiments are quoted, which show that not only was the total yield of barley greater, but that the weight also of the grains harvested was heavier in free air and direct sunlight than in diffused light. Barley plants were grown under coloured glass—cobalt glass, which allowed of the passage of the red and green rays as well as of the violet, and yellow carbon glass in which the violet and blue were extinguished,—with this result, that under the influence of the blue light less ash and more organic matter were produced than under the yellow. Those under the blue glass grew well, whilst those under the yellow seemed to be retarded in their growth, and when shaded were long in the internodes, and the leaves were thin and delicate. Taking this experiment in conjunction with another somewhat similar one, the author comes to the conclusion that plants are not very sensitive to moderate changes in the composition of the light which falls on them, consequently that the light as altered by the roof and walls of a glass-house cannot have any serious detrimental influence on the plants growing in that house.

In order that land should produce a maximum crop, it is necessary that each plant should have assigned to it a definite volume of porous soil for the proper development of its roots; that there be a sufficiency of moisture, enough of available nutriment, and finally a definite quantity of light and heat. Of all these factors which make up the fertility of a soil, the last two are not under the guidance of man. The author, therefore, in 1870, tried to estimate the influence exerted by the light and heat, but failed; the account of the experiments is given in detail. In a second series, barley and peas were grown in glass vessels of two sizes, and the plants as soon as they appeared were shaded by cylinders of cardboard placed vertically, so that no side light could reach the plants; those cylinders were of different sizes, some being broader than the vessel holding the soil, others of the same diameter; some broader above than below, and *vice versâ*; the results obtained were unexpected—the stems grew lengthy and rapidly, being thin and weak; the lower leaves were pale; those of the peas reddish; it appears, then, that under the influence of the shades the growth is somewhat abnormal, and this is the more marked the narrower the shading cylinder; under all these disadvantages, however, the plants fruited, but under all conditions those plants growing unshaded produced the most fruit, and, as the cylinder narrowed, the yield of grain decreased, whilst the chaff and the straw (peas excepted) increased. The author had previously believed that when the plants grow freely in the field, it was the light which fell on the crown of the plants which influenced their growth, as so much of the rest of the plant was shaded. It was also remarked that under the medium-sized shades with the upper opening of the same size as the pots, although the other conditions were so various, yet the amount of dry matter in the plants was approximately the same.

As regards the warmth necessary for the proper growth and ripening of plants, the experiments are detailed very fully, but it will suffice to state the results obtained. For the growth of four-rowed barley, the average daily temperature during the first half of the period of vegetation must be about 15°, in the latter half when the blossom forms, &c., the average must be 17—18°, and the average of the whole season 16°. The average of the mid-day during the first period must be 20°, during the second period about 25°, the average during the whole season about 21°. E. W. P.

Relation between Chemical Metamorphosis and Transformation of Forces during the Germination of Seeds. By H. Roedwald (*Ann. Agronomiques*, **10**, 236—237).—Two equal weighed quantities of clover-seeds are taken, and one of them used for the determination of total dry solids; the other portion is moistened and allowed to germinate for 5 or 9 days, the soluble matters formed during germination being absorbed by a layer of glass wool. The total dry solid matter in the germinated seed is then ascertained and ultimate analyses are made of this dry matter and of that from the corresponding quantity of ungerminated seed. The calorific power of 1 gram of dry matter from each source is next found by combustion in a calorimeter with a deflagrating mixture composed of potassium chlorate, antimony sulphide, and cane-sugar—the sum of the heat disengaged by combustion of the flux and dissociation of the potassium chlorate being deducted from the total amount obtained. Experiments conducted in this way show that 1 gram of the dry matter consumed by respiration disengages 2564 calories and 5938 calories during a germination of 5 and 9 days respectively. The matter which disappears during the first five days is of sensibly the same composition as starch, and outside of the seed would be capable of disengaging 4479 calories per gram by combustion. The matter oxidised during the nine days corresponds in composition with a mixture of 60 per cent. starch and 40 per cent. fat, and is theoretically capable of disengaging 6641 calories per gram.

There is therefore a considerable amount of force absorbed during germination. J. M. H. M.

Comparative Growth of Peas and Maize in Mineral and Organic Solutions. By V. JODIN (*Ann. Agronomiques*, **10**, 193—215).—In this paper are collected the details of experiments made some years ago on the culture of peas and maize in certain artificial solutions.

1. *Organic solution* consisting of a certain weight of dried and powdered pea plants (seed and straw) inclosed in a porous cell placed in a porcelain crucible full of water, so that gradual exosmose of the soluble matter took place through the walls of the cell. The crucible was furnished with a lid pierced with two holes to admit the stems of the pea and maize plants. The weighed seeds were allowed to germinate in water or in soil, and the plants then transferred to the artificial solution. Growth took place in both cases, that of the maize being much more luxuriant than that of the pea—the dried crop from the maize seed being 29·38 times the weight of the seed, and that of the pea 4·18. Determinations were made of nitrogen and minerals contained in these crops, in the manure supplied, and in the residual liquid, and from these figures the proportions of nutritive substances in the manure utilised by the growing plants were calculated.

2. *Mineral Solution.*—This contained all the minerals of the preceding organic solution, and in about the same proportions, but the nitrogen was supplied as a nitrate. The experiments were conducted as with the preceding solution, and the amount of growth was about the same.

3. *Mixed Solution.*—A quantity of the powdered pea-manure was placed in a funnel provided with a stop-cock, and moistened with water. From time to time the water was allowed to run through into a flask and was again poured into the funnel. This treatment was prolonged for about a year, when the residue in the funnel was only a fifth of its original weight. The solution thus obtained (A) was employed alone in some of the cultivations, and in others was mixed with a mineral solution (B) made by dissolving the ash of an equal weight of dried pea plant in the smallest possible quantity of nitric acid, and diluting with water. The solution B was also employed alone in some of the experiments, and the results of the three methods go to show that in the mixture of the solutions A and B each produced its proportional effect, and no increase of crop was obtained by the mixture. Solution A gave very small and feeble plants, whilst those grown in B were comparatively luxuriant and robust.

The results of all the experiments, which are given in great detail, go to show that the plants derived no benefit from the decaying organic matter of the manure, except in so far as the nitrogen was gradually transformed by putrefaction and fermentation into the mineral forms of ammonia and nitric acid. In all cases in which estimations were made, there was a loss of nitrogen—often amounting to 50 per cent. of that in the seed and manure. J. M. H. M.

Function of Tannin in Vegetable Cells. By W. GARDINER (*Ann. Agronomiques*, **10**, 188—189; from *Proc. Cambridge Phil. Soc.*, IV).—By means of Rose's reagent, the author has made some microchemical observations on the occurrence of tannin in vegetable cells. Rose's reagent consists of ammonium molybdate dissolved in a saturated solution of ammonium chloride, and strikes a red colour with tannin glucosides and tannic acid. An excess of the reagent produces a voluminous precipitate, if the tannin be a glucoside. Tannins are very abundant in the motor tissue of the sensitive plant and similar tissues, and there is possibly some connection between the presence of tannin and the irritability of the tissue. It is probable that tannin is one of the ultimate products of the metamorphosis of immediate principles, that it is not utilized by the plant, and that its disappearance when once deposited is doubtful. J. M. H. M.

Acidity of Cell Sap. By G. KRAUS (*Ann. Agronomiques*, **10**, 238—240).—By means of dilute (0·1 per cent.) standard solution of sodium hydroxide, the author has determined the total acidity of the cell sap contained in the different organs of growing plants in various circumstances. The leaves are the most acid parts of ordinary herbs and shrubs, the roots the least. This rule is reversed in the Crassulaceæ. The wood and bark are more acid than the pith. In many leaves, the acidity often increases from the tip to the base. The acidity of a stem generally increases with the age, *i.e.*, from above downwards, but in some cases, young lupins for example, it remains constant for some time. The petals of the Boraginaceæ, red when young, are more acid than when blue and full grown. In an organ undergoing geotropic curvature, the acidity diminishes on the convex side. When a plant germinates in darkness the acids increase; they diminish when it is transported into the light, but subsequently increase. A plant may grow in the dark without any increase of acidity. It has been known for some time that the leaves of the Crassulaceæ become very acid during the night, but lose their acidity in the day. The author shows that this periodicity is a general phenomenon differing only in intensity in different plants, and directly dependent on the illumination. Not only can the acidity be caused to increase by shading the plants during the day, but a local accumulation or development of acid can be produced by darkening a particular leaf or part of a leaf. The red rays of the spectrum are more potent than the blue in relation to this phenomenon. In an atmosphere of carbonic anhydride or hydrogen, acids are not formed during the night nor are they decomposed during the day, so that these changes are not related to the diurnal assimilation of carbon. In the night, when the acidity is greatest, the quantity of glucose is least, and during the day as the acids diminish so the glucose increases.

J. M. H. M.

"Butter Beans," a new Variety of Fatty Seeds. By F. v. HÖHNEL and J. WOLFBAUER (*Dingl. polyt. J.*, **252**, 333—337).—During the last few months, fatty seeds of remarkable size have been brought into commerce by way of Marseilles and Trieste consisting of the split embryo of endospermless seeds, which belong to the *Valeria* *indica*, a tree growing in India (especially Malabar), whence large quantities of vegetable fat (Malabar tallow) have been recently imported into Europe. The seeds are brought into the market in a decayed condition, the fruits being gathered triennially and not as they fall from the trees. The seeds have an aromatic and bitter taste, and a faint aromatic odour. Examined under the microscope, they appear to be made up of thin isodiametric parenchyma cells, the contents of which are composed of three ingredients: (1) yellow hyaline, or fine-grained masses of albuminous bodies (protoplasm) insoluble in boiling alcohol; (2) fatty substances, which are colourless, hyaloid, and crystalline, at places forming masses which, in consequence of the decay of the seeds, are quite separate from the *yellow* albumin; (3) numerous starch granules (to the extent of from 15—20 per cent.). The seeds of the *Vateria indica* when dried in the air contain 49·21 per cent. of a greenish-yellow solid fat characterised by its agreeable slightly balsamic odour. The fat resembles mutton tallow in hardness and viscosity, has a sp. gr. of 0·915 at 15° and melts at 42°. It consists of 81 per cent. neutral fatty acid glycerides, and trioleïn; and 19 per cent. free fatty acids. The fatty acids separated from the products of saponification melt at 56·6°, solidify at 54·8°, and represent a mixture of oleic acid and solid fatty acids melting at 63·8°, and constituting 60 per cent. of the total weight of vegetable fat. D. B.

Action of Hydroxylamine Salts on Plants. By V. MEYER and E. SCHULZE (*Ber.*, 17, 1554—1558).—The position which hydroxylamine occupies between the two nitrogenous foods of plants, ammonia and nitric acid, and its great chemical activity as compared with the inertness of these food-stuffs, seem to point to a probable formation of hydroxylamine in the organisms of plants, and to its playing an important part in the assimilation of starchy and other matters and the formation of albuminoids.

With the view of throwing some light on this subject, the authors have made some experiments on nourishing maize and barley by means of artificially prepared food solutions. One solution contained in 1 litre, 0·25 gram $CaSO_4$, 0·25 gram $MgSO_4$, 0·5 gram KH_2PO_4, 0·15 gram NaCl, and 0·80 gram $Ca(NO_3)_2$, and a trace of ferric chloride. In the other solutions, the calcium nitrate was replaced by its equivalent proportion of ammonium sulphate, hydroxylamine hydrochloride, or hydroxylamine sulphate respectively. The plants throve well in the nitrate solution, moderately well in the ammoniacal solution, but very soon died in each of the hydroxylamine solutions. In pure water, they lived and put forth leaves long after those in the hydroxylamine solutions were dead. It is thus clear that hydroxylamine acts on plants as a poison, and this is confirmed by the fact that a very little hydroxylamine salt added to a solution of gelatin and to hay extract acted antiseptically, preventing the formation of mould, &c. It is still possible that hydroxylamine may be formed in plants as a transition-product and yet act as a poison when taken up by the roots, just as peptone acts as a poison when introduced into the veins of animals. L. T. T.

Importance of Silicic Acid in the Culture of Oats. By C. KREUZHAGE and E. WOLFF (*Landw. Versuchs-Stat.*, 30, 161—198).—The experiments described were carried out at the experimental station of Hohenheim in water culture, the silicic acid was obtained by treating chemically pure silica with warm caustic potash solution and neutralising the potash by free nitric acid previously added to a nutritive solution employed at Hohenheim in agricultural experiments—the silicic acid was thus left in a free state dissolved in the solution containing the other fertilising matters.

Three sets of experiments were made, one without silica, and the others with weak and strong solutions of silica.

The details are voluminous, but summarised show that the absorption of silica greatly assists the assimilation of other plant foods, and that plants to which it is supplied show a decidedly more healthy development of grain and straw than others not so treated. Previous experiments at the same station had shown that phosphoric acid acted in a similar way (assisting the assimilation of ordinary plant foods); the authors therefore ask the question if it is possible to replace phosphoric by silicic acid in the composition of artificial manures. Attempts in this direction have been made by manure manufacturers but without success, due, the authors think, to the use of the silica in an unsuitable form; its success depends greatly on its correct preparation, and extensive experiments are desirable; they should be made under normal agricultural conditions, experiments in water culture not being decisive, as plants absorb more nutriment from the solutions employed than if the same matters are applied in ordinary culture in earth.

The authors doubt the possibility of silicic acid replacing phosphoric in manures, but they look forward to a combination of both, which will yield excellent results in the culture of the Graminaceæ.

J. F.

Feeding Cattle on Lupines. By L. SEELING (*Bied. Centr.*, 1884, 273)—The author has been successful in feeding cattle with lupines freed from the bitter principle.

E. W. P.

Cultivation of Sugar Beet and other Roots. By MÄRCKER and others (*Bied. Centr.*, 1884, 262—271).—Märcker in his experiments found "Little Wanzlebener original" produced the heaviest yield of sugar per morgen, whilst "Dippe's Wanzlebener" had the highest quotient of purity. Scholz obtains most sugar from "Eigene Schlesische," but the highest quotient was from Little Wanzlebener in humous soil. F. Bastian grew roots on sandy loam and manured with dung, dung and super, and dung mixed with ammonium superphosphate; the heaviest crop of roots was produced by the last mixture, and the quotient of purity was also the highest, viz., 87. The analyses of roots made by Pagnoul are of interest, as they show that large quantities of salts and nitrates are retained in the ripened root; in the roots manured with dung, there was found of salts 1·066 per cent.; of nitrate 0·728; or referred to 100 parts of sugar, 24·12 and 16·47 respectively; this is the more interesting, as it shows the formation of nitrate when dung decomposes; the presence of salts causes a rapid development of leaves, which in their turn cause the nitrate which the plant when manured with nitre had absorbed to be decomposed. Pagnoul further experimented on the influence of light on the decomposition of nitre in the plant, by raising the plants under glass, some of which was transparent, the rest blackened. In the shade there was much more nitrate undecomposed, showing that the activity of leaf-growth was necessary for the proper decomposition of this compound; consequently, when the leaf-growth is rapid and ripening occurs early, the leaves produce sugar in those months when the days are long and the sky clear, whilst the late ripening kinds produce more sugar because the growth of the leaves is carried on into autumn when the weather is warm and moist.

B. Corenwinder grew beet in pots filled with sand to which manures containing no carbon in any form were added, also in pots containing carbonaceous manures, and in the field, with the result that the beet leaves were capable of obtaining all necessary carbon for their growth; in fact, the weight of the crop grown on the sand was very little less than that grown in the field, whilst the percentage of sugar was much higher. The other articles on the subject are of no chemical interest. E. W. P.

Researches on the Sugar-cane. By W. Knop (*Landw. Versuchs-Stat.*, 30, 277—287).—Several samples of sugar-cane which had been attacked by a fungoïd growth were sent to the author from Pernambuco: this disease has caused great injury to the plantations, but the author is unable to propose a remedy, and thinks the subject should be studied on the spot. The paper contains remarks of interest on the analysis of the cane, and of the soil on which it was grown, samples of which were also sent to him. The analyses Nos. 1 and 2 are of the ash of diseased canes, No. 3 of sound. The author considers that the differences do not exceed those observed in the ashes of other grasses at various stages of their growth.

	No. 1.	No. 2.	No. 3.
Silicic acid	34·5	32·7	38·8
Lime	2·5	7·5	4·0
Magnesia	6·8	14·1	7·5
Phosphoric acid	3·4	4·3	4·0
Sulphuric acid	3·4	3·3	3·2
Chlorine	12·3	9·6	10·6
Potash	36·7	28·0	30·3
Soda	0·4	0·5	1·6

He draws special attention to the large amount of potash present, more than sufficient to saturate the acids and chlorine, and leave a considerable surplus. Manganese and iron were present but in small quantities, and in presence of phosphoric acid were not estimated.

The soil consists of decomposed quartz and quartzite, containing iron and manganese; its mechanical condition showed a proportion of 53 per cent. of fine clay to 47 per cent. of different grades of sand and gravel. J. F.

Volume-weight of some Manures. By V. Magerstlin (*Bied. Centr.*, 1884, 281).

Manure.	1 hectol weighs	Max. of moisture absorbed after three days' exposure to moist air.	Volume increase, per cent.
	kilos.	kilos. per hectol.	
Potassium sulphate	128	0·66	5·0

E. W. P.

Report on Experiments on Manuring Grain. By Emmerling, Loges, and Metger (*Bied. Centr.*, 1884, 217—227).—These experiments, made in 1882, are a continuation of those made in 1880—81 (Abstr., 1881, 309; 1882, 333; 1884, 211). The season was good, although the harvesting suffered somewhat by storms; the manures included superphosphate, precipitated phosphate, blood, ammonia, &c. The results on the crops, barley, oats, on the different classes of soil in the neighbourhood of Kiel are fully given, as also the analyses of the soils. The experiments on marsh land show a loss when precipitated phosphates are used, because the superphosphate penetrates deeply, rapidly and more completely into such a soil than does the other manure. Ammonia in all cases brought an increase, but that increase was insufficient to pay for the extra cost; but as for Chili saltpetre there was, beside a gain in crops, also an increase sufficient to pay expenses. The combination of phosphate with ammonia always brought an increased yield, and although there was no direct financial gain, yet a sufficient quantity of manure was left in the soil for the succeeding crop, so saving something in the succeeding season. Chili saltpetre with phosphoric acid on loam and sandy loams gave excellent results, but when the soil was deficient in lime, the precipitated phosphates worked well. Finally, the authors show that in the loamy soils of Holstein the value of superphosphate compared with precipitated phosphate is 40 : 21 (eliminating the action of the nitrogen); in the previous season of 1880, which was bad, this value came out 40 : 22, the money ratio of the two being 40 : 32, consequently in such districts the former material is better than the latter. As regards bone meal and blood, it is only in those soils wanting lime that steamed bones take first rank. E. W. P.

Loss of Nitrogen by Organic Matters during Putrefaction. By A. MORGEN (*Landw. Versuchs-Stat.*, **30**, 199—216).—This subject has been studied by many chemists, and its importance to agriculture fully admitted. Different processes have been suggested to prevent the loss. Lawes and Gilbert proposed the addition of burned earth to the decaying substance, König and Kiesow of ordinary garden soil unburned, and the same experimenters recommended gypsum.

The author undertook a series of experiments on the subject, and arrived at the following conclusions:—The loss of nitrogen during putrefaction of nitrogenous organic substances is large and constant; its amount greatly depends on the mechanical condition of the substance; if loose, porous, and moist, it loses much more than if densely packed and moderately dry. The loss he attributes to a process of oxidation and nitrification, free nitrogen being set free simultaneously with the formation of nitrites and nitrates. As a preventative he tried the addition of clay, without success; 5 per cent. of gypsum diminished the loss very materially, but the greatest success was obtained by the use of 5—10 per cent. of kainite, which in all cases reduced the loss to a very small amount, and in some instances prevented any loss whatever. The reason that this result was obtained is not understood, but the author promises to investigate the matter.

J. F.

Retrogression of Superphosphates. By W. KNOP (*Landw. Versuchs-Stat.*, **30**, 287—291).—The author first draws attention to the discovery of Märcker, that samples of commercial superphosphate kept in glass-stoppered bottles do not retrograde, but that samples of the same in tin boxes show a gradual return from the soluble to the insoluble form. The general opinion is that the retrogression is due to the presence of salts of iron and alumina, but the author thinks there are other causes not yet fully investigated. In the preparation of a liquid fertiliser, consisting of a solution of calcium nitrate, potassium nitrate, and potassium phosphate, he found that after a time a pulverulent crystalline salt was deposited, which on analysis he found to be bibasic calcium phosphate, with variable amounts of combined water. Two specimens very carefully prepared were of the following composition:—

Sample A .... $Ca_2H_2P_2O_8 + H_2O$.
Sample B .... $Ca_2H_2P_2O_8$. J. F.

Analytical Chemistry.

An Indicator. By A. GAWALOWSKI (*Bied. Centr.*, 1884, 286).—A mixture of an alcoholic solution of phenophthalein with dimethylaniline orange is recommended as indicator in alkalimetry or acidimetry. The mixture is lemon-yellow when quite neutral, whilst when acid it is rose-red; when alkaline, deep-red. E. W. P.

Analysis of Volatile Organic Sulphur-compounds. By V. MEYER and O. STADLER (*Ber.*, **17**, 1576—1577).—In the estimation of nitrogen in volatile compounds containing sulphur by Dumas' method, great care must be taken to carry on the combustion *very slowly*. If burned at all quickly, carbonic oxide is evolved, probably formed by the reduction of carbonic anhydride by sulphurous acid in the presence of heated metallic copper. A very volatile substance containing a large percentage of sulphur was analysed to ascertain whether nitrogen was also present, when the authors obtained a considerable quantity of permanent gas; this, however, was found to be carbonic oxide, and not nitrogen. Satisfactory results were obtained on performing the combustion very slowly. L. T. T.

Examination of H. Grouven's Method of Nitrogen Estimation. By U. KREUSLER and H. LANDOLT (*Landw. Versuchs-Stat.*, **30**, 245—271).—This new method (Abstr., 1883, 1028) is said to have many advantages over other processes, especially in analyses of manures and agricultural products. The Prussian Ministry of Agriculture appointed the authors to fully examine the method, and this paper is their report. They purchased two sets of apparatus from the holders of the patent, and carried out two sets of experiments, one at the Experimental Station of Poppelsdorf, the other at the Agricultural High School in Berlin, where the personal supervision of Dr. Grouven was in many cases available. It is unnecessary to say that the experiments were conducted with every precaution to ensure impartiality. In those at Poppelsdorf the results were controlled by the soda-lime process and sometimes volumetrically; those in Berlin were made with substances from the laboratory, previously carefully analysed or of known composition.

The details of each experiment are given; but the results were all unfavourable to the new method, and the reporters say that it requires numerous precautions, and in the end does not easily yield correct results. They admit that the apparatus is thoughtfully constructed, and that the principle of burning the substances in a current of superheated steam is good, but in its present state it is not likely to supersede other and better known methods. J. F.

Detection and Estimation of Ammonia in Animal Liquids. By J. LATSCHENBERGER (*Monatsh. Chem.*, **5**, 129—154).—Numerous methods have been devised for the estimation of ammonia in animal liquids, but so far with very inaccurate results. The author, as the result of a long investigation of many different processes, recommends the following method :—20 c.c. of a cold saturated solution of cupric sulphate is placed in a beaker of about 120 c.c. capacity, weighed, 20 c.c. of the liquid under investigation added, and the whole again weighed. The mixture is then carefully neutralised with baryta-water, washed into a litre flask, and water added to make up a litre. The liquid after filtration should be perfectly clear and colourless. The amount of ammonia in the liquid is now determined colorimetrically by means of Nessler's solution; a standard solution of ammonium chloride whose strength = 0·01 mgrm. of NH_3 per c.c. being used for comparison. The results obtained show a very close agreement. The following table gives the mean results obtained :—

Liquid employed.	Per cent. of NH_3.
Human urine, sp. gr., 1·021......	0·05550
Dog's urine, sp. gr., 1·018	0·08038
Cow's milk....................	0·02106
Ox blood......................	0·00781
Ox gall	0·00283

A. J. G.

Apparatus for the Estimation of Carbonic Anhydride. By R. Baur (*J. pr. Chem.* [2], 29, 489—493).—The author claims that by means of the apparatus which has been patented in Germany he has obtained a quick and, for technical purposes, correct method of estimating carbonic anhydride volumetrically. A drawing of the apparatus is appended to the paper.

The apparatus consists of two parts, the generator and the gas-measuring tube. The generator is a bottle in which the carbonate is placed, together with a bulb containing acid. This bottle is connected by an india-rubber tube and a three-ways stopcock to the measuring tube. This stopcock allows of direct communication between the two parts, or between the air and either or both of the two parts. The calibrated measuring tube is placed vertically in a cylinder; the top is drawn out and, passing through an india-rubber stopper fixed on the top of the cylinder, is attached to the three-ways stopcock. The lower end is open, and by means of a cork support is fixed in the lower part of the cylinder, which is slightly restricted for the purpose. The stopper at the top of the cylinder is fitted with a funnel for admitting liquid into the space between the cylinder and the measuring tube, and the bottom is also closed with an india-rubber stopper and fitted with a stopcock. The author uses a liquid for filling the cylinder and measuring tube which absorbs very little carbonic acid, but he does not mention what this liquid is.

The process consists, after the apparatus has been proved to be air-tight, in filling the cylinder and measuring tube through the funnel with the liquid up to the zero mark, and at the same time preserving atmospheric pressure in both parts of the apparatus by means of the three-ways stopcock. The connection with the air is then closed, but made between the two parts of the apparatus, and the acid is poured on the weighed carbonate in the generator. As the carbonic anhydride is generated the liquid sinks in the measuring tube, and to keep the pressure constant is run out by opening the stopcock at the bottom of the outer cylinder. To withdraw the carbonic acid dissolved in the liquid in the generator, the pressure in it is diminished for a time by continuing to withdraw the liquid from the outer cylinder. The level of the liquid in the two tubes is afterwards restored by pouring sufficient liquid in at the top of the outer tube, and the amount of carbonic anhydride read off, and correction made for atmospheric pressure and temperature. The form of the apparatus prevents rapid change of temperature, and by withdrawing the carbonic anhydride from the liquid in the generator, the absorption coefficient may for technical purposes be neglected. A. B.

Estimation of Morphine in Opium. By v. PERGER (*J. pr. Chem.* [2], **29**, 97—110).—The author has carefully examined the methods in ordinary use for the estimation of morphine in opium, as to their relative accuracy, making analyses of the same sample of opium by each method, and finds that they give most variable results. The methods in common use are Godeffroy's, Austrian Pharmacopœia, and Merk's.

Godeffroy's method is as follows:—10 grams of dry opium powder are mixed with 25 c.c. of hot water, and then pressed between folds of linen, this operation being repeated until the water is no longer coloured. The liquid is then boiled two or three times with 8 to 10 grams of slaked lime and filtered; ammonium chloride is added to the filtrate until after standing it smells of ammonia. The morphine crystallises out after 12—24 hours, and can be estimated by collecting it on a tared filter and washing it with dilute ammonia.

The Austrian Pharmacopœia method is as follows:—10 grams of dry powdered opium are treated with 90 grams of a mixture consisting of 110 grams of distilled water and 40 grams of hydrochloric acid (12·2 per cent.). The residue remaining after filtering and washing is weighed. If the opium be good, it should not exceed 4·5 grams. The filtrate is mixed with 20 grams of powdered sodium chloride, and allowed to remain for 24 hours in the cold. The precipitate is then collected and washed with a saturated solution of sodic chloride. The filtrate is treated with ammonia and allowed to stand for 12 hours. The morphine which crystallises out is separated by decantation, collected on a filter, and washed with as small a quantity of distilled water as possible; it is then dried in a porcelain basin, and treated with an equal weight of a mixture consisting of equal weights of acetic acid (20·4 per cent.) and water. After adding water, the liquid is filtered. The filtrate should not exceed 70—80 grams. An excess of ammonia is added to it, and it is allowed to remain for 12 hours, when the precipitate is collected and weighed. The weight should exceed 1 gram.

H. Merk's method is as follows:—15 grams of opium are cut up and boiled with 100 grams of 45 per cent. alcohol. The extract is separated from the residue by filtration, and the latter is again treated with 100 grams of alcohol; 8 grams of crystallised soda are added to the solution, and it is evaporated without stirring. The residue is treated with 60 grams of cold water, and decanted into a glass cylinder; the clear liquid is poured off, and the undissolved portion washed again with 30 grams of cold water, and then with 45 grams of alcohol (90 per cent.), and finally collected. The crystalline mass remaining on the filter is dried between filter-paper, dissolved in 15 grams of acetic acid (1 part of acid sp. gr. 1·06 to 8 parts of water) and 15 grams of distilled water, and then filtered through the same paper on which the residue was collected. The filtrate is treated with ammonia, and the precipitate is collected and weighed after standing for 12 hours.

The author has devised the following method:—10 to 20 grams of the opium to be examined are boiled for a short time with 15 to 30 grams of caustic baryta and about 150 to 200 c.c. water. The mixture is then filtered, and the residue repeatedly boiled with small quantities of water until the solution fails to give a reaction with molybdic acid and sulphuric acid. Excessive boiling is to be avoided, and as a rule the filtrate should not amount to more than 400—500 c.c. A stream of carbonic anhydride is passed into this solution, which contains all the morphine, until the liquid is supersaturated, and then the whole is evaporated on a water-bath as quickly as possible. The residue is moistened with absolute alcohol, transferred to an Erlenmeyer's flask, and exhausted with successive quantities of boiling absolute alcohol until a sample evaporated on a watch-glass no longer gives a morphine reaction. This usually requires from 300 to 400 c.c. alcohol. The alcohol is removed by distillation, and the residue left in the flask is allowed to stand for some time with 15 c.c. of ammonia. It is next collected on a tared filter, dried at 40°, and treated repeatedly with chloroform. This is the crude morphine. It should be light-brown to straw-coloured. Crude morphine generally contains substances which can be classed under two heads, namely, (1) those which are insoluble in acetic acid; (2) those which are soluble, but which are reprecipitated by ammonia and potassium ferrocyanide. The author finds that the amount of the impurities is always small, and that the difference between the crude and the pure morphine is principally due to the loss of morphine in the process of purification. The following table gives the percentages of morphine found by employing the various methods. The impure products are marked thus *.

Percentage of Morphine.

Examination of Sugar-beet and Sugar. By F. STROHMER and others (*Bied. Centr.*, 1884, 277—279).—For the estimation of sugar in *pure* aqueous solutions only, Abbe's refractometer is recommended; in the original paper tables are given to assist the necessary calculations.

Kohlrausch reports on a new observation tube for saccharimeters introduced by Schmitt and Hänsch; this novelty tends greatly to the exactitude of the polarisation method. Sostmann makes some remarks on the method described by him (Abstr., 1883, 782), for in the earlier part of the season the old method of estimating the sugar in the juice by the polariscope gives higher results than his own when alcohol is used; but as the season advances the difference between the two methods becomes less and less: this must be due to the removal of non-saccharine matters by ripening, which disturbs the polarisation by the old method. E. W. P.

Amount of Fatty Acids in Butter. By REICHARDT (*Arch. Pharm.* [3], **22**, 93—102).—Hehner, Turner, and the author have shown that not more than 88 per cent. of solid fatty acids are contained in butter fat. Vegetable oils and animal fats contain 93·8—95·87 per cent. of solid fatty acids. Fleischmann and Vieth found 85·79—89·73 per cent., but accepted Hehner's maximum of 88 per cent.; Kretschmar, by a slight variation of the method, has obtained 89 and 90 per cent.

Reichert's method (*Arch. Pharm.*, 1879, 163; *Zeitschr. Anal. Chem.*, 1879, 68) of determining the volatile fatty acids affords a much better criterion, since 2·5 grams of butter contain volatile acids equivalent to 14·0 ± 0·45 c.c. of decinormal caustic soda solution, whilst cocoanut oil requires 3·70 c.c., and lard, &c., less than 1 c.c. The above method has been modified in its details by Meissl (*Arch. Pharm.*, 1879, 215, 531), who gives 13·5 c.c. as the lowest limit, and finds that soft butters contain more volatile acids than do harder butters. This method has been again modified by Munier (Abstr., 1882, 247), who found that much less alkali was required, viz., 9·2 to 12·4 c.c., and that the amount, moreover, varies with the season. Ambuhl has obtained numbers confirming Meissl and Reichert's results. In a series of 43 experiments extending from December to the end of October, it is shown that no such variation either in the amount of solid acids or of fatty acids occurs, the numbers obtained being 87·0 to 88·0, mean 87·6, and 13·8 to 14·7, mean 14·16; the animals during this time received very various fodder, and hence the conclusion that neither season nor feeding perceptibly influences the ratio of solid fatty acids to volatile acids. Recent experiments by Birnbaum, and other numerous determinations, have confirmed the numbers given by Reichert and Hehner; Munier's results are not confirmed. H. B.

Researches on Milk and Milk-analysis. By H. VOGEL and others (*Bied. Centr.*, 1884, 273—276).—Vogel recommends the use of the Müller-Soxhlet lactodensimeter when estimating the specific gravity. The dry matter and fat should be estimated by weighing in iron boats half filled with sand, and enclosed in closed glass cylinders fitted with stoppers; after evaporation the boats should be again weighed in the cylinders; when the fat is to be determined, it is extracted by ether from the sand, &c., wrapped up in filter-paper; the results thus obtained coincide well with those obtained by using Soxhlet's areometer. In legal cases, the lactodensimeter graduated to 29° is recommended; in cases of watering and creaming the Feser lactoscope is useful. G. Dangers recounts the police regulations in Celle; amongst them we find that the sp. gr. at 15° must lie between 1·029 and 1·033, and the fat must not be less than 2·8 per cent.; the sp. gr. of skim-milk must exceed 1·033; milk under 1·027 is to be considered as watered. Wolff finds Liebermann's method (*Zeitschr. Anal. Chem.*, 1883, 383) unsatisfactory, and amends it by adding to the 50 c.c. of milk 3 c.c. potash solution, 54 c.c. ether, and then evaporating 20 c.c. of the ethereal solution of the fat. Small additions of water are frequently detected by Uppelmann by testing for nitrates, &c., which may be in the bad water added. He proceeds thus: the caseïn in 350 c.c. milk is precipitated by acetic acid, 100 c.c. of the clear filtrate are then boiled with 3 drops of hydrochloric acid, cooled, and filtered. Of this filtrate 50 c.c. are employed for estimating ammonia by distillation and Nessler's reagent; whilst in the remainder nitrates and nitrites are to be detected by diamidobenzene, zinc iodide, starch, and diphenylamine.

E. W. P.

Iodine Extraction. (*Dingl. polyt. J.*, **253**, 48.)—The process formerly employed in Antofagasta of treating the Caliche mother-liquors with sodium hydrogen sulphite did not extract more than 70 per cent. of the iodine present (*Dingl. polyt. J.*, **231**, 375). Loire and Weissflog first reduce the sodium iodate with calcium sulphide, and precipitate the sodium iodide with copper sulphate and sodium sulphite. The calcium sulphide is produced by igniting calcium sulphate with coal in a rotating furnace. After complete reduction of the iodate, copper sulphate and sodium sulphite are added:—$2NaI + 2CuSO_4 + Na_2SO_3 + H_2O = Cu_2I_2 + 2NaSO_4 + Na_2SO_4$. The precipitated cuprous iodide is washed and dried. J. T.

Purification of Gas Liquor. (*Dingl. polyt. J.*, **252**, 411.)—Kunheim and Co. propose to remove the ammonium sulphide contained in gas liquor by allowing a powerful and finely divided current of air to act on the crude gas liquor, the ammonium sulphide being split up into hydrogen sulphide and ammonia. The former is passed through finely divided ferric hydroxide suspended in a dilute solution of alkaline earths. D. B.

Working up Gas Liquor and Gas Purification Residues. (*Dingl. polyt. J.*, **252**, 476—479.)—In order to obtain the whole of the ammonia contained in gas liquor as ammonium carbonate, Seidler distils the liquor with addition of limestone, dolomite, or similar carbonates. The non-volatile ammonium salts are decomposed thus: $2NH_4.CNS + CaCO_3 = (NH_4)_2CO_3 + Ca(CNS)_2$. The ammonium carbonate contains a small amount of ammonium sulphide. It is therefore treated in a concentrated aqueous solution with carbonic anhydride, the precipitated ammonium bicarbonate being separated from the mother-liquor and converted into ordinary ammonium carbonate by sublimation. The carbonic anhydride given off during the sublimation is passed into fresh portions of ammonium carbonate solution, whilst the mother-liquor is treated with sulphuric acid and worked up into ammonium sulphate.

For the recovery of ferrocyanides from gas purification residues, Kunheim and Zimmermann desulphurise the liquors in the usual manner, and remove the soluble ammonium salts by washing with water. The product is then mixed intimately with caustic lime and heated in closed agitators at 40—100°. Thus the fixed ammonia salts are decomposed, their ammonia being passed into sulphuric acid, whilst a solution of calcium ferrocyanide is obtained. The latter is converted into ferric ferrocyanide (Prussian blue) by precipitation with a proto-salt of iron and subsequent oxidation. If it be desired to obtain potassium ferrocyanide from the liquors, potassium and calcium ferrocyanide is first prepared by evaporating the liquors and adding the quantity of potassium chloride necessary to form the double salt: on boiling the latter with a solution of potassium carbonate, it is converted into potassium ferrocyanide. The advantage of this process is the saving of potassium carbonate, only half the requisite quantity being used, the remaining half being supplied by potassium chloride, a less valuable salt of potassium. D. B.

Loss of Nitre in the Manufacture of Sulphuric Acid. By G. Eschellmann (*Dingl. polyt. J.*, **252**, 431—434).—The loss of nitre in the manufacture of sulphuric acid is of two kinds, first mechanical loss, such as nitrous acid kept in solution by sulphuric acid, nitrous acid escaping unabsorbed at the Gay-Lussac tower and through leakage of the chambers; secondly, chemical loss through reduction of nitrous gases to nitrous oxide and nitrogen. To trace out these losses, the author has made a series of experiments on the chambers in Muspratt's works at Widnes. The mechanical loss at the Glover tower is in the acid used for the manufacture of salt-cake; this, as well as the loss through leakage of the chambers, is very slight. The Glover acid, by analysis, showed only traces of nitrous anhydride. The mechanical loss by non-absorption at the Gay-Lussac tower was determined by drawing the gases with a water-pump through concentrated sulphuric acid, then through caustic soda, and finally through potassium permanganate, to absorb nitric oxide. The sulphuric acid was tested in the nitrometer, the permanganate was reduced with a solution of a proto-salt of iron, then boiled with a known weight of iron solution, and titrated back with permanganate. Simultaneously, a second test was taken by means of an aspirator, the gases not absorbed by caustic soda being tested for oxygen. These analyses were performed daily, the following table giving average results for several quarters :—

	Cubic metres of chamber space per kilo. S.	Nitre used per cent. on S.	Oxygen at outlet per cent.	Unabsorbed nitric oxides soluble in H_2SO_4 per cent. total loss of $NaNO_3$.
		First System.		
Quarter I ..	1·34	3·24	6·0	10·70
Quarter II ..	1·47	2·75	7·0	11·50
		Second System.		
Quarter I ..	1·34	3·24	6·1	12·02
Quarter II ..	1·47	2·75	7·0	12·50

The Gay-Lussac towers belonging to these systems represented 1·6 per cent. of the total chamber space, the strength of the nitrous liquors being 1 per cent. N_2O_5. The loss through escape of nitric oxide at the Gay-Lussac tower amounted to 7 per cent. of the total. The mechanical loss is represented by the following percentages :—

1. Glover acid, traces (below 1 per cent.)
2. Gay-Lussac tower } as N_2O_3 12 per cent.
   19 per cent. } as NO 7 „
3. Leakage, &c............ 2 „

From the results obtained by Lunge and Naef, the author infers that the best way to avoid loss of nitre is to have all gases leaving the system of chambers in the form of nitrous anhydride, and to prevent the presence of nitric oxide or tetroxide in the gases. The author further shows that an increase of steam by one-third raises the temperature by 2·6°, the variation of temperature caused by variation of steam is therefore very slight, and depends mainly on the energy of the chemical reaction, that is, on the quantity of sulphuric acid formed. Experiments were made with two systems of chambers. The first system received a continuous supply of nitrous liquors, and therefore showed no variation of temperature, whilst the second system was fed with periodical supplies at intervals of two hours, the temperature varying between 48° and 68°, this variation repeating itself regularly after each addition. It appears to be more advantageous, therefore, to have a continuous supply of nitrous gas entering the chamber.

Lunge has shown that on mixing sulphurous anhydride, air, water, and nitric oxide, considerable quantities of nitrous oxide are formed. These conditions are fulfilled in the chambers at the inlet of the steam. It being impossible to analytically determine nitrous oxide, the author tried to find out whether, in the manufacture of very weak acid (114° Tw. = $SO_3 + 4H_2O$ instead of $3H_2O$) an increase in the loss of nitre through increased reduction took place in the first chamber. The temperature, perfectly constant under ordinary conditions, rose at once 3°, after which it began to fall to 46°, which fall took 48 hours, so that nitre had to be introduced, the same fall of temperature repeating itself. During the 96 hours the experiment lasted, the extra nitre used weighed 30 kilos., representing 10½ per cent. of the total loss of nitre (2·76 per cent). This is the loss through reduction in the production of $SO_3 + 4H_2O$ instead of $SO_3 + 3H_2O$. Assuming that the same amount is reduced for the first three equivalents of water, 31·5 per cent. of the total nitre is lost through reduction.

In conclusion, it is stated that there has always been much difference of opinion as to the amount of oxygen in the chamber exit gases. According to the author, it depends greatly on the available chamber space, the following table giving the results of working chambers with different spaces:—

Chamber space, cubic metres per kilo. S.	Oxygen per cent. per vol.	Loss of nitre per cent. on sulphur.
1·0	4·5—5·0	4·0
1·1	5·0—5·5	3·7
1·2	5·5—6 0	3·5
1·3	6·0—6·5	3·1
1·4	6·5—7·0	2·8

Working the chambers much higher in oxygen increases the loss of sulphurous anhydride considerably, whilst when the oxygen is reduced, a greater quantity of extra nitre has to be used. The total loss of nitre (2·75 per cent.) may be apportioned as follows:—

	Percentage on S.		Percentage of total loss.	
Gay-Lussac tower ..	0·330 p. c.	=	12 p. c.	as nitrous gases soluble [in H_2SO_4.
„ „ ..	0·192 „	=	7 „	as NO.
Glover tower, leakage, &c.	0·082 „	=	3·0 „	
	0·866 „	=	31·5 „	reduced by the steam.
	1·470 „	=	53·5 „	accounted for.
	1·280 „	=	46·5 „	unaccounted for.

D. B.

Strontium Hydroxide. (*Dingl. polyt. J.*, **253**, 82—84.)—C. F. Claus proposes to obtain strontium hydroxide from the chloride by the addition of an equivalent of barium hydroxide to the hot solution. Strontium hydroxide crystallises out, and barium chloride is obtained by evaporation and crystallisation. Similarly, Claus prepares strontium hydroxide from the sulphide or sulphydrate by adding to the hot sulphide solution an equivalent of barium hydroxide. Further, if to a hot solution of strontium sulphide a solution of barium sulphide be added in equivalent quantity, strontium hydroxide is formed, and crystallises out on cooling, whilst barium sulphydrate remains in solution. It is advisable to employ an excess of strontium compound to avoid contamination of the product with baryta. On mixing hot solutions of sodium sulphide and strontium sulphide, a similar reaction takes place. By evaporating solutions of barium sulphydrate and sodium sulphydrate, mixing with coal-dust, igniting gently, and lixiviating, solutions of barium sulphide and sodium sulphide, respectively, are obtained, which can be again employed. Mother-liquors containing strontium sulphydrate, when evaporated and ignited with coal-dust, give strontium hydroxide on lixiviation with hot water. The mother-liquor, after the separation of the crystals, consists of strontium sulphydrate, and is treated in a similar manner until all the strontium is obtained as hydroxide. If the solution of strontium sulphydrate is treated with an equivalent of sodium sulphate, a precipitate of strontium sulphate is formed, which can be filtered off, mixed with coal-dust, and ignited like fresh celestine. The ignited mass, when extracted with water, gives strontium hydroxide. Strontium sulphydrate can also be decomposed by magnesium sulphate. Strontium carbonate is obtained from a solution of the sulphydrate by adding an equivalent of magnesium chloride, boiling to expel hydrogen sulphide, and then passing into the solution carbonic anhydride, by which strontium carbonate is precipitated and magnesium chloride is reformed. Hot furnace gases, deprived of free oxygen, can be used for this purpose.

To obtain zinc sulphide and strontium hydroxide, Claus treats calamine with ammonia solution, precipitates zinc sulphide by means of potassium sulphide, and distils off the ammonia from the solution. The potassium carbonate remaining in solution is rendered caustic by means of lime, and treated with a hot solution of strontium sulphide. On cooling, strontium hydroxide falls out, and the potassium sulphide can be used over again to precipitate fresh zinc solution.

J. T.

Process for Working up Strontium Sulphate. (*Dingl. polyt. J.*, **252**, 332.)—Urquhart and Rowell treat native strontium sulphate (cœlestine) with sulphuric acid to remove the greater portion of the iron and alumina. The product is then boiled with a mixed solution of sodium sulphate and sodium carbonate. The resulting mixture of strontium sulphate and carbonate is heated in a furnace with an excess of sodium carbonate, and on lixiviating the melt with hot water strontium carbonate is obtained, together with the liquor used for the first treatment of the strontium sulphate. D. B.

Cement and its Adulteration. (*Dingl. polyt. J.*, **253**, 426—431.)—This paper is an abstract from the report of the general meeting of the German Society of Cement Manufacturers, held in February 1884. The question in regard to the adulteration of Portland cement with less valuable substances was again discussed. Böhme stated that in his experiments on the influence of additions to mixed

cements, he never experienced an increase in the tenacity as against that of unadulterated cement; moreover, the bearing qualities of mixed cements are less than those of unmixed cement. Dyckerhoff experimented in a similar direction. His results, which are tabulated in the original paper, clearly demonstrate the injurious effect of additions on the tenacity and durability of Portland cement.

Fresenius has undertaken a series of experiments on Portland cement at the request of the above Society. He obtained twelve samples of pure cement from different parts of Germany, England, and France, and these were compared with three kinds of hydraulic lime, three of weathered slag-dust, and two of ground slag. The results are illustrated by the table, p. 1225.

The numbers in the case of pure Portland cement should be as follows:—(1), sp. gr. at least 3·125, not lower than 3·1; (2), loss on ignition between 0·34 and 2·59 per cent., or at least not much higher; (3), alkalinity of aqueous solution of 0·5 gram of cement, corresponding to 4 to 6·25 c.c. of decinormal acid; (4), volume of normal acid neutralised by 1 gram of the cement 18·80 to 21·67 c.c.; (5), weight of potassium permanganate reduced by 1 gram of cement between 0 79 and 2·80 mgrms., or at least not much higher; (6), weight of carbonic anhydride absorbed by 3 grams of cement 0 to 1·8 mgrms. The tests, I, III, IV, and V, are applicable for the detection of slag, and I, II, III, and VI, for the detection of hydraulic lime. Experiments were made by mixing 9 parts of pure Portland cement with 1 part of hydraulic lime, with 1 part of slag-dust, and with 1 part of ground slag respectively, and it was found that the adulteration could in every case be detected by the determinations given above.

D. B.

Process for the Recovery of Slag. (*Dingl. polyt. J.*, **252**, 528.) —Frank (Ger. Pat. 27,106, September, 1883) utilises a solution of magnesium chloride of 1·06 sp. gr. for dissolving sulphuretted and phosphoretted slags. The fluid mass is poured into this solution, the sulphides and sulphites contained in the slag being decomposed; whilst the combined lime present in the basic slag is converted into calcium chloride, and thus indirectly effects a concentration and facilitates the solution of the phosphates contained in the slag.

D. B.

Formation and Employment of Slags. (*Dingl. polyt. J.*, **253**, 163—173; 204—206)—G. Hilgenstock finds that no phosphorus is carried away by the waste gases of the blast furnaces. The phosphorus is usually introduced as iron or calcium phosphate, and as the presence of iron induces the reduction even of earthy phosphates by carbon, it may be accepted that the whole of the reduced phosphorus is reduced only on account of its great affinity for iron, and forms iron phosphide.

Finkener has shown (*ibid.*, **249**, 264) that tribasic iron phosphate, heated in a stream of hydrogen, first gives steam at a clear red heat, and at a white heat hydrogen phosphide and phosphorus are produced; but the reaction is not very probable in a blast furnace where the hydrogen from the moisture introduced by the blast is so dilute, and the amount of phosphate is so small. The less reducing agent is present, and the lower the temperature, the more phosphoric acid goes into the slag. The analyses of 23 successive runnings of highly phosphoric pig show the following limits:—

P....	3·26 per cent.	Si....	1·03	C....	2·01
,,....	12·12 ,,	,,....	0·02	,,....	0·87

so that, other things being equal, silicon and carbon diminish as phosphorus increases. Carbonic oxide, at high temperatures, is more stable than silica or phosphoric acid, and silica is more stable than phosphoric acid. It is not the phosphorus as such which replaces the carbon and silicon, but the phosphoric acid, at whose expense silicon and carbon are oxidised. If the oxygen of the phosphoric acid be not present, that is, if an iron rich in phosphorus be fused with one rich in silicon or in carbon, the whole amount of the three elements is found in the alloy. Iron rich in phosphorus, with 0·8 per cent. carbon and no silicon, is exceedingly fluid when fused. The amount of phosphorus that may be retained by iron appears to be unlimited, as in the case of manganese. One sample contained 25·65 per cent. The iron becomes more and more brittle, and the fracture crystalline, similar to that of ferromanganese. Such iron also becomes less and less affected by the magnet. Iron with 9·6 per cent. phosphorus is sensibly less magnetic than ordinary iron. With 16 per cent., a powerful magnet had only slight action, whilst with 25·6 per cent. the action was scarcely perceptible.

A. Ledebur considers fluid slags as solutions of various oxygen compounds in one another, whose constituents can arrange themselves in various groups during cooling. Analyses are given of slags which had been slowly and rapidly cooled; but the differences in composition are too slight to account for physical differences. It is noticeable that slag cooled quickly is rapidly and almost completely decomposed by hydrochloric acid, whilst that cooled slowly resists the action of the acid very strongly.

The richer a pig iron is in carbon, silicon, and manganese, and the higher the furnace temperature is, so much the less iron goes into the slag. The lower the temperature, the more manganese goes into the slag. If the temperature be higher and the fuel applied be more than is required to reduce all the manganese in the charge, then silicon is reduced. Grey pig is formed when the amount of manganese present is not sufficient to prevent the formation of graphite induced by the silicon, or in presence of much manganese a silicon-iron-manganese alloy is formed. Owing to the higher temperature in the Bessemer process, the affinity of carbon for oxygen is considerably increased as compared with the puddling process. As long as carbon is present in the bath, the amount of iron in the slag will be less than in puddling furnace slag. When the carbon has disappeared, the slag is still poorer in iron, owing to the action of the iron in the slag on the converter lining. The higher the temperature and the richer the iron is in manganese, the less iron goes into the slag. Continued blowing after the carbon has been removed increases the proportion of iron in the slag; but if, on the other hand, the burning of certain substances, as phosphorus in the basic process, increases the final temperature, and also increases the amount of slag, the proportion of iron is diminished thereby.

In the Siemens-Martin process, the temperature is high and the furnace lining is siliceous, so that the slag must contain considerably more silica and less iron than in the older refining processes for producing wrought iron. On the whole, the slags range between the same limits as Bessemer slags do. A detailed account is given of the working of two baths in this process The silica in the slag always increases with the manganese, and with the temperature at which the charge has been worked, whilst the amount of iron falls as the temperature has been higher, and as the manganese and carbon of the iron have been higher.

L. Garnier has applied blast furnace slag as a preventive of phylloxera in vineyards with advantage: this is attributed to the sulpher present in the slag.

R. Hasenclever describes Scheibler's method of treating basic slags (this vol., p. 783). The slag is roasted, treated with steam, and free lime removed as milk of lime by washing with water. The residue is then treated with hydrochloric acid in suitable quantity, about 1·25 to 1·5 kilos. of acid to 1 kilo. of slag. The solution separated from the insoluble residue is now precipitated by means of the milk of lime previously obtained. The dicalcium phosphate can be directly applied for agricultural purposes. The calcium phosphate can easily be obtained containing 35—37 per cent. of phosphoric acid.

Potassium Ferrate and Manganate.—B. Platz found a deposit in a blown-out blast furnace, reaching down to the boshes, about 0·6 m. thick, consisting of a slaggy mass of grey to black colour. In water it gave a deep-red solution of potassium ferrate. Minute black needle-shaped crystals were visible in the cavities of the mass; also a bluish-green crust of potassium manganate covered some of the fragments. Two samples of the deposit had the following composition:—

Fe_2O_3	13·72	7·83
FeO	24·75	12·77
MnO..........	0·46	0·92
SiO_2..........	11·98	6·66
Al_2O_3	6·72	3·10
CaO	33·02	59·62
MgO..........	1·27	1·41
CaS	1·35	1·37
	93·27	93·66

The remainder was mainly alkaline carbonates and sulphates.

J. T.

Utilisation of Metallic Slags rich in Phosphorus. (*Dingl. polyt. J.*, **253**, 135—136.)—Rocour, in a supplementary patent, modifies his plan for treating such slags. By a reducing fusion in a blast furnace, a regulus is obtained containing 20—20·5 per cent. phosphorus. The powdered regulus is mixed with finely-divided anhydrous sodium sulphate, say 3—7 parts to each part of phosphorus in the regulus, and the mixture is heated to redness in a flame as little oxidising as possible; a large portion of the phosphorus becomes converted into sodium phosphate with development of heat; whilst a portion of the iron and manganese becomes converted into phosphate, sulphide, and oxide. The mass, when treated with water, gives a solution of sodium phosphate. If the insoluble residue contains a considerable amount of iron and manganese phosphate, it is dried, powdered, and heated with sodium sulphate and coal-dust. On heating the mixture to redness in a reducing flame, the sulphate becomes sulphide, and, at a high temperature, sodium phosphate is formed, the iron and manganese becoming converted into sulphide. After washing out the soluble sodium phosphate, the residue can be roasted free from sulphur, and may be used as a manganiferous iron ore. The procedure is rapid, but the reactions are not very complete, so that a considerable amount of phosphorus remains insoluble. Instead of sodium sulphate, soda or potash may be used; also nitrates of these bases. The phosphorus regulus can also be blown in a basic-lined converter, with gradual addition of lime or dolomite. A basic slag, relatively poor in iron and manganese, is obtained, which is sufficiently rich to serve as manure, or may be used for the production of superphosphate. The metals may be converted into steel in the same heat. J. T.

Earthenware Enamels. (*Dingl. polyt. J.*, 252, 374—379.)—Heinecke gives an account of experiments made with different glazes, from which the following conclusions may be drawn: Alumina glass, composed of several flux radicles, is more transparent than glass of a similar character, but containing less flux radicles. Glaze composed of materials which yield glass with great difficulty, should contain a larger proportion of silicic acid than glaze formed from more readily fusible substances, to prevent their decomposition by the action of the clay mass at an elevated temperature, or of the atmosphere at the ordinary temperature. A certain amount of boric acid prevents the devitrification of the glaze by the bases of the clay substance. Acid alumina enamels are less subject to devitrification than enamels containing a smaller amount of acid and alumina. Calcareous enamels do not adhere firmly to clay masses, when they contain a large percentage of lime, such as the Velten clay masses.

Schumacher attributes the cause of the severance of the enamel from the clay substance to a tension between them, occasioned mainly by the presence of a large amount of silicic acid.

Seger discusses, at some length, the influence of sulphuric acid on glazes. The formation of blisters on porcelain is due to the presence of sulphuric acid, or sulphates in the composition of the enamel, or in the water employed for making it up. D. B.

Extraction of Metals by Electricity. (*Dingl. polyt. J.*, 253, 32—33.)—R. P. Hermann treats zinc ores with acids, and precipitates the metal electrolytically, after converting it into a double alkaline, or alkaline earthy salt.

M. Kiliani proposes to extract calamine, zinc-ash, &c., with ammoniacal liquor containing carbonate, and then to precipitate electrolytically, employing iron anodes.

M. Body recommends mixing the powdered ore with ferric salts alone, or with the addition of common salt, by which advantage is taken of the property of ferric salts to pass into the ferrous state in the presence of metallic oxides or sulphides, under the influence of an electric current. This change leads to the solution and precipitation of the metal, subsequently the ferrous salt can be readily converted into the ferric state, and is again ready for use. The finely powdered mineral is exposed, in moist heaps, to the action of the air, and repeatedly ground. The ore may then be placed in a tank provided with a bottom of pressed coke, in which is embedded the negative pole of a dynamo, whilst the other pole is connected with the ore at one or more points.

In treating certain ores of gold and silver, a cast-iron drum is employed, which is connected with the negative pole of a dynamo, and is slowly revolved. Within the drum are several cast-iron balls. Through the drum, and isolated from it, passes a fixed axle, which is connected with the positive pole of the machine, and which carries a series of coke or graphite plates dipping into a solution of ferric salts containing the mineral. The axle is hollow, and serves for the introduction of liquid to the drum; a steam pipe, terminating within the liquid, also passes through it. When the silver is reduced, mercury is passed into the drum, and the amalgam is collected in the ordinary way. The method is advantageous for ores which contain only 0·05 per cent. of silver. J. T.

Improvements in Metallurgy. (*Dingl. polyt. J.*, **252**, 515—519.) —For the preparation of aluminium, and alloys of aluminium, Weldon fuses cryolite with calcium chloride, or other non-metallic chloride, or sulphide, and reduces the resulting aluminium chloride, or sulphide, with manganese, to which sodium may be added.

Frishmuth proposes to heat ignited bauxite, or corundum, in retorts, to the temperature of volatilisation. The ascending fumes of alumina are brought into contact with the vapour of sodium, the resulting aluminium being obtained in the form of a fine dust, which is made into balls by fusion with fluxes.

Niewerth mixes ferrosilicon with aluminium fluoride in equivalent proportions, and fuses the mixture, the products being volatile silicon fluoride and an alloy of iron and aluminium. In order to prepare aluminium-bronze therefrom, the alloy is fused with copper. By substituting aluminium chloride for the pure aluminium fluoride, silicon chloride and an alloy of aluminium and iron are said to be formed; pure silicon is said to yield pure aluminium with aluminium chloride.

To extract metals from certain ores, burnt pyrites, slag, &c., Föhr employs a weak solution of magnesium, calcium, or sodium chloride, with or without the application of heat. The main portion of copper, lead, and similar metals, are dissolved. The lixiviated ore is then treated with bromine-water in the dark, which dissolves the gold completely and the silver partially, all metallic sulphides of copper, lead, zinc, &c., being decomposed. Finally the ore is again treated with the above chloride liquor, when the silver and lead are completely removed.

Lipp and Schneider give the following analyses of iron: I, charcoal pig iron from Hieflau in Styria; II, grey pig iron from Witkowitz in Moravia; III, the same from Rokycau in Bohemia; IV, grey pig iron; V, steel; VI, steel plate, all three from Neuberg in Styria; and VII, "Kudsiver Normalstahl."

II.	68·363	28·181	0·986	trace	0·233	0·008	trace	1·882

The method adopted by Lipp and Schneider for conducting these analyses is briefly described in the original paper. D. B.

Preparation of Magnesium. By J. WALTER (*Dingl. polyt. J.*, **252**, 337—339).—The author has made a series of experiments in order to determine whether Marquardt's suggestion to prepare magnesium by distilling magnesia with coal in zinc furnaces is practicable. According to the views upheld by Weldon, this reduction would be impossible, as in this case the same thermochemical relations which stand for aluminium are applicable. By the combustion of magnesium 74,900 cal. are liberated, according to the equation Mg + O = MgO.

The reduction would be effected in accordance with the equation $2MgO + C = 2Mg + CO_2$, which requires 2 × 74,900 = 149,800 cal. (whilst the heat of formation of carbonic anhydride only amounts to 97,000 cal.), or according to the equation $MgO + C = Mg + CO$, which requires 74,900 cal., the combination of $C + O = CO$, yielding only 29,000 cal. These numbers do not however correspond with the conclusion drawn therefrom, viz., that the reduction of an oxide only takes place when the heat of combination of the element with oxygen is less than that of the reducing agent with oxygen. Weldon explains this contradiction by supposing that, in the case of aluminium, the reduction of sodium from its carbonate, by means of carbon, depends on a preliminary process of dissociation. Fischer, on the other hand, shows that the decomposition of steam by carbon occurs at 300—350°, a temperature at which steam could not undergo dissociation.

In order to obtain the requisite temperatures, the author made use of Perrot's gas furnace. In the first series of trials, the temperature employed was a bright red heat, magnesium in the form of oxide, carbonate, and tartrate, being used, whilst in the second series of experiments, the same materials were exposed to an extreme white heat. Although the conditions were more favourable than in the case of zinc furnaces, the author failed to obtain reduced magnesium.

D. B.

White Lead Manufacture. (*Dingl. polyt. J.*, **252**, 372—374.)—Roth and Sylvester propose to pass an electric current through a solution of sodium acetate, using lead plates as poles. Lead acetate is said to be formed at the positive pole, whilst free sodium hydroxide is produced at the negative pole, the mixture of the two resulting in the precipitation of lead hydroxide, which is converted into white lead by the introduction of carbonic anhydride.

Gardner recommends to heat lead with graphite, carbon, plati[illegible], or similar substances (all of which should be electronegative to lead) in a solution consisting of 1 part lead acetate, or 1 part nitric acid, in 40 parts water, or acetic acid in 24 parts water. Basic lead salts, or lead oxide, or lead suboxide, is said to be produced. After the lapse of one to two hours, the lead is taken out of the solution, and the latter on addition of acetic acid, or nitric acid, used for a further operation. If the conversion of the lead is effected in chambers, the metal is brought into contact with carbon or platinum, according to various modes of arrangement. Ozonised air is introduced into the chamber, or produced therein by electric discharges. D. B.

Manufacture of Cuprammonium and Zincammonium Compounds, and their Technical Application. By C. R. A. Wright (*Dingl. polyt. J.*, **253**, 37—38, from *Jour. Soc. Chem. Industry*, 1884, 121).—During the past few years, many attempts have been made to utilize on a manufacturing scale the power possessed by cuprammonium and zincammonium solutions of pectising cellulose and similar substances, so as to produce a kind of vegetable parchment. The process consists essentially in the preparation of a concentrated solution of cuprammonium hydroxide, and the passing of the goods to be treated through a bath of this material at just such a rate as will permit of the pectising and gelatinising of the exterior of the fibres composing the paper or canvas, &c., without wholly disintegrating the mass; so that the material on emerging from the bath retains coherence enough to enable it to be passed through the usual drying apparatus of a paper-mill. This drying converts the film of pectised cellulose coating each filament into an insoluble solid varnish. In order to build up thick cards, two or more layers of paper are passed simultaneously through the bath, and then pressed together and dried as a whole. By careful treatment, the copper present in the solution taken up by the material is wholly converted during the drying into a compound with the pectised cellulose. Mineral acids dissolve out the copper. Instead of cuprammonium hydroxide alone, in certain cases a mixture of this with zincammonium hydroxide may be used. The pectised cellulose then contains both zinc and copper, indicating apparently that a zinc cellulose compound has also been formed. Zincammonium hydroxide alone, however, does not pectise paper sufficiently to give good results. Cuprammonium salts give less satisfactory results than the hydroxide. The solution employed contains from 100 to 150 grams ammonia and 20 to 25 grams of copper per litre; this is prepared by the action of ammonia solution on copper turnings in the presence of a current of air. Brass turnings give the zinc-copper compound. Zinc alone is only slightly attacked under these conditions. The presence of iron accelerates the solvent action. Pure cuprammonium solution has absolutely no effect on iron.

Experiments made to ascertain the amount of ammonia carried off from an aqueous solution by a current of air showed that in dissolving 11·4 kilos. (25 lbs.) of copper in ammonia solution (150 grams NH_3 in 1 litre), 2 to 9 kilos (5 to 20 lbs.) ammonia, according to the temperature, were removed. In practice, this ammonia is recovered in the form of a weak copper solution. The solubility of the copper diminishes gradually as the liquid becomes richer in that metal. Also when the solution is proceeding most rapidly only a small portion of oxygen passed into the solution is absorbed. When the concentration of the copper solution does not exceed 12 to 15 grams per litre, it is very stable; such a solution is well adapted for the preservation of sleepers and timbers generally. J. T.

Extraction of Cobalt and Manganese from their Ores. (*Dingl. polyt. J.*, **252**, 392.)—Herrenschmidt and Constable treat ores containing cobalt or manganese with ferrous sulphate and enough water to form a paste; the iron salt is said to react on the oxides of cobalt and manganese contained in the ores; on boiling the mixture a solution of cobaltous or manganous sulphate is obtained, which is separated from the residue and treated with a suitable agent, so as to convert the proto-salt into the corresponding per-salt.

D. B.

Absorption of Carbonic Anhydride by Beer. By T. LANGER (*Bied. Centr.*, 1884, 286).—The amount of gas which beer will absorb is dependent on the temperature and on the pressure, for at 0—5° with constant pressure the amount present = 0·01 weight per cent. = 50 c.c. per litre for every 1°; and the same increase is observable when the temperature remains constant, but the pressure increases 31·3 mm. mercury. Strong beer absorbs a larger volume of gas than weak beer, other things being equal. Water mixed with alcohol absorbs less gas than water alone, and the reducing effect of alcohol on absorption increases within limits with the increase of alcohol, and more especially is this remarked at low temperatures; yet, for all this, 1 litre beer can absorb more carbonic anhydride than the same quantity of water at the same temperature.

E. W. P.

Date-sugar. (*Bied. Centr.*, 1884, 284.)—Date-sugar is obtained from the palm by making incisions in the lower branches, and collecting the sap which flows nearly continuously from November up to March; the sap is then clarified and boiled down. E. W. P.

Manufacture of Starch. By C. SCHAUB (*Bied. Centr.*, 1884, 285). When the yield of potato-starch is low, it arises from one of three causes—(1) low quality of potatoes; (2) the potatoes, although good, may, by reason of a deficiency of water, not yield up all the starch they contain, and this is frequently the case, especially in small factories; (3) potatoes and supply of water being good, the machinery may work ineffectively. The author mentions additions to the machinery which should be made. E. W. P.

Bleaching Yarns and Fabrics. (*Dingl. polyt. J.*, **252**, 392.)—Thomson and Rückman (Ger. Pat., 26,839, March, 1883) boil linen yarns and fabrics for three hours in a solution containing 2·4 grams potassium cyanide in a litre of water, wash, and repeat this treatment. For cotton, this operation may be omitted, unless the material has been brought in contact with fatty or oily substances, in which case the above solution is used in a more dilute form (half the strength). The fabric thus prepared is placed in closed vessels, and treated with a solution of chloride of lime containing 5·3 grams per litre. As soon as the vessel is full, the solution is drawn off, and carbonic anhydride passed in. This operation is repeated until the fabric assumes the desired degree of whiteness. It is then taken out, washed in water, and pressed. In most cases a slight yellow tinge is retained within the fabric, owing to the presence of traces of iron in the bleaching agent. To remove this coloration, the fabric is drawn through a bath of oxalic acid (about 4·6 grams per gallon), washed with water, pressed, and toned with indigo or aniline violet.

Gaseous Chlorine as Discharge in Calico-printing. By A. SCHEURER (*Dingl. polyt. J.*, **253**, 208—211).—In his handbook on calico-printing, J. Persoz has pointed out that indigo-blue can be discharged by gaseous chlorine; chlorine in the dry state attacks indigo slowly, but in the presence of water the action is rapid. Experiments, however, show that the practical application of the proposal is difficult, as the goods must be exposed to the gas for at least two minutes, and in this time the dry blue colour is sensibly affected. The following is a means of reducing the time of exposure required: a piece moistened with weak soda-lye had its blue colour discharged with only 10 seconds' exposure to chlorine; a lye of about 16—17° B. is most suitable. Turkey-red thus treated became yellow in 20 seconds, and white in 50 seconds. Aniline black is destroyed immediately. A mixture of aniline oil and soda-lye, printed and exposed to chlorine, causes the formation of an intense black compound which contains chlorine, whilst a solution of aniline salt alone under similar conditions gives a lively chamois-yellow of very stable character, which is not destroyed by prolonged exposure to chlorine. If on the contrary a drop of soda-lye be placed on the dye, and it be again exposed to chlorine, the colour is then discharged. Hypochlorites, even when concentrated, do not act rapidly on indigo. Free hypochlorous acid acts like chlorine in the presence of soda. This acid cannot act in the free state in this reaction, since free alkali is present; and in fact after the colour has been discharged by chlorine in the presence of soda, the piece has an alkaline reaction. The active agent is apparently oxygen as hydroxyl, $2NaHO + 2Cl = 2NaCl + 2HO$ and $2HO = H_2O + O$. J. T.

Kephir. By H. Struve (*Ber.*, **17**, 1364—1368).—Kephir is a variety of fermented milk prepared in the Caucasus, the use of which for medicinal purposes has in the last two years spread over a great part of Russia. It is prepared from milk by fermentation with the so-called kephir-grains in leather bottles. During the fermentation, a considerable quantity of the ferment is produced: it is removed, dried in the sun, and preserved to effect fresh fermentations. An analysis of kephir-grains dried at 100° gave—

Water	11·21
Fat	3·99
Soluble peptone-like substances	10·98
Proteids soluble in ammonia	10·22
,, ,, potash	30·39
Insoluble residue	33·11

Microscopic examination of the insoluble residue showed it to consist of a mixture of yeast cells with Kern's "*Bacterium dispora caucasica.*" In a few cases, *Lepthothrix* and *Oidium lactis* were also observed. The whole of the active matter of the ferment was contained in the insoluble residue. From fermentation experiments made by the author, it appears that the yeast-cells alone are essential to the fermentation, the *Bacterium dispora caucasica* taking no part whatever in the action. The yeast-cells have been modified to a certain extent by having grown in contact with the leather of the bottles, and thus rendered capable of exciting the peculiar kephir-fermentation. A. J. G.

Improvements in the Manufacture of Sugar. (*Dingler*, **252**, 287—293.)—Steffen's defecation process for obtaining sugar from molasses is conducted in the following manner:—Molasses or syrups are diluted with cold water in vessels fitted with agitators. The temperature of the solution should not exceed 35°, and its concentration should correspond with 6—12 per cent. of sugar. A known quantity of this solution is run into a vessel provided with an agitator and treated with from 50 to 100 parts of powdered lime to each 100 of sugar, to form calcium saccharate. The mixture is passed through filter-presses and the solution of calcium saccharate collected in suitable vessels; to 100 parts of sugar contained in this filtrate, about 65 parts of lime are then added for the separation of the insoluble saccharate, which is washed and decomposed in the usual way.

To facilitate the use of half-shadow saccharometers, Allary, instead of illuminating the polarising apparatus, proposes to enclose it in a black paper cylinder, the circular opening of which is covered with translucent yellow paper or with yellow glass. The observer covers his head and the whole apparatus with a black cloth and places the tube in the direction of a light wall. The reading of the degrees is effected in daylight.

Stuckenberg (Ger. Pat., 25.218, May, 1883) has found that in the production of strontia-sugar from molasses by Scheibler's process, the excess of strontium hydroxide necessary to effect the separation of strontium disaccharate acts essentially as free alkali. Since strontium disaccharate is almost insoluble in alkaline solutions, the excess of strontium hydroxide may be replaced by potassium or sodium hydroxide. D. B.

Adulteration of Verdigris. By M. ASTRE (*J. Pharm.* [5], 7, 386—388).—The author has found that a commercial specimen of verdigris was adulterated to the extent of about 10 per cent. with a siliceous earth coloured by Prussian blue. W. R. D.

Abridged Process for Turkey-red Dyeing and Printing with Alizarin. By A. MÜLLER (*Dingler*, 252, 219).—It is known that a number of the volatile organic ammonia bases produce precipitates with alkyl radicles, alumina (and tin), and saline solutions, which dissolve in an excess of the precipitant, for instance, mono-, di-, and tri-ethylamine, butyl- and amyl-amine, and di- and tri-amines. The author utilised this property experimentally in order to combine the mordanting of the fabric with oil and alumina in one operation, whereby the chalk-bath necessary at other times is omitted, the fabric being ready to receive the alizarin after it has been dried and the base removed by volatilisation. A clear saturated solution of aluminium hydroxide in 10 per cent. ethylamine was treated with about 15 per cent. Turkey-red oil neutralised with ethylamine. The fabric after being boiled and dried was treated with the clear mordant and dried at the ordinary temperature. It was then dyed with alizarin and soaped, a bright red colour being obtained.

The author is of opinion that if it were possible to prepare ammonias of the above type cheaply on a large scale, the success of this method would be established, especially if the volatile bases employed could be recovered by some suitable arrangement. D. B.

General and Physical Chemistry.

Infra-red Radiation Spectra of Metallic Vapours. By H. BECQUEREL (*Compt. rend.*. **99**, 374—376).—The metals were volatilised in the electric arc, and the spectra, obtained by means of a Rutherford's grating or a carbon bisulphide prism, were projected on a screen covered with some phosphorescent substance (Abstr., 1883, 761). A table is given showing the wave-lengths of a number of lines in the infra-red spectra of potassium, sodium, strontium, calcium, magnesium, aluminium, zinc, cadmium, lead, thallium, bismuth, silver, and tin. C. H. B.

Chemical Action of Light. By D. AMATO (*Gazzetta*, **14**, 57—72).—The author has long held the opinion that many reactions which are said to take place through the direct action of light are not due entirely to that cause, but that light acts only under certain determinate conditions of temperature; consequently, there are limits of temperature within which light does not act in this way. In support of this opinion, the author has made numerous experiments, which are given in detail in the paper.

It is usually stated in text-books that light acts on liquid hydrogen phosphide, and decomposes it into solid and gaseous hydrogen phosphides. The author found, however, that inflammable gaseous hydrogen phosphide (containing liquid phosphide) loses its property of taking fire spontaneously on contact with the air, if kept over water *in the dark* for 24 hours at a temperature of 10—12°, whilst the same gas confined over mercury remains unchanged. It was proved that this decomposition is due to the oxygen dissolved in the water. At a temperature of 29°, and exposed to diffused light, gas confined over mercury was decomposed with deposition of solid hydrogen phosphide, whilst the same gas, if kept at 10°, was not decomposed, even when exposed to the brilliant July sunlight of Italy. In another experiment, in which the gas was exposed to the full heat of the sun (39°), whilst the light was completely excluded by a black varnish (made with glue and lampblack), the gas was not acted on. From this it would seem that neither the most brilliant sunshine (at temperatures below 10°) or heating to a temperature of 39°, are individually capable of effecting the decomposition of liquid hydrogen phosphide, but that this takes place readily by the joint action of sunlight and heat.

Similar experiments were made with a mixture of chlorine and hydrogen, and it was found that, if cooled to —12°, it could be exposed to the direct rays of the sun for hours without combination taking place. Care, however, must be taken that the chlorine is not exposed to the sun's rays even for an instant *before cooling*, as insolation renders chlorine capable of combining with hydrogen even in the dark. At a temperature of 39°, there is no action if light is excluded.

Silver chloride, if cooled to −12°, is not acted on by the direct solar rays, but if allowed to get warm, decomposition begins immediately. Paternò has also observed that chlorine and ethylene do not combine in diffused light if the temperature is low, or only very slowly.

Another substance which is usually supposed to undergo decomposition on exposure to light is Fehling's test. The author finds, however, that this change is due to dust from the atmosphere, and the fact of keeping the bottle containing the solution wrapped up in paper and in a cupboard preserves it, merely inasmuch as it keeps it comparatively free from dust. If the solution be boiled in a narrow-necked flask for some hours, and after being allowed to settle, the clear liquor is decanted into a clean well-stoppered bottle, it may be exposed for any length of time to the direct rays of the sun without undergoing any change. In order to ensure success, the bottle should be rinsed out successively with permanganate solution and distilled water before introducing the Fehling's test. In order to prove that the dust in the air is the cause of decomposition, two samples prepared as above were taken, and through one of them a current of air from the laboratory was passed previously to closing the bottle. After exposure to light for a year, cuprous oxide was deposited in the solution contaminated with dust from the air, whilst the other remained unchanged.

The author has also noticed that solutions prepared in the ordinary way, after being kept for some time—a year or more—yield an abundant deposit of cuprous oxide if cautiously neutralised with sulphuric acid, and this even in the cold, but more readily when heated. A solution recently prepared, or one treated in the manner above described, does not behave in this way.

From these experiments the author concludes that—at all events for the substances above mentioned—light acts only under certain conditions as to temperature, and heat only under the influence of light, and that neither of them acts in the absence of the other.

C. E. G.

Electricity of Flames. By J. Elster and H. Geitel (*Ann. Phys. Chem.*, **22**, 123—127).—This paper is a reply to a communication of Kollert's on the same subject (this vol., 651). The authors think that Kollert has overlooked the results of their investigation on "The Development of Electricity by the Contact of Gases with Incandescent Bodies" (*Ann. Phys. Chem.* [2], **19**, 558), by which they show that the so-called electricity of flames is merely a special case of a much more general class of phenomena, namely, that gases in contact with any incandescent substances become positively electrified. Thus the stratum of air surrounding the flame has a positive charge, which in Kollert's mode of experimentation affects the indications of the electrometer, which also are liable to be modified by the electrical condition of the air of the room. The present paper gives determinations made by the author's arrangement of the electrodes after the air of the apartment had been electrified to a high potential, sometimes positively and sometimes negatively, by means of an electrical machine. The observed value of the flame potential was independent of this condition and nearly constant, having a mean of 0·65 Daniell. A flame is regarded by the authors as merely a current of heated gas, which negatively electrifies the incandescent bodies in contact with it, or the incandescent particles it may contain.

A New Cell founded on the Oxidation of Carbon in the Cold. By A. Bartoli and G. Papasogli (*Gazzetta*, **14**, 85—90).—The authors allude to their experiments on the electrolysis of different liquids, using carbon electrodes, in which the latter were attacked, giving rise to organic compounds, such as mellic and hydromellic acids, mellogen, &c. (Abstr., 1882 and 1883). From thermochemical considerations, they were led to determine the electromotive force of different varieties of carbon in contact with platinum and gold; and the results of these measurements were so favourable, that they were enabled to construct a cell, somewhat feeble, but still sufficiently constant to be used for several months for working electric bells.

Experiments were made with electrodes of gold or platinum, and gas-carbon, charcoal, or graphite, using sulphuric, hydrochloric, acetic, nitric, and chromic acids; also solutions of sulphates, nitrates, chromates, and permanganate, and in all cases the electromotive force was appreciable. The carbons employed were rather long, only about one quarter of their length being immersed in the liquid, and every care was taken to guard against polarisation currents.

With solutions of sodium or potassium hydroxide, sp. gr. 1·1 to 1·3, platinum and different specimens of gas-carbon and charcoal, the electromotive force varied from 0 06 to 0·17 Daniell, after 24 hours' immersion. With solutions of sodium and potassium carbonate, the electromotive force was feeble, but amounted to 0·10 to 0·17 Daniell if the carbons had been previously saturated with a solution of the hydroxide.

Strong solutions of sodium hypochlorite, made by decomposing "chloride of lime" with sodium carbonate, gave an electromotive force equivalent to 0·4 to 0·5 Daniell after 24 hours' immersion. With graphite, it was rather less. Gas-carbon *by itself* is not attacked even by concentrated solutions of alkaline hypochlorites, but the action commences immediately if contact is made with a plate of platinum or gold immersed in the liquid. Arc-light carbons were entirely disintegrated and destroyed in a month's time, the solution becoming deep yellow, and containing mellic acid and other benzenecarboxylic acids. Calcium hypochlorite gives similar results, but the electromotive force is less, varying from 0·10 to 0·20 Daniell.

The influence of temperature on the cell was also studied in a gold | gas-carbon element, with sodium hypochlorite: the electromotive force varied from 0·18 to 0·27 Daniell, as the temperature was raised from 14° to 100°.

By modifying the conditions, surrounding the platinum pole with a solution properly chosen, and separated from the hypochlorite by a porous septum, the authors have arranged a cell which remains practically constant for months.

C. E. G.

Battery with Carbon Electrodes. By D. Tommasi and Radiguet (*Compt. rend.*, **99**, 129—130). — This battery consists of a rectangular porcelain cell, on the bottom of which is placed a carbon plate surrounded by a paste of lead peroxide, which constitutes the positive pole. Above this is another plate of carbon, on the upper surface of which are placed pieces of gas-carbon, the two plates being separated by parchment paper, which divides the cell into two compartments. A small quantity of a saturated solution of common salt is poured into each of the compartments in such a way that the lead peroxide is not disintegrated, and the fragments of gas-carbon on the second plate are only partially covered. The electromotive force of the pile is 0·6 volt, and is not sensibly altered by the substitution of a solution of ammonium sulphate or chloride, or sodium sulphate, or even dilute sulphuric acid, for the sodium chloride. C. H. B.

Galvanic Batteries for the Electric Light. By I. Probert (*Dingl. polyt. J.*, **253**, 252).—From a comparison of the cost of producing the electric light by means of dynamo-machines and galvanic batteries, the author infers that for working the light on a large scale, galvanic (primary) batteries have no prospect of success. A reduction in the cost of batteries suitable for the illumination of houses may be possible in four directions:—(1) by substituting cheaper metals for zinc, *e.g.*, lead or iron; (2) by employing hydrochloric acid in the place of sulphuric acid; (3) by completely exhausting the solution; and (4) by recovering valuable bye-products.

In referring to primary batteries, the author states that Holmes and Burke's element consists of eight cells filled with sodium nitrate dissolved in dilute sulphuric acid. It is provided with a syphon arrangement for filling and emptying the cells and conducting the gaseous products to a vessel, where they are dissolved or absorbed. The hydrogen decomposes the sodium nitrate, sodium sulphate and nitric acid being formed. The electrodes are carbon and amalgamated zinc. In Ross's element each cell contains two carbon plates, which are placed in dilute hydrochloric acid. To the latter a substance called "eureka" is added, the composition of which is kept secret. In the Edco or Heap battery, zinc carbons and potassium dichromate are the depolarisers, and dilute sulphuric acid is the exciting agent. The cells are lined with lead, their capacity being equal to 6·75 litres (1·5 galls.). The cost of the solution amounts to one shilling per gallon. The zinc plates are 254 mm. long and 152 mm. wide, and weigh 1·36 kilos. The E.M.F. is equal to 2 volts and the resistance 0·2 ohm. The zinc plates in Oliphant, Burr, and Gowan's battery are coated with a thin film of gold before amalgamation, whereby a diminution in the local action is said to be effected. D. B.

Conversion of Liquid Batteries into Dry Piles. By Onimus (*Compt. rend.*, **98**, 1577—1578).—Batteries containing solution of ammonium chloride, zinc chloride, &c., may be converted into dry piles by mixing these solutions with plaster of Paris and allowing the mixture to solidify. If mixtures of ferric oxide or manganese peroxide with plaster of Paris are employed, the electromotive force is slightly higher than with plaster of Paris alone, and when ferric oxide is used the battery quickly regains its original electromotive force when the circuit is broken. When the battery is exhausted the solid plaster is simply again moistened with the solution.

C. H. B.

Electrolysis of Solid Glass. By E. Warburg (*Ann. Phys. Chem.*, 21, 622—646).—When calcium sodium glass is submitted to electrolysis at a temperature of 300° between electrodes of mercury, a badly conducting film of SiO_2 separates at the anode, and in a short time reduces the intensity of the current to a small fraction of its original value. This film has a greater or less thickness according as a greater or less electromotive force has been in operation for a given time. It acts like the dielectric of a condenser between plates, one of which is the conducting part of the glass and the other the mercury of the anode. The capacity of this condenser is independent of the difference of potential between its conducting surfaces, and it varies from 1 to 20 B.E. But when sodium amalgam is substituted for the mercury at the anode, the same weight of sodium is taken up by the glass as is liberated at the kathode, so that the weight of the glass remains unchanged, and its transparency and other properties are not perceptibly affected by the electrolysis. R. R.

Electrical Conductivity of Distilled Water and of Ice. By G. Foussereau (*Compt. rend.*, 99, 80—82).—The specific resistance of distilled water at 15° was found to vary between 118,900 ohms and 712,500 ohms, the maximum being obtained with water which had been redistilled two or three times in a platinum apparatus. The resistance of water kept in a glass vessel at about 15° diminishes by about one-thirtieth after 24 hours, owing to the solvent action of the water, and the diminution is very much more rapid at higher temperatures. If the water is kept in platinum vessels exposed to the air, its resistance diminishes slowly, owing to the solution of the small quantity of salts and acid vapours present in the atmosphere. Carbonic acid has but little effect on the conductivity. In many cases the resistance of distilled water is affected by small quantities of dissolved substances carried over during distillation.

The variation in the resistance of distilled water with the temperature between 0° and 21° is represented with great accuracy by Poiseuille's formula for the variation of the internal friction, $1 + at + bt^2$, or, in other words, the resistance of distilled water is proportional, within certain limits, to the coefficient of internal friction.

The resistance of water becomes 15,000 times greater at the moment of congelation, the specific resistance of ice varying between 4865 megohms at $-1°$, and 53,540 meghoms at $-17°$. The resistance of ice shows variations corresponding with the resistance of the water from which it was formed. C. H. B.

Electrical Conductivity of Dilute Solutions. By E. Bouty (*Compt. rend.*, 99, 30—32).—Many organic substances do not sensibly diminish the resistance of distilled water, whilst even those which are the best conductors have a resistance from 50 to 200 times as great as that of neutral salts.

Anhydrous acids and alkalis are non-conductors; hydrated acids and alkalis conduct in the same manner as salts.

Organic alkalis in dilute aqueous solution have a resistance 600 to 800 times as high as that of salts; and ammonia, which forms no definite compound with water, has a resistance 110 times as great as that of salts. On the other hand, potassium, sodium, barium, calcium, lithium, and thallium hydroxides are good conductors. The ratio of the resistance of a solution of potassium hydroxide to that of an equivalent solution of potassium chloride, for example, is about 0·4, but the ratio is higher the more dilute the solution.

An aqueous solution of arsenious anhydride is practically a non-conductor, and solutions of carbonic anhydride and hydrogen sulphide have a resistance far higher than that of salts. None of these substances form definite compounds with water. A solution of sulphurous anhydride at 20°, on the other hand, has a resistance only 2·33 times as great as that of an equivalent solution of potassium chloride. The conductivity of the acid solution decreases much less than that of the salt solution when cooled down to 0°, probably owing to the formation of a further quantity of a hydrate. The resistance of dilute solutions of sulphuric acid varies in a complex manner with the degree of dilution, but is never more than about one-third of the resistance of an equivalent salt solution. The different inorganic and organic acids furnish every degree of conductivity between the non-conductor arsenious anhydride and the good conductor sulphuric acid. Boric acid and pyrogallol have a resistance as high as arsenious oxide, whilst nitric, hydrochloric, and picric acids conduct almost as well as sulphuric acid. C. H. B.

Compounds obtained by Means of Gas Batteries and the Silent Discharge. By A. Figuier (*Compt. rend.*, **98**, 1575—1577).—The apparatus employed consisted of two hollow graphite cylinders closed at one end, and coated internally with spongy metal or spongy carbon so as to prevent polarisation. These cylinders were supported by a lid which closed hermetically the vessel containing the liquid conductor, the latter being alkaline when the product of the reaction was acid, and *vice versâ*. In some cases the gases were subjected to the silent discharge before being placed in the battery. The compounds produced are formed in contact with the poles, and in greater abundance at the positive pole. Although the current produced may be very feeble, the energy of the reaction may be relatively large. In the following table the substance placed second constituted the positive pole:—

Air and sulphurous anhydride	produce	sulphuric anhydride.
Hydrogen and chlorine	„	hydrochloric acid.
Oxygen and chlorine	„	chloric acid.
Nitrogen and oxygen	„	nitric anhydride.
Hydrogen and nitrogen	„	ammonia.

Carbonic oxide and sodium carbonate	produce	sodium oxalate and formate.
Ethylene and oxygen	„	formic and acetic acids.
Hydrogen and carbonic anhydride	„	formic and acetic acids.
Methane and carbonic anhydride	„	acetic acid.

The ozonisers employed were provided with armatures coated with platinum black, and were so arranged that their temperature could be raised. Under the influence of the discharge oxygen combines directly with sulphur, selenium, chlorine, iodine, and bromine, but has no action on tellurium. Hydrogen combines with sulphur, selenium, ordinary phosphorus, and nitrogen, but has no action on tellurium, arsenic, antimony, and red phosphorus. Oxygen oxidises formic acid and formates, carbonic oxide combines with hydroxides, &c.

C. H. B.

Action of the Induction Spark on Benzene, Toluene, and Aniline. By A. DESTREM (*Compt. rend.*, **99**, 138).—The spark from a coil of moderate size worked by three Bunsen cells was passed into the liquids between platinum points placed very close together, and the gaseous products of decomposition were collected and analysed:—

Benzene yields acetylene 42—43; hydrogen 57—58 = 100.
Toluene „ „ 23—24; „ 76—77 = 100.
Aniline „ „ 21; hydrogen, 65; hydrocyanic acid, 9; nitrogen, 5 = 100.

Carbon is also liberated in a bulky form, that from the aniline being considerably more dense than that from the other two compounds. Benzene and toluene yield some diphenyl and a brown-red compound soluble in the hydrocarbons. C. H. B.

New Method of directly Measuring Absolute Magnetic Intensity. By A. LEDUC (*Compt. rend.*, **99**, 186—187).—A modified form of the manometer of Lippmann's galvanometer (this vol., p. 881) is employed. A current of from 1 to 3 ampères is passed through the manometer, and the latter is placed in the magnetic field, the intensity of which is measured by the rise or fall of the mercury in the arm of the manometer. C. H. B.

Magnetism of Organic Bodies. By S. WLEÜGEL and S. HENRICHSEN (*Ann. Phys. Chem.*, **22**, 121—123).—The authors have examined the magnetism of compounds of the C_nH_{2n+1} alcohol radicals. The results show that the molecular magnetism is increased by a nearly constant amount for each CH_2 in the compound, and that it is equal to the sum of the partial magnetism of the alcohol radicals and that of the remaining parts of the compound. In the compounds the specific magnetism is nearly the same for OH, I, Br, and S, but for Cl it is much greater. Propyl alcohol and isopropyl alcohol show exactly the same value, whilst isobutyl alcohol has the value found by calculation for butyl alcohol. For H in alcohol radicals, the value − 780·5 is found, whereas C has only − 5·6. The latter value is so insignificant compared with the former, that the observed results agree nearly as well with C = 0, H = − 807·6. R. R.

Specific Heat of Mellite. By A. BARTOLI and E. STRACCIATI (*Gazzetta*, **14**, 105—114).—Three well-crystallised examples of mellite were examined: the first, from Bohemia, had a sp. gr. of 1·60; the second, from Artern in Thuringia, was of sp. gr. 1·57, and the third from Malanka in the Urals, of sp. gr. 1·59. The results of the analysis in each case corresponded with the formula $C_{12}Al_2O_{12} + 18H_2O$. The specific heat of the specimens was determined between the temperatures of 80° and 0° in three several ways: namely, with Bunsen's calorimeter, with a water calorimeter, and by Kopp's method. Full details of the experiments are given, and the results tabulated. The mean of the results is as follows:—

Bohemian mellite, by Bunsen's calorimeter, between 0° and 79° = 0·33005.
Bohemian mellite, by the water calorimeter, between 47° and 79° = 0·32816.
Thuringian mellite between 25° and 79° = 0·33155.
Uralian mellite between 27° and 79° = 0·33489.
Mellite by Kopp's method between 15·5° and 69° = 0·33592.

The mean of all these gives the number 0·33211.

By means of Person's formula (*Gazzetta*, **8**, 429), the approximate value 0 20958 is deduced for the specific heat of anhydrous mellite, $C_{12}Al_2O_{12}$. C. E. G.

Thermal Effect of Mixing Liquids. By KONOVALOFF (*Bull. Soc. Chim.*, **41**, 340).—The thermal effect of mixing liquids depends on the cohesive energy of each liquid, indicated by the heat of vaporisation and on the degree of disaggregation, that is to say, upon the relative quantities of the two liquids. This view is confirmed by the existence of liquids which, when mixed, give rise either to an absorption or evolution of heat depending on their relative quantities. The former effect ensues in the solution of a liquid of great cohesive energy. The author agrees with the statement of Dossios, that solution may be regarded as the result of a strain between the force of molecular cohesion of homogeneous and heterogeneous liquids, but does not attribute an absolute character to the cohesive force.

W. R. D.

Thermal Effect of Solution. By ALEXÉEFF (*Bull. Soc. Chim.*, **41**, 256).—In the case of liquids, solubility is always attended with an absorption of heat if the substances do not react with each other. Solution is thermally distinguished from mixture by the fact that in the latter instance thermal absorption reaches the maximum when the liquids are present in equal proportions. Thus aniline with

5 per cent. of benzene = − 26 5 cal.
32 „ „ = − 154 „
48·4 „ „ = − 182 „
77 „ „ = − 145 „
91 „ „ = − 51 „

But when solution occurs the amount of heat absorbed increases as the quantity of substance dissolved becomes greater. Thus the solution of 1·85 parts of aniline in 100 parts of water is equal to — 5 cal., and when the quantity of aniline is raised to 97·01 parts the thermal effect is equal to — 228 cal. W. R. D.

Displacement of Chlorine by Bromine in Silver Chloride. By T. S. HUMPIDGE (*Ber.*, **17**, 1838—1839).—Before becoming acquainted with Potilitzin's work on this subject (this vol., 955), the author had observed a displacement of chlorine by bromine in silver chloride even at the ordinary temperature. Freshly precipitated and well washed silver chloride was covered with bromine-water, and allowed to stand for some time: after 24 hours at 11°, 5·28 per cent.; after 76 hours at 11·9°, 10·15 per cent.; after 7 hours at 44·4°, 11·28 per cent.; and after 12 hours at 44·4°, 14·53 per cent. of chlorine had been displaced by bromine. The author points out that these results are even more opposed to Berthelot's "principe du travail maximum" than those given by Potilitzin, who employed higher temperatures. The author undertook these researches and is continuing them, for the purpose of throwing light on the influence of time, temperature, and mass in chemical reactions. L. T. T.

Thermochemical Researches on Fluorine Compounds. By GUNTZ (*Ann. Chim. Phys.* [6], **3**, 1—66).—In this memoir are collected the author's various determinations on the heats of combination, formation, and solution of the metallic compounds of fluorine; a greater part of the work has already appeared in abstract (Abstr., 1884, 5, 544—546, 704, 884). A few incidental points of interest are alluded to in the course of the memoir.

Potassium fluoride is described by Berzelius as having an alkaline reaction; the perfectly dry salt is however quite neutral, and its alkalinity in aqueous solution is due to a slight loss of acid during evaporation, and the consequent formation of free alkali. As the heat of formation of potassium hydrogen fluoride is considerable, the author examined its degree of dissociation in dilute solution by causing to react together various proportions of potassium fluoride, hydrofluoric acid, and water; the results were—

KF (1 eq.) with HF (1 eq.) in 4 kilos. water, absorbs — 0·33 cal.
KF „ „ HF (½ eq.) „ „ „ — 0·36 „
KF „ „ HF (5 eqs.) „ „ „ — 0·78 „

The heat of absorption increases with increase in the proportion of acid; the results of the converse reaction were—

HF (1 eq.) with KF (1 eq.) in 4 kilos. water, absorbs — 0·33 cal.
HF „ „ KF (½ eq.) „ „ „ — 0·36 „
HF „ „ KF (5 eqs.) „ „ „ — 0·54 „

The same phenomenon is here noticeable, and thus the presence of an excess of one or other of the components modifies the chemical equilibrium and increases the proportion of constituents combined, a result analogous to that obtained by Berthelot and P. de Saint Gilles in their researches on etherification.

The interaction of hydrofluoric acid with potassium chloride, and of hydrochloric acid with potassium fluoride, was also studied with the following results:—

$2HF$ (gas) + $2KCl$ (solid) = $2KF$ (solid) + $2HCl$ (gas) absorbs.. − 22 cal.
$2HF$ (gas) + $2KCl$ (solid) = $KF.HF$ (solid) + KCl (solid) + HCl (gas) evolves...................... + 10 „
$2HCl$ (gas) + $2KF$ (solid) = $2KCl$ (solid) + $2HF$ (gas) absorbs.. − 22 „
$2HCl$ (gas) + $2KF$ (solid) = $KF.HF$ (solid) + KCl (solid) + HCl (gas) evolves...................... + 32 „

These experiments show that the hydrochloric acid is converted into the chloride, in presence of excess of fluoride, while the liberated hydrofluoric acid forms potassium hydrogen fluoride; whilst, in presence of excess of chloride, the hydrofluoric acid is gradually converted into potassium hydrogen fluoride, but on account of the decomposition of this salt by water the change is limited to one-fifth of the theoretical quantity.

On comparing the heats of neutralisation of various bases with hydrochloric, hydrofluoric, and sulphuric acids respectively, it is seen that the values for hydrofluoric and sulphuric acids are far closer to one another than those of hydrochloric and hydrofluoric acids.

Determinations of the heat of formation of the chloride and oxychloride of antimony are also given, and an investigation on the fluosilicates (cf. Abstr., 1884, 884).

Antimony trichloride is decomposed by water with formation of the oxychlorides, SbO_2Cl, Sb_2O_5Cl, and the hydrated oxide. The heat of neutralisation of antimonious oxide was determined either by the direct solution of the oxide in hydrochloric acid, or indirectly by dissolving antimony trichloride in hydrofluoric acid, and comparing the heat evolved with that disengaged by the solution of an equivalent weight of antimonious oxide in hydrofluoric acid.

The mean result of these two independent methods was—

Sb_2O_3 (anhyd.) + $6HCl$ (gas) = $2SbCl_3$ (solid) + $3H_2O$ (solid) .... = 94·4 cal.

It was found that the decomposition of antimony chloride by water does not give exactly the oxychloride Sb_2O_2Cl; definite equilibrium is established only after a long interval of time.

Silicon Fluoride.—From Thomsen's data of the heat of solution of silicon in hydrofluoric acid, and of silicon fluoride in water, the author calculates for the heat of formation of silicon fluoride:

$$Si \text{ (cryst.)} + F_4 \text{ (gas)} = SiF_4 \text{ (gas)} = 269{\cdot}4 \text{ cal.}$$

The action of steam on silicon fluoride with formation of hydrofluoric and silicic acids is an endothermic change:

$$SiF_4 \text{ (gas)} + 2H_2O \text{ (gas)} = 2HF \text{ (gas)} + SiO_2 \text{ (sol.)} = -25{\cdot}8 \text{ cal.};$$

consequently it can only take place provided that the temperature is sufficiently high to prevent the secondary reaction, viz., combination of hydrofluoric acid with water, and formation of hydrofluosilicic acid, which develops an amount of heat sufficient to compensate the absorption. This theoretical deduction is completely in accordance with the experiments of Hautefeuille, who demonstrated that silicon fluoride is not decomposed by steam above 150°. V. H. V.

Combustion of Explosive Gases in various States of Dilution. By A. WITZ (*Compt. rend.*, **99**, 187—190).—The heat developed by the explosive combustion of water-gas, mixed with twice its volume of oxygen, is notably less than that developed by the explosion of water-gas alone, and the difference is greater when carbonic anhydride is substituted for oxygen. C. H. B.

Non-existence of Ammonium Hydroxide. By D. TOMMASI (*Bull. Soc. Chim.*, **41**, 441—445).—The author points out that there is a great discrepancy between the calculated and experimental heat of formation of ammonium hydroxide. The former is 54·2 cal., but the latter only 21 cal., whereas the heats of formation of other hydroxides (sodium, lithium, calcium, &c.) determined experimentally, agree with the calculated results. From this the author concludes that a hydroxide of ammonium is not contained in the aqueous solution of ammonia-gas, or, more strictly, that the constitution of this solution differs from that of the other alkaline hydroxides.

W. R. D.

Lithium Oxide. By BEKETOFF (*Bull. Soc. Chim.*, **41**, 311—312). —The heats of formation of the oxides of lithium, sodium, and potassium were determined, and also the heats of hydration of the same oxides, with the following results, which are in accordance with the theoretical predictions of the author:—

	$M_2 + O$.	$M_2O + H_2O$.	$M_2O + Aq$.
Li	140,000	13,000	26,000
Na	108,000	35,400	55,000
K	97,000	42,000	67,000

Lithium oxide prepared by Troost's method always contains carbonate. When anhydrous lithium carbonate is dissolved in water, heat is evolved; moreover, the solubility of this compound decreases with an increase of temperature. These facts point to the existence of an unstable hydroxide. W. R. D.

Mixed Liquids of Constant Boiling Point. By D. KONOVALOFF (*Ber.*, **17**, 1531—1539).—In a former communication (Abstr., 1881, 1093) the author showed that two miscible liquids form a mixture of constant boiling point when the vapour-tension curve (taken as a function of the composition of the mixture) has a maximum or a minimum. From a review of existing data, and an examination of many fresh mixtures, the author now draws the following conclusions.

i. When the vapour-tension curve of a mixture of constant boiling point has a minimum (*i.e.*, when the vapour-tension of the mixture is less than that of either of the constituents), the constituent of lower boiling point preponderates in the mixture. ii. When the tension-curve shows a maximum (*i.e.*, exceeds that of either of the constituents), the liquid of greater vapour-tension forms the larger proportion of the mixture. iii. The ratio between the two constituents of a mixture of constant boiling point approaches more nearly to equality the nearer together their vapour-tensions are in the free state; and diverges more from equality the further apart their vapour-tensions are. iv. The greater the mutual action of the two liquids on one another, the greater is the tendency to the formation of a mixed liquid having a minimum curve. L. T. T.

Different Methods of Distillation compared. By H. Kreis (*Annalen*, **224**, 259—269).—A series of quantitative experiments on fractional distillation shows that the best results are obtained for mixtures boiling about 100° by using Linnemann's tubes (*Annalen*, **160**, 195), or the simpler and less expensive apparatus devised by Hempel (*Zeits. Anal. Chem.*, **20**, Part IV). A flask provided with a bulb on its neck yields better results than a long-necked flask for mixtures boiling about 300°. W. C. W.

Production of very Low Temperatures by Means of Methane. By L. Cailletet (*Compt. rend.*, **98**, 1565—1566).—When methane is slightly compressed, and cooled by means of liquid ethylene boiling under ordinary atmospheric pressure, it condenses to a colourless very mobile liquid, and if this liquid methane is allowed to boil under atmospheric pressure the temperature produced is sufficiently low to liquefy oxygen immediately. C. H. B.

The Freezing Point of Saline Solutions. By F. M. Raoult (*Compt. rend.*, **99**, 324—326).—Determinations of the freezing points of solutions of salts of polyatomic metals which are not decomposed by water give the following results:—

	Molecular weight.	Reduction of freezing point by 1 gram of salt in 100 grams of water.	Molecular reduction.
Stannic chloride	260	0·370	96·3
Aluminium chloride....	268	0·481	129·0
Chromic chloride (violet)	318	0·408	130·0
Ferric chloride	325	0·396	129·0
Aluminium nitrate	283	0·458	129·8
Chromic nitrate (violet).	333	0·384	128·0
Aluminium sulphate....	343	0·129	44·4
Chromic sulphate (violet)	393	0·115	45·4
Ferric sulphate	400	0·115	46·0

From these results, and others previously obtained (this vol., pp. 701 and 808), it follows that—

(1.) When in a solution of a salt of a monovalent metal containing 1 equivalent of the metal in 100 grams of water, the monovalent metal is replaced by an equivalent quantity of a bivalent or multivalent metal, the molecular reduction of the freezing point is diminished by a practically constant quantity, about 10·5.

(2.) When in a solution of a salt of a strong monobasic acid containing 1 equivalent of the acid in 100 grams of water, the monobasic acid is replaced by an equivalent quantity of a strong dibasic acid, the molecular reduction of the freezing point is likewise diminished by a practically constant quantity, about 14.

The sums and differences of the partial reductions of the freezing point by saline radicles being thus known, it is possible to calculate the absolute values of these reductions if it is admitted that there is a constant ratio between the partial reductions produced by electronegative and electropositive radicles of the same atomicity. It is thus found that the partial reductions caused by saline radicles approximate to the following values:—

		Partial molecular reduction.
Univalent electronegative radicles	(Cl, Br, OH, NO_3, &c.)	20
Bivalent ,, ,, ,,	(SO_4, CrO_4, &c.)	11
Univalent electropositive ,,	(H, K, Na, &c.)	15
Bi- or multivalent electropositive radicles	(Ba, Mg, Al_2)	8

From these data it is possible to calculate approximately the molecular reduction of the freezing point caused by the majority of salts formed by the union of a strong acid with a strong base. The values thus obtained agree very closely with the results of experiment, and it follows that *the molecular reduction of the freezing point, produced by salts formed by the monobasic and bibasic acids, is sensibly the sum of the partial molecular reductions of the electropositive and electronegative radicles*. These facts prove that, contrary to the author's previous belief, the *general law of congelation* is not applicable to salts dissolved in water, and they justify the criticisms of Debray (*Compt. rend.*, 1883, **97**, 825). It would seem, however, that this law is applicable to the constituent radicles of the salts, almost as if these radicles were simply mixed in the solutions, and this constitutes further evidence that the radicles of salts dissolved in water act independently in modifying the physical properties of the solvent. C. H. B.

Absorption of Chlorine by Carbon, and its Combination with Hydrogen. By BERTHELOT and GUNTZ (*Compt. rend.*, **99**, 7—8).—Melsens found that when hydrogen is passed over purified wood-charcoal saturated with chlorine, hydrochloric acid is formed, but there is a reduction of temperature. The authors find that the absorption of 35·5 grams of chlorine by purified charcoal develops + 6·78 cal., a quantity almost double the heats of volatilisation of liquid bromine and iodine, but still considerably below the heat of formation of hydrochloric acid. When, however, hydrogen is passed over the charcoal saturated with chlorine, hydrochloric acid is formed, and a considerable proportion of the absorbed chlorine is given off unchanged. The amount of chlorine thus given off is seven times as great as the volume of hydrochloric acid formed, the heat absorbed by the first change is greater than that developed by the second, hence the reduction of temperature. C. H. B.

Behaviour of Vegetable Tissues, Starch, and Charcoal, towards Gases. By J. Böhm (*Bied. Centr.*, 1884, 316—319).—Experimenting with cork and pine-wood, the author found that the first portions of the gas removed from them in a vacuum contained from 6 to 12 per cent. more oxygen than common air; raspings of wood or cork did not absorb hydrogen or oxygen, and the same was found to be the case with pine-wood, which was easily permeated by air under pressure, as also was deal which had lain long in water, and was, therefore, to some extent, decayed. As the tissue of wood contains air rich in oxygen, it follows that this gas must diffuse more readily through the walls than nitrogen. Carbonic anhydride is absorbed in quantities which vary in proportion with the amount of aqueous vapour present, cork powder absorbing less than wood. Starch absorbs most carbonic anhydride when perfectly dry, and the gas is not wholly removable in a vacuum, but completely by immersion in water. Charcoal condenses but a small amount of air, and that which is first removed is richer in oxygen than that which follows. Freshly-ignited charcoal absorbs many times its volume of air, and relatively more oxygen than nitrogen, the latter being completely removable, the former only partly by boiling water. Freshly-ignited coal absorbs neither nitrogen nor hydrogen, but some carbonic anhydride and much oxygen, which probably is employed in oxidising hydrocarbons. E. W. P.

Coagulation of Colloïds. By E. Grimaux (*Compt. rend.*, 98, 1578—1581).—Colloïds may be divided into two groups, according as their coagulation is prevented or hastened by dilution.

The first group includes ferric hydroxide, soluble silica, the nitrogenised colloïds, albumin, and the amidobenzoic colloïds, the coagulation of which requires a longer time or a higher temperature the more dilute the solution. In such cases, coagulation is analogous to etherification. Just as ethereal salts are formed with elimination of water, so ferric hydroxide and silicic hydroxide, $Si(OH)_4$, undergo condensation with elimination of water, forming respectively in the first place such compounds as $Fe_4O(OH)_{10}$ and $Si_2O(OH)_6$. Coagulation, like etherification, takes place very slowly at the ordinary temperature, especially if the solutions are dilute, but both changes are accelerated by the action of heat, and attain their maximum limit more quickly the higher the temperature. Salts which promote coagulation act as dehydrating agents, just as barium chloride impedes the saponification of ethyl benzoate (Berthelot). Coagulation, however, unlike etherification, is generally not reversible, but even here the difference is not absolute, for under certain conditions coagulated silicic or ferric hydroxide can redissolve in water, and, on the other hand, the decomposition of ethereal salts by water is never complete, whatever the proportion of water. The gradual contraction of the coagulum is due to a continuation of the process of condensation, with further elimination of water.

When coagulation is promoted by dilution, as in the case of ferric derivatives, Schweizer's reagent, calcium saccharate, &c., it is due to dissociation produced by the action of the water. This explanation is supported by the fact that in these cases coagulation by addition of water is impeded, or even entirely prevented, by the presence of an excess of one of the constituents of the colloïd. C. H. B.

The Dehydrating Action of Salts. By D. TOMMASI (*Compt. rend.*, **99**, 37—38).—Grimaux's researches on the coagulation of colloïds lead to the conclusion that salts promote the coagulation of some colloïds by acting as dehydrating agents There are, however, cases in which certain salts produce an exactly opposite effect, and prevent the dehydration of other substances. The temperature required to convert cupric hydroxide into cupric oxide, for example, is higher in presence of sodium acetate, sulphate, and hydroxide, potassium bromide, chlorate, and iodide, than in pure water, and the presence of 10 per cent. of calcium chloride, of saccharose, and of even 0·3 per cent. of manganese sulphate, prevents the dehydration of cupric hydroxide, even at 100°. Potassium chloride, sodium carbonate, and stronger solutions (10 per cent.) of sodium hydroxide facilitate the conversion of cupric hydroxide into the oxide. C. H. B.

Cohesion of Saline Solutions and of their Admixtures. By O. ROTHER (*Ann. Phys. Chem.*, **21**, 576—615).—In his determinations of capillary cohesion, the author has made use of tubes of an elliptical section, which he has found very uniform in calibre, and in which the liquid rises to a greater height than in the more usually employed circular tubes of equal area of bore, thus admitting of more accurate measurements being made. He distinguishes the *actual cohesion* of each solution from the *specific cohesion*, the latter being obtained by referring the observed value to the molecular weight of the salt. The experimental results are shown in an extended series of tables, and a plate accompanies the paper, giving graphic representations of the determinations. Among the general laws proceeding from these, and fully discussed in the paper, the most interesting are, perhaps, the following:—The *actual* cohesion increases with the quantity of salt in the solution, being, in fact, a linear function of that quantity, and it is greater with salts of smaller molecular weights. Solutions containing equal percentages of K_2SO_4 and of Na_2SO_4 have the same *actual* cohesion. The *specific* cohesion increases more rapidly with the small than with the larger percentages of salt. Equal quantities of NaCl and of KCl, dissolved in equal quantities of water, give solutions of the same *specific* cohesion. The cohesion of solutions containing known quantities of one or more salts may be expressed in mathematical formulæ involving the capillary constants. R. R.

Diffusion of Gases through a Porous Septum. By G. HANSEMANN (*Ann. Phys. Chem.*, **21**, 546—562).—The object of the researches recorded in this paper is to test the validity of the theory of the diffusion of gases through a porous septum, enunciated in 1871

by Stefan (*Wien. Akad. Ber.*, **63**, 111), who treats it as a particular case of his general theory of gas motion, in which he regards the porous substance as a gas with immovable particles. This theory involves the assumption that the free diffusion of the two gases in the very narrow spaces of the porous body takes place exactly as in larger spaces, but according to the author's results and deductions, this does not appear to be the case, and his experiments do not confirm Stefan's theory.
R. R.

Colour of Chemical Compounds, mainly as a Function of the Atomic Weights of the Component Elements. By T. CARNELLEY (*Ber.*, **17**, 2151—2156).—The colour of chemical compounds has been studied by Ackroyd, who drew the conclusions (I) that with increasing temperature the colour of a compound approaches more and more to the red end of the spectrum, and at a sufficiently high temperature passes into brown and black; (II) in binary compounds an increase in the amount of the electronegative element causes a change of colour towards the red end of the spectrum, and finally into brown and black. To these rules the author adds a third:—In a series of compounds, A_xR_y, B_xR_y, C_xR_y, &c., in which R is an element or group of elements, and A, B, C., &c., are elements belonging to the same sub-group in Mendelejeff's table of the natural classification of the elements, with the increasing atomic weight of the elements A, B, C, &c., the colour of the compound approaches the red end of the spectrum, and in many cases passes into brown and black. Of 426 substances examined only 14 exceptions to the last rule were found, and only four of these did not admit of explanation. The paper concludes with a theoretical explanation of the subject.
A. J. G.

Specific Volumes of Liquids. By W. LOSSEN and A. ZANDER (*Annalen*, **225**, 109—120).—This memoir, a continuation of former researches (Abstr., 1882, 1259; 1883, 13), deals with observations of the coefficients of expansion and specific volume of additive compounds of the aromatic hydrocarbons. The results obtained are compared with previous determinations for olefine hydrocarbons metameric with them, and also with their isologues in the aromatic series. The following table contains a summary of results; in the first column is the name of the substance, in the second the observed boiling point, the third, fourth, and fifth the experimental values for a^{-1}, b^{-6}, c^{-9}, in the general equation $V = 1 + at + bt^2 + ct^3$, and in the sixth the specific volumes at the boiling point:—

Substance.	Boiling point.	a^{-4}.	b^{-6}.	c^{-9}.	Sp. vol.
Hexahydrotoluene, C_7H_{14}....	96	11·436	0·13104	16·551	142·0
Hexahydroisoxylene, C_8H_{16}..	118	10·672	1·0061	7·5268	164·8
Naphthalene, $C_{10}H_8$	217·1	8·6962	0·56843	3·9971	147·2
Hexahydronaphthalene, $C_{10}H_{14}$..................	200	8·2059	0·7227	1·4935	171·2

It has been remarked by Wreden that the sp. gr. of the additive compounds of the aromatic hydrocarbons is greater than that of the isomeric olefines; the presumable converse of this statement, viz., that the specific volume of the former is less than that of the latter, is confirmed, for the observed specific volume of hexa-hydroisoxylene and -hydrotoluene are less by about 12·5 than those of their corresponding metamerides, caprylene and heptylene.

Cymene and hexahydronaphthalene are metameric, the specific volume of the latter derived from the benzene nuclei is 12·8 less than that of the former, containing one such nucleus, this difference being approximately equal to that observed between the olefines and their metamerides in the aromatic series.

In the table given in the memoir, the specific volumes of hydrocarbons containing the same number of carbon-atoms, but a different number of hydrogen-atoms, are compared; it is thus shown that the difference of specific volumes of isologues in the paraffin and the aromatic derivatives are approximately equal.

Thus toluene, xylene, and naphthalene are precisely to the same degree unsaturated hydrocarbons as amylene, styrene, and diallyl. This conclusion is in direct opposition to the observations of Schiff on the specific volume, and of Thomsen on the heat of combustion of benzene, which have tended to establish that in this hydrocarbon, each carbon-atom is united to three other carbon-atoms, and thus is formed a combination with affinities completely satisfied. V. H. V.

A Hydrometer for Demonstrating Alterations in Weight in Chemical Changes. By M. Greger (*Ber.*, **17**, 568—571).—A description of a sensitive hydrometer for lecture purposes, requiring the accompanying plates to be of service. P. P. B.

Apparatus for Collecting Solid Carbonic Anhydride. By Ducretet (*Compt. rend.*, **99**, 235—237).—The apparatus consists of a cylindrical ebonite receiver, provided with a hollow ebonite handle, and fitted with a cover which can be fastened by means of a bayonet joint. A tube, also of ebonite, is fixed obliquely in the cover, and passes down nearly to the bottom of the receiver. This tube is connected with the reservoir of liquid carbonic anhydride, and the latter strikes against the ebonite sides of the receiver. A much greater yield of the solidified gas is obtained than with the original Thilorier's apparatus. The displaced air and the evolved carbonic anhydride escape down the hollow handle.

The impact of the liquefied gas on the ebonite develops sufficient electricity to produce a continuous discharge of sparks 1 cm. long, between the metallic fittings of the ebonite tube and the connecting tube of the reservoir of the liquid. C. H. B.

Inorganic Chemistry.

Apparatus for Preparing Oxygen Quickly. By B. TACKE (*Ber.*, 17, 1831—1832).—This consists of a wrought-iron cylinder, 1 metre long and 4 cm. internal diameter, to the open end of which a flanged iron elbow delivery tube is screwed, the joint being made perfectly tight by the help of a leaden washer. The cylinder is filled with 700—800 grams of potassium chlorate, and laid horizontally, the end of the elbow tube (which points downwards) is then joined by means of a cork and mercury joint to a glass tube a metre long, and ending under mercury. The end of this tube is turned up under a funnel which contains a little caustic potash to wash the oxygen, and the funnel is connected with any convenient delivery tube. When as much oxygen as is required has been obtained, the source of heat is removed, and the mercury rises in the glass tube. The joints remain tight for any length of time, and the apparatus is ready for use again at a moment's notice. Should by any chance a leak take place, this is at once shown by the fall of the mercury in the glass tube.

L. T. T.

Crystallisation of Sulphur. By MAQUENNE (*Bull. Soc. Chim.*, 41, 238—239).—When hydrogen persulphide, either alone or mixed with carbon bisulphide, is allowed to decompose spontaneously, octahedral sulphur is deposited. If, however, the hydrogen persulphide is mixed with ether, the sulphur is deposited in perfectly transparent scales, which are extremely thin, and rapidly become opaque and transformed into a mass of octahedra, plainly visible under the microscope. When hydrogen persulphide is allowed to remain for 24 hours in the cold in contact with ether, decomposition takes place slowly, and orthorhombic crystals are formed, which often attain the length of from 8—10 mm. The yield is small; 500 grams of hydrogen persulphide gave only 4 grams of crystals perfect enough to examine. The crystalline form of the product, which was proved to be pure sulphur, was that of an orthorhombic prism, of 106° 20′, surmounted by an apex, the angles of which were identical with those of the ordinary octahedron. The faces *b* of the ordinary octahedron exactly form an angle of 106° 20′, and hence it would seem that this prism is a deformation of the octahedron, in which half the faces have been developed to the detriment of the others. The crystals melt at about 117°, and have a density of 2·041—2·049. They thus appear to be a variety intermediate between the α and β varieties of crystallised sulphur. The crystals dissolve in carbon bisulphide and in benzene, and are deposited in octahedra when these solutions are evaporated. When immersed in superfused sulphur, or in a supersaturated solution, the crystals give rise to octahedra, which seem to be identical with those described by Gernez (Abstr., 1884, 889), under the name of nacreous beads. It is probable that the crystals discovered by the author have previously been confounded with the clinorhombic variety of sulphur, which they resemble in being readily transformed into the α-form of the octahedron. W. R. D.

Experiments to Combine Sulphur with Sulphur. By H. Prinz (*Annalen*, **223**, 371—378).—The author has tried a number of reactions in which it appeared probable that compounds would be formed containing sulphur in union with sulphur. In no case were such products formed. The reactions investigated were the following:—Sulphurous chloride and hydrogen sulphide do not react at ordinary temperatures; at 60° they yield hydrochloric acid, sulphur, and sulphurous anhydride. Sulphuric hydroxychloride and hydrogen sulphide react at ordinary temperatures, forming sulphuric acid, hydrochloric acid, sulphur sulphochloride, and sulphur. Ethyl sulphate and sulphur do not react at 100°. Ethyl sulphite and sulphur at 200° do not react, but the ethyl salt is decomposed. Ethyl sulphite and ethyl sulphide do not react at 180°. Sulphurous chloride and sodium mercaptide yield diethyl disulphide, sulphurous anhydride, hydrochloric acid, sodium chloride, sulphur, and carbon. Ethylsulphonic chloride and sodium mercaptide react at 150°, yielding sulphurous anhydride, hydrochloric acid, diethyl disulphide, sodium chloride, and carbon. Diethylic sulphoxide and sulphur do not react. A. J. G.

Constitution of Disulphur Dichloride. By H. Prinz (*Annalen*, **223**, 355—371).—Carius having obtained disulphur dichloride, S_2Cl_2, by the action of phosphoric sulphide on sulphurous chloride, regarded its formation as being analogous to that of phosphoric sulphochloride from phosphoric sulphide and phosphoric oxychloride, and assigned to it the constitution $S{=}S{<}\substack{Cl\\Cl}$ (sulphur sulphochloride). The author has reinvestigated the question with results that are, in his opinion, not in accord with Carius' theory.

Experiments to convert Disulphur Dichloride into Sulphurous Chloride.—Disulphur dichloride does not react with sulphurous anhydride even when heated with it for a day at 100°. It reacts with antimonious anhydride, or antimonic anhydride, forming antimonious chloride, sulphurous anhydride, and sulphur. With arsenious or arsenic anhydride, it yields arsenious chloride, sulphurous anhydride, and sulphur. It has no action on phosphorous or phosphoric anhydride. With selenious anhydride, it yields diselenium dichloride and sulphurous anhydride.

Experiments to convert Sulphurous Chloride into Disulphur Dichloride.—Sulphurous chloride when heated with sulphur for six hours at 100° is converted into disulphur dichloride and sulphurous anhydride. This, however, according to the author is not due to the replacement of oxygen by sulphur, but to the decomposition of sulphurous chloride into sulphurous anhydride and sulphur tetrachloride, the latter being then converted by the sulphur into disulphur dichloride. Sulphur has no appreciable action on phosphoric oxychloride, on acetic chloride or anhydride, on benzoic chloride, or on ethyl alcohol. Sulphurous chloride and antimony trisulphide react to form antimonious chloride, sulphur, and sulphurous anhydride. Sulphurous chloride when heated with phosphoric sulphide for eight hours at 100° yields sulphurous anhydride, phosphoric sulphochloride, phosphoric oxychloride, and sulphur, not a trace of disulphur dichloride being formed. At 150°, disulphur dichloride is formed, but in all probability is due to the action of the liberated sulphur on sulphurous chloride. Selenium when heated for four hours at 180° with sulphurous chloride yields sulphurous anhydride, selenious chloride, and disulphur dichloride.

A. J. G.

Compounds of Sulphurous Anhydride. By A. GEUTHER (*Annalen*, **224**, 218—224).—The crystalline hydrate of sulphurous acid melts at 14°, and has the formula $SO_2,7H_2O$, or $H_2SO_3,6H_2O$.

Potassium hydrogen sulphite, $KHSO_3$, has an acid reaction. At 190°, it is decomposed into a mixture of sulphate and thiosulphate, and at a higher temperature sulphur sublimes and a polysulphide is produced.

Potassium pyrosulphite, $K_2S_2O_5$, behaves in a similar manner under the influence of heat.

The *neutral sulphite*, $K_2S_2O_3 + 2H_2O$ is decomposed at a temperature below a red heat forming sulphate and polysulphide.

Ethoxythioxyl chloride, which has been described by Michaelis and Wagner (*Ber.*, **7**, 1074), is decomposed on distillation into ethyl chloride and sulphurous anhydride.

W. C. W.

Density of Sulphuric Acid. By G. LUNGE (*Ber.*, **17**, 1748—1751). In answer to Mendelejeff (*Ber.*, Ref., 1884, 302), the author shows that the number 1·8384 obtained by him and Naef for the density of sulphuric acid at $\frac{15^\circ}{4^\circ}$ is probably amongst the most correct, if not the most correct yet obtained, and does *not* "differ considerably" from Marignac's two determinations, but lies between them. He shows that the corrections applied by Mendelejeff to Marignac's earlier determination are not justifiable.

L. T. T.

Compounds of Tellurous Anhydride with Acids. By D. KLEIN (*Compt. rend.*, **99**, 326—328).—*Basic Tellurium Nitrate*, $4TeO_2,N_2O_5 + 1\frac{1}{2}H_2O$.—Tellurium is treated with a large excess of moderately strong nitric acid (sp. gr. 1·15—1·35), and the liquid evaporated at a gentle heat until crystals appear on the surface. As the liquid cools, crystals of the basic nitrate separate in considerable quantity. Basic tellurium nitrate is soluble in warm nitric acid diluted with five or six times its volume of water, and is deposited unchanged when the liquid cools. It begins to decompose at the melting point of lead, and the whole of the nitric acid is expelled at a dull red heat, a residue of tellurous anhydride being left. When this anhydride is dissolved in hot nitric acid, the basic nitrate is again formed.

Basic tellurium sulphate, $2TeO_2,SO_3$, is obtained by dissolving tellurous anhydride in hot sulphuric acid diluted with three or four times its weight of water, and evaporating the solution on a sand-bath. The basic sulphate is deposited in scales consisting of rhombic tables. It is only slightly soluble in cold dilute sulphuric acid.

Both the basic nitrate and the basic sulphate are decomposed by a large excess of warm water, a residue of tellurous anhydride being left. The basic sulphate is probably the compound described by Berzelius as $TeO_3,2SO_3$. C. H. B.

Critical Temperature and Pressure of Nitrogen. Boiling Points of Nitrogen and Ethylene under Low Pressures. By K. Olzewski (*Compt. rend.*, **99**, 133—136).—The following table gives the boiling point of ethylene under different pressures:—

Pressure.	Boiling point.	Pressure.	Boiling point.
750 mm.	− 103°	107 mm.	− 126°
546 „	− 105	72 „	− 129·7°
441 „	− 108	56 „	− 132°
346 „	− 111	31 „	− 139
246 „	− 115·5°	12 „	− 148
146 „	− 122°	9·8 „	− 150·4°

The critical temperature of nitrogen is − 146°, and the critical pressure 35 atmos. The following table shows the relation between the boiling point of liquid nitrogen and the pressure:—

Atmos.	Boiling point.
35	− 146°
31	− 148·2°
17	− 160·5
1	− 194·4
vacuum	− 213°

The author criticises some of Wroblewski's observations.

C. H. B.

Critical Temperature and Pressure of Air; Relation between its Boiling Point and the Pressure. By K. Olzewski (*Compt. rend.*, **99**, 184—186).—The air was liquefied under pressure in a glass tube cooled by means of ethylene. Its critical temperature is −140°, and the critical pressure 39 atmos. The relation between the boiling point of liquid air and the pressure is shown in the following table:—

Pressure in atmos.	Boiling point.	Pressure in atmos.	Boiling point.
39·0	− 140°	12·5	− 160·5°
33·0	− 142	6·8	− 169·0
27·5	− 146	4·0	− 176·0
20·0	− 152	1·0	− 191·4
14·0	− 158·5°	vacuum	− 205·0

The boiling point of air under atmospheric pressure is practically that calculated from the boiling points of its constituents, but in a vacuum this relation does not hold good, and it would seem that the nitrogen evaporates more rapidly than the oxygen. C. H. B.

Product of the Action of Bromine on Nitric Oxide. By O. Fröhlich (*Annalen*, **224**, 270—273).—Landolt states that three compounds, $NOBr$, $NOBr_2$, and $NOBr_3$ are formed by the action of bromine on nitric oxide. The author, however, regards the di- and tri-bromide as mixtures of nitrosyl bromide with free bromine, as they are completely separated into these constituents by distillation. When the so-called tribromide acts on sodium ethylate, a mixture of sodium bromide, sodium acetate, ethyl nitrite, and alcohol is obtained, showing that the body acts like a mixture of bromine and nitrosyl bromide.

W. C. W.

Vitreous and Ordinary Amorphous Silica. By D. LINDO (*Chem. News*, **50**, 25—26).—According to text-books, silica. as obtained in the analysis of silicates, has the aspect of a white earthy powder. If the contents of the dish are stirred when crusts begin to form, and the stirring be continued until the mass is dry, the silica will always present this appearance to the unaided eye; under the microscope with reflected light, it will appear either in the form of amorphous dead-white masses, which in very thin layers are slightly translucent —ordinary amorphous silica; as a mass entirely composed of perfectly transparent particles with sharp edges and angles—vitreous silica; or, as a mixture of these two varieties. If the melt has been acted on by strong acid without dissolving it first in water, or if very little water has been used to dissolve it, the silica left on evaporating to dryness will be the ordinary amorphous form. If the melt has been dissolved in a considerable quantity of water, so that on adding the strong acid none of the silica is precipitated, all the silica will be in the vitreous form. If the melt has been dissolved in a moderate amount of water, so that on adding the acid part the silica is precipitated, and a portion held in solution, the silica will be found of both forms. If an acid solution of the melt in which all the silica remains dissolved is evaporated to dryness without stirring, the silica will form a transparent jelly, and on continuing to heat vitreous silica will be obtained in transparent particles, having the appearance, when washed and dried, of coarsely-powdered glass. It contains water, which can only be expelled completely by strong ignition. Ordinary amorphous silica examined in a drop of water under the microscope by transmitted light, will be found to consist of granular flakes, which have a yellowish-brown colour, whilst vitreous silica appears colourless. Ignited intensely over the blast it appears unaltered, and samples so treated retain their transparency after being exposed to the air for several weeks. Some samples retain their hygroscopic property after several intense ignitions; other samples lose this property completely after the first ignition. The author failed to detect any difference either in composition or appearance under the microscope in those samples that lost their hygroscopic property so readily, although he is inclined to attribute this peculiarity to the presence of foreign matter. Since Jenzsch has shown the existence of amorphous silica of sp. gr. 2·6, increase of density is no proof that the amorphous has passed into the crystalline state.

J. T.

Phosphoric Anhydride. By P. HAUTEFEUILLE and A. PERREY (*Compt. rend.*, **99**, 33—35).—Phosphoric anhydride exists in three modifications, viz., crystalline, amorphous and pulverulent, amorphous and vitreous. All three varieties are produced when phosphorus is burnt in a glass tube in a current of air, the crystalline form being deposited in the cold part of the tube, the pulverulent in the hotter part, and the vitreous in that part which is heated just to redness.

Crystallised phosphoric anhydride is obtained by distilling the products of the complete combustion of phosphorus. It forms colourless transparent highly refractive monoclinic crystals, which are either isolated or in snow-like masses, or in the form of an opaline crust, according to the conditions of condensation. At about 250°, the crystallised anhydride has a vapour-tension of 760 mm., but at a somewhat higher temperature it polymerises, and the vapour-tension sinks to a few mm. It can be rapidly distilled in a current of gas at 250°, but at a higher temperature distillation is much more difficult. It dissolves immediately in water, with development of 89·16 cal. for P_2O_5, forming a limpid solution.

Amorphous pulverulent phosphoric anhydride is a polymeride of the crystalline variety, and is obtained by heating the latter at 440°. It dissolves comparatively slowly in water, with development of 82·64 cal. for P_2O_5. The difference between this value and the heat of hydration of the crystalline variety, 6·52 cal., is the heat developed by polymerisation, and approaches closely to the heat of polymerisation of cyanuric acid (6·4 cal., Troost and Hautefeuille). The pulverulent anhydride is less volatile than the crystalline variety, and yields the latter when sublimed.

Vitreous phosphoric anhydride is obtained by heating either of the preceding varieties to incipient redness under pressure. It forms a colourless transparent glass which splits up, with phosphorescence, on cooling, owing to unequal contraction. It volatilises slowly but completely when heated to incipient redness, and yields the crystalline anhydride. The vitreous anhydride dissolves very slowly in water.

C. H. B.

Phosphorus Sulphides. By E. DERVIN (*Bull. Soc. Chim.*, **41**, 433—436).—When two parts of sulphur and one of phosphorus trisulphide (P_2S_3) are dissolved in carbon bisulphide, and the solution exposed to the light for one or two months, fine pale-yellow transparent needles of the tetrasulphide, PS_4, are formed. This compound is not affected by heating under pressure with carbon bisulphide. In the above reaction crystalline spherical grains of $P_4S_{11}(P_2S_3,2PS_4)$ are also formed. This compound is produced more readily by heating in sealed tubes at 180° sulphur with phosphorus trisulphide, the latter in excess, dissolved in carbon bisulphide. When this compound is heated with carbon bisulphide under pressure at 200°, it is resolved into PS_4 which crystallises out, and P_2S_3 which remains dissolved. But this decomposition does not occur if a considerable quantity of the trisulphide is previously dissolved in the carbon bisulphide. Unsuccessful attempts were made by similar means to form compounds of the trisulphide with PS_3 and PS_5. The pentasulphide, PS_5, was obtained by fusing sulphur with amorphous phosphorus, and was crystallised by heating under pressure with carbon bisulphide, but the compound PS_3 could not be produced in a similar way; the fused mass yields crystals of PS_4 when heated under pressure with carbon

bisulphide. The author considers that either the compound known as PS_3 is a mixture of $(P_2S_3,2PS_1)$ with PS_4, or that the compound really exists in the fused mass, but is decomposed when heated with carbon bisulphide, yielding the tri- and tetra-sulphide $5PS_3 = P_2S_3 + PS_4$.
W. R. D.

Polysulphides of Sodium. By H. Böttger (*Annalen*, 335—342). —*Sodium monosulphide*, $Na_2S + 5H_2O$, was prepared by saturating one-half of an alcoholic solution of soda with hydrogen sulphide, then adding the other half of the soda and allowing it to crystallise; access of air being carefully prevented. It forms long white prisms, loses 3 mol. H_2O at 100°, is rendered anhydrous by heating to 180°, and oxidises readily on exposure to air. The hydrated salt is readily and completely decomposed by carbonic anhydride in the cold, whilst the anhydrous salt is only appreciably decomposed on heating above 100° in a current of the gas.

The polysulphides were prepared by heating on the water-bath alcoholic solutions of the monosulphide with the calculated amount of sulphur, the liquid being subsequently cooled to − 10° to − 15° to obtain crystals.

Sodium disulphide, $Na_2S_2 + 5H_2O$, forms groups of sulphur-yellow crystals. It loses 3 mols. H_2O at 100°.

Sodium trisulphide, $Na_2S_3 + 3H_2O$, forms dark golden-yellow concentrically grouped crystals. It loses 2 mols., H_2O at 100°, fusing to a liver-coloured mass, and becomes anhydrous at 190°.

Sodium tetrasulphide, $Na_2S_4 + 8H_2O$, is obtained in orange-red, concentrically grouped crystals. Heated above 100°, a part of its sulphur is evolved as hydrogen sulphide.

Sodium pentasulphide, $Na_2S_5 + 8H_2O$, forms dark orange-yellow crystals. It commences to decompose at 100°.
A. J. G.

Constitution of the Alkali Polysulphides. By H. Böttger (*Annalen*, **223**, 342—345).—If the alkali tetra- and penta-sulphides are the analogues of the sulphites and sulphates, containing sulphur in place of oxygen, they should, in the author's opinion, on being boiled with lead hydroxide, yield plumbic sulphide, and the alkaline sulphite or sulphate respectively. On boiling a solution of sodium pentasulphide with lead hydroxide, the products obtained were lead sulphide and sodium thiosulphate. Sodium tetrasulphide yields the same products, and, in addition, sodium hydroxide.
A. J. G.

Constitution of Polysulphides and Polyoxides. By A. Geuther (*Annalen*, **224**, 201—218).—The author is of opinion that the constitution of the polysulphides and polyoxides can only be explained on the assumption of the variable valency of the elements. He fixes the maximum valency of potassium and sodium at 5, and of barium, strontium, and calcium at 10.
W. C. W.

Relation between the Pressure and the Temperature of Transformation of Silver Iodide. By Mallard and Le Chatelier (*Compt. rend.*, **99**, 157—160).—Silver iodide changes at 146° from the hexagonal to the cubic system (this vol., p. 16), with absorption of heat and contraction of volume. The phenomenon is analogous to the freezing of water, and it might be expected that an increase of pressure would lower the temperature of transformation, and that under very high pressure the transformation would take place at the ordinary temperature. By means of a screw press provided with a Bourdon manometer similar to that used in their experiments on combustion, the authors find that the transformation of silver iodide takes place at the ordinary temperature under somewhat high pressure, and when the pressure is released the iodide returns to its original condition. At 20° the pressure required to effect the change is about 2475 kilos. per square centimetre, and under this and all higher pressures the silver iodide crystallises in the cubic system, whilst under lower pressures it crystallises in the hexagonal system.

The change under pressure is accompanied by a contraction of 0·16, a contraction about ten times as great as that observed by Rodwell at 146° under atmospheric pressure; approximate determinations by the authors indicate that the contraction at 146° is about 0·11. C. H. B.

Ammonio-silver Compounds. By A. Reychler (*Ber.*, **17**, 1840—1842).—Dry silver phosphate, Ag_3PO_4, was kept for some time in an atmosphere of ammonia. At the end of 14 days absorption had almost entirely ceased, and 1 mol. of phosphate had then absorbed between 3 and 4 mols. NH_3. As the silver compound always shows a slight tint of yellow, the author believes the pure compound to have the formula $Ag_3PO_4,4NH_3$. By the action of ethyl iodide on ammonio-silver nitrite, nitroethane is formed besides the compounds already mentioned (this vol., 157). With methyl iodide the reaction is quite analogous to that with ethyl iodide, ammonia, silver iodide, methyl nitrite and nitromethane being produced. L. T. T.

Crystallised Barium Manganite. By G. Rousseau and A. Saglier (*Compt. rend.*, **99**, 139—141).—A mixture of 2 grams barium manganate and 10 grams barium chloride was heated in a platinum crucible in a Forquignon and Leclercq furnace at 1500—1600° for four hours, allowed to cool, and the fused mass treated several times with boiling water to remove chloride and undecomposed manganate, and finally with dilute acid to remove a small quantity of carbonate. The residue consisted of small opaque bluish-black crystals, with a lustre resembling that of crystallised silicon; sp. gr. = 5·85. These crystals have the composition $BaMnO_3$, and dissolve readily in hydrochloric acid with evolution of chlorine, but are not so soluble in nitric acid. This crystallised barium manganite is quite distinct from psilomelane, and its existence affords further evidence that manganese peroxide is really an acid-forming oxide. C. H. B.

Compounds of Haloid Salts with Oxysalts of the same Metal. By H. Le Chatelier (*Compt. rend.*, **99**, 276—279).—When a mixture of boric anhydride and calcium oxide in any proportions is thrown into fused calcium chloride, the mixture becomes incandescent and dissolves completely to a clear liquid, but after some time the liquid becomes turbid owing to the separation of a crystalline *calcium chloroborate*, which can be obtained, by gradual solidification, in triclinic prisms several millimetres in length. This compound has the composition $3CaO,B_2O_3,CaCl_2$. It is slowly decomposed by alcohol and rapidly by water or moist air.

Calcium chloroferrite, $2CaO,2Fe_2O_3,CaCl_2$, is obtained in a similar manner, and forms very brilliant prisms with easy cleavage. the angle between the faces of the prism being 139°. This compound is usually obtained in thin lamellæ which are not altered by water or air.

Similar experiments with sulphuric and carbonic acids, chromium, aluminium, and zinc oxides, and manganese peroxide gave negative results. C. H. B.

Calcium Oxychloride, Silicates, and Chlorosilicates: Artificial Production of Wollastonite. By A. Gorgeu (*Compt. rend.*, 99, 256—259).—When calcium chloride is fused at a bright red heat in a current of moist air, it is gradually converted into oxychloride and eventually into oxide. The oxychloride appears to have the composition $CaCl_2,CaO$, but cannot be isolated because it is rapidly decomposed by alcohol and water. As the fused mass approaches this composition, the evolution of hydrochloric acid slackens considerably, but never ceases entirely until the whole mass is converted into oxide. If fusion is stopped at this point and the broken residue is left in contact with strong alcohol for two days, it yields insoluble slender needles, or birefractive lamellæ, which contain only 1 mol. calcium chloride to 8 mols. of calcium oxide, and are soluble in a solution of sugar. The presence of silica facilitates the decomposition of the chloride, but the presence of alkaline chlorides retards it considerably.

The action of precipitated silica on calcium chloride, in equal molecular proportions, at a high temperature, in presence of water-vapour, yields the silicate $CaSiO_3$, whilst with twice the amount of chloride the normal silicate Ca_2SiO_4 is formed. If the proportion of chloride is as high as 7 mols., chlorosilicates alone are obtained, and in presence of 20 per cent. of an alkaline chloride, the product is identical with wollastonite. With finely powdered sand in place of precipitated silica, decomposition takes place more slowly.

One of the chlorosilicates obtained, $SiO_2,2CaO,CaCl_2$, has been described by Le Chatelier (*Compt. rend.*, 1883). It forms rectangular birefractive plates belonging to the rhombic system. The other seems to have the composition $SiO_2,CaO,CaCl_2$, and forms almost regular hexagonal plates, the two optical axes of which approach each other very closely. The formation of the first compound requires prolonged fusion in presence of moisture, whilst the second is formed much more rapidly. Both compounds are decomposed by water and a solution of carbonic acid, and dissolve easily in dilute acids, although the acid silicate is insoluble in a 5 per cent. solution of acetic acid.

Artificial wollastonite is obtained by fusing 1 gram of silica with 15 grams of calcium chloride and 3 grams of common salt at a cherry-red heat in a current of moist air for half an hour. The product is treated with cold water and acetic acid, and a residue is obtained consisting of long prisms of wollastonite mixed with round grains of tridymite. Artificial wollastonite is identical in chemical and optical properties and crystalline form with the natural mineral, but is somewhat softer, the hardness of the mineral being 5, whilst that of the artificial product is only 3·5. C. H. B.

Calcium Oxysulphides. By A. GEUTHER (*Annalen*, **224**, 178—201).—The crystals which Herschell obtained by boiling sulphur in milk of lime and allowing the solution to cool in a vessel from which air was excluded, have been analysed by Rose, Schöne (*Pogg. Ann.*, **117**, 17) and others. They have the composition $CaS_3,2CaO + 10$ or $11H_2O$. The crystals dissolve in hydrochloric acid with formation of hydrogen supersulphide, H_2S_3, and a slight evolution of sulphuretted hydrogen. Schöne regarded the compound as $CaS_1,3CaO + 12H_2O$, but his results are vitiated by the fact that he decomposed the crystals before analysis by washing them with water.

Buchner's crystals, prepared by acting on milk of lime with sulphuretted hydrogen and slightly exposing the solution to the atmosphere, or by boiling calcium monosulphide with water and sulphur, have also been investigated by Rose and by Schöne. The former assigns to the compound the formula $CaS_5,5CaO + 20H_2O$, while the latter regards it as $CaS_4,4CaO + 18H_2O$. The author considers that the composition of the crystals is best represented by $CaS_3,3CaO + 14$ or $15H_2O$ (compare Divers, Trans., 1884, p. 270). The existence of the strontium oxysulphide, $SrS_4,SrO + 12H_2O$, described by Schöne, is regarded by the author as doubtful. W. C. W.

Preparation of Di- and Tri-calcium Phosphates by Precipitation. By E. L. DE BOUQUET (*Bied. Centr.*, 1884, 411).—The process is the subject of a patent. Into a hydrochloric acid solution of a phosphate is run, in fine jets, a solution of calcium hydrosulphide, preferably obtained from the residues of the Leblanc soda process. Sulphuretted hydrogen escapes, and the diphosphate is precipitated; if the acid solution is treated with the reagent to complete alkaline reaction, the triphosphate is reformed. J. F.

Crystallised Aluminium Orthophosphate. By A. DE SCHULTEN (*Compt. rend.* **98**, 1583—1584).—A concentrated solution of sodium aluminate is strongly acidified with phosphoric acid and heated in sealed tubes at 250° for several hours. Aluminium orthophosphate $Al_2(PO_4)_2$, is deposited in small pointed hexagonal prisms of sp. gr. about 2·59. The crystals do not lose weight at a bright red heat, and do not melt even at a white heat. They are insoluble in concentrated nitric and hydrochloric acids and are attacked with difficulty by hot concentrated sulphuric acid, but they are decomposed when fused with sodium carbonate.

The presence of sodium phosphate seems to be essential to the crystallisation of aluminium phosphate. If aluminium hydroxide or aluminium chloride is heated with phosphoric acid in a sealed tube, only a fine crystalline powder is obtained, but if the phosphoric acid is replaced by a very acid solution of sodium phosphate, the aluminium phosphate is obtained in distinct prisms.

By varying the proportions of the reagents, crystallised double phosphates may be obtained. Arsenic acid yields similar derivatives.

C. H. B.

Some Fluorine Compounds of Copper. By L. Balbiano (*Gazzetta*, **14**, 74—84).—The compounds formed by the action of ammonia on cupric chloride, bromide, and iodide have been prepared and examined, but as the corresponding fluorine derivatives are unknown, the author thought it desirable to undertake their investigation.

Copper Fluorides.—A fluoride and an oxyfluoride of copper were described by Berzelius, but no analysis of the latter was made. The author endeavoured to prepare cupric fluoride, by mixing warm solutions of cupric sulphate and potassium fluoride, but found that a greenish-white precipitate of cupric oxyfluoride, $CuF.OH$, was at once formed, whilst potassium cupric sulphate remained in solution, and was deposited as the solution cooled, the reaction being $2CuSO_4 + 2KF + H_2O = CuF.OH + CuK_2(SO_4)_2 + HF$. Similar results were obtained with cupric chloride except that no double potassium salt was formed.

The oxyfluoride is formed with great readiness, for when cupric oxide or carbonate is added to solution of hydrofluoric acid, the oxyfluoride begins to separate long before the acid is saturated. In order to prepare cupric fluoride, cupric carbonate is dissolved in aqueous hydrofluoric acid, and alcohol of 95 per cent. added, when the fluoride, $CuF_2,2H_2O$, is precipitated as a pale blue crystalline powder which is only sparingly soluble in water and is very readily decomposed, with formation of the oxyfluoride. This happens if the solution is heated; the crystals decompose also in 4 or 5 days with evolution of hydrofluoric acid if kept in a glass bottle, and more slowly in a platinum vessel. Cupric fluoride absorbs ammonia readily in accordance with the requirements of the equation $CuF_2,2H_2O + 3NH_3 = CuOHF(NH_3)_2 + NH_4F + H_2O$, yielding a product soluble in water; all attempts, however, to isolate a cuprammonium compound were ineffectual, the oxyfluoride being invariably obtained instead.

Cupric Fluosilicate.—This salt was prepared by Stolba's method (*J. pr. Chem.* **102**, 7) and twice recrystallised. It contains 6 mols. H_2O (Marignac 6; Stolba $6\frac{1}{2}$), two of which it loses at 90°, or in a vacuum over sulphuric acid. When heated to 130—140°, it is decomposed in accordance with the equation $CuSiF_6,6H_2O = CuF.OH + SiF_4 + HF + 5H_2O$, a residue of cupric oxyfluoride being left. Cupric fluosilicate containing 4 mols. H_2O, absorbs ammonia, but no cuprammonium derivative of hydrofluosilicic acid is formed. On treating the bright blue product of the reaction with water, a blue mass is left undissolved, consisting of silica and a cuprammonium compound; the latter is soluble in dilute ammonia, and on heating this solution cupric oxyfluoride is deposited. The action of ammonia on the fluosilicate is therefore: $CuSiF_6,4H_2O + 7NH_3 = CuF.OH,2NH_3 + 5NH_4F + SiO_2 + H_2O$.

The water of crystallisation in the fluorine compounds of copper seems to have great influence on the action of ammonia. It is possible, however, that cuprammonium compounds might be formed from the anhydrous fluorides by the action of ammonia.

C. E. G.

Bromine Compounds of Tin. By B. RAYMAN and K. PREIS (*Annalen*, **223**, 323—334).—Most of the results detailed in this paper have already appeared (Abstr., 1883, 424), the following are new:—

Stannous bromide, $SnBr_2$, prepared according to Baland's method, by heating tin in a current of hydrobromic acid, and purified by distillation, forms a transparent crystalline mass of pale-yellow colour, melts at 215·5° to a pale-yellow transparent liquid, and resolidifies at 215°. It has sp. gr. 5·117 at 17°. Water partly decomposes it with separation of a white oxybromide.

A hydrate of stannous bromide, $SnBr_2 + H_2O$, is obtained by dissolving tin in warm concentrated hydrobromic acid. It can be obtained crystallised in colourless needles or in thin prisms. *Ammonium stannous bromide*, $(NH_4)_2SnBr_4 + H_2O$, forms fine colourless needles. *Ammonium stannous chlorobromide*, $(NH_4)_2SnBr_2Cl_2 + H_2O$, is obtained by strongly cooling mixed solutions of stannous bromide and ammonium chloride. It forms white porcelain-like crystals of the rhombic system, $\breve{a} : \bar{b} : c = 0·69588 : 1 : 0·77240$. Observed faces ∞P, $\infty P\breve{\infty}$, $P\breve{\infty}$. Crystals were also obtained containing less chlorine than the above.

Stannic bromide is obtained by sublimation in small well-formed crystals showing numerous faces and possessing almost the lustre of the diamond. The following double salts are described; they are obtained by evaporation and crystallisation of mixed solutions of the component salts:—

Sodium stannic bromide, $Na_2SnBr_6 + 6H_2O$, forms pale-yellow prismatic crystals, very soluble in water. *Calcium stannic bromide*,

$$CaSnBr_6 + 6H_2O,$$

crystallises in slender needles and is very deliquescent. *Strontium stannic bromide*, $SrSnBr_6 + 6H_2O$, could only be obtained mixed with stannic bromide as a pale-yellow, deliquescent, crystalline mass. *Magnesium stannic bromide*, $MgSnBr_6 + 10H_2O$, forms deliquescent pale-yellow tabular crystals. *Manganous stannic bromide*, $MnSnBr_6 + 6H_2O$, forms large pale-yellow deliquescent crystals. *Ferrous stannic bromide*, $FeSnBr_6 + 6H_2O$, forms granular crystals of green to yellow colour. *Nickel stannic bromide*, $NiSnBr_6 + 8H_2O$, forms apple-green granular deliquescent crystals. *Cobalt stannic bromide*, $CoSnBr_6 + 10H_2O$, is obtained in yellowish-red tabular deliquescent crystals.

A. J. G.

Idunium, a New Element. By M. WEBSKY (*Dingl. polyt. J.*, **253**, 391).—The author found an element resembling vanadium in a mineral obtained from the Aquadita Mine, La Plata. This mineral was composed mainly of zinciferous lead vanadate. On treating the vanadic acid with ammonium chloride, ammonium vanadate is precipitated, idunic acid remaining in the mother-liquor, which on addition of ammonium sulphide is separated as red idunic oxide.

D. B.

Arsenovanadic Acid. By P. FERNANDEZ (*Ber.*, **17**, 1632).—Chemically pure vanadic acid, obtained by precipitating ammonium metavanadate with nitric acid, is added in excess to a warm concentrated solution of arsenic acid, and the whole boiled for some hours. The solution is then filtered and concentrated, when brilliant gold-coloured crystalline nodules are obtained. The arsenovanadic acid thus formed has the composition $As_2O_5,V_2O_5,11H_2O$.

A. K. M.

New Tungstoborates. By D. KLEIN (*Compt. rend.*, **99**, 35—37).—When 3 parts of boric acid are dissolved in a boiling solution of 4 parts of sodium paratungstate, the liquid yields no precipitate with inorganic acids. The excess of boric acid and the borates which are formed are removed by crystallisation, when a heavy mother-liquor is obtained closely resembling that produced by the action of boric acid on normal sodium tungstate (Abstr., 1881, 224, and *Compt. rend.* **91**, 1070). When this mother-liquor is evaporated over sulphuric acid, it deposits the disodium tungstoborate previously described. If the still liquid portion is acidified with hydrochloric acid and mixed with barium chloride, it yields a pulverulent white precipitate, and the filtrate on concentration deposits rhombohedral crystals which are under examination, and afterwards triclinic prisms, which when recrystallised yield a salt crystallising in quadratic octahedra—in all probability di-barium tungstoborate (*loc. cit.*). The triclinic salt has the composition $10WO_3,B_2O_3,2BaO + 16H_2O$.

If the mother liquor from the sodium tungstoborate is concentrated without addition of hydrochloric acid, it yields first a pulverulent deposit and afterwards monoclinic crystals which have the same composition as the triclinic crystals already described, and like them are decomposed by recrystallisation.

C. H. B.

Double Chlorides of Chromium. By L. GODEFFROY (*Compt. rend.*, **99**, 141—144).—The amorphous violet substance obtained when an excess of hydrochloric acid acts on potassium dichromate in presence of a little alcohol is not pure chromic potassium chloride, but is a mixture of this salt with chromic chloride. Compounds of chromic chloride with other metallic chlorides are formed whenever the two chlorides are brought in contact in presence of hydrochloric acid of at least 32·5 per cent. Combination is promoted by elevation of temperature, but is prevented within certain limits by the presence of water. The best method, however, of preparing the chromic potassium chloride, $Cr_2Cl_6,4KCl$, for example, is to mix 700 grams of alcohol with 300 grams of finely powdered potassium dichromate, and pass chlorine gas into the mixture for six or eight hours. The theoretical yield of the double chloride is obtained as a violet-red precipitate.

The double chlorides obtained by this method form crystalline powders of various colours, the colour deepening and varying in tint with elevation of temperature. They can be obtained in distinct crystals by heating the powders with a sufficient quantity of 40 per cent. hydrochloric acid in sealed tubes at 120—130°, and cooling very slowly. The double chlorides are very stable even at a high temperature, but they decompose rapidly in presence of a trace of moisture. When thrown into water, they at first dissolve with their characteristic colour, but the double salt quickly decomposes with formation of hydrochloric acid, the chloride of the second metal, and an oxychloride which crystallises with difficulty. Decomposition ceases when the liquid contains 32·5 per cent. of free hydrochloric acid.

Double iodides and bromides are obtained under the same conditions.

Chromic Acid and Chromic Anhydride. By H. MOISSAN (*Compt. rend.*, **98**, 1581—1583).—*Purification of Chromic Anhydride.*—In order to purify chromic anhydride from sulphuric acid, which it frequently contains, it is very carefully fused in a platinum capsule, heated until the greater part of the sulphuric acid is driven off, and the contents of the capsule then poured on to a porcelain slab. The unexpelled sulphuric acid runs out first, and the chromic anhydride which afterwards flows from the capsule and solidifies almost instantly contains but traces of sulphuric acid.

Chromic Acid.—An excess of chromic anhydride is mixed with a small quantity of water, the mixture heated at 100° for a short time, and the liquid poured off and cooled in melting ice. After some time, it deposits small red highly deliquescent crystals which melt readily, and give off water when heated, leaving chromic anhydride. The crystals have the composition H_2CrO_4.

Action of Hydrochloric Acid Gas on Chromic Anhydride.—When purified and dry chromic anhydride is treated with hydrochloric acid gas, chromyl dichloride is formed at ordinary temperatures, and the reaction is accelerated by heat. The water which is also produced decomposes part of the chromyl dichloride, and yields an oily substance entirely soluble in water. This substance was obtained by Dumas, but has not been analysed. Hydrobromic and hydriodic acids under the same conditions give no similar reaction. Perfectly dry chlorine has no action on chromic anhydride, but if it contains hydrochloric acid, or if it contains water and is heated at 150°, chromyl dichloride is formed.

The chromates of the alkalis, barium, lead, and silver all yield chromyl dichloride when treated with hydrochloric acid gas.

C. H. B.

Sulphur Compounds of Molybdenum. By G. KRÜSS (*Ber.*, **17**, 1769—1774).—In a previous communication (this vol., 160) the author described, under the name of orthoxythiomolybdates, a series of salts derived from an acid, $H_2MoO_2S_2$, lying midway between H_2MoO_4 and H_2MoS_4. He has now obtained other intermediate acids, and therefore proposes to modify his nomenclature by calling the above compounds dithiomolybdates. The following table contains the new compounds he has obtained :—

Name.	Formula.	Character.	Behaviour with water.
Sodium monothiomolybdate..	Na_2MoO_3S	Pale yellow crystalline	Soluble to golden solution.
Potassium dithiomolybdate ..	$K_2MoO_2S_2$	Golden yellow needles	Soluble.
Potassium sulphomolybdate..	$K_8Mo_4S_9O_7$	Yellow monoclinic prisms	Soluble.
Perthiomolybdic acid	H_2MoS_5	Red, amorphous	Very sparingly soluble.
Hydrogen potassium perthiomolybdate	$KHMoS_5$	Red, crystalline	—

The three first-named salts were obtained by melting together molybdic acid and the respective alkaline carbonate, and treatment of the melt with alkaline sulphide. The free acid may be obtained from the last salt in the above list by treating it with acetic acid. Potassium sulphide dissolves this acid to a brownish-red solution, which probably contains K_3MoS_5. This salt is, however, very unstable, and its solution is decomposed by boiling with evolution of hydrogen sulphide, separation of sulphur, and formation of molybdenum trisulphide. L. T. T.

Sulphur Compounds of Molybdenum. By G. Krüss (*Annalen*, **225**, 1—57).—In this paper a fuller account is given of the preparation and properties of sulphur compounds of molybdenum described by the author in the *Berichte* (this vol., p. 160, and preceding Abstract). The principal classes of compounds here investigated are the oxythiomolybdates, the thiomolybdates, and the perthiomolybdates.

Oxythiomolybdates, intermediate between the molybdates and the thiomolybdates, are divisible into several series according as the oxygen-atoms of molybdic acid are replaced by sulphur. *Monothiomolybdates* of general formula M'_2MoO_3S, in which M' represents a monatomic metal. The sodium salt obtained by treating sodium trimolybdate with sodium hydrogen sulphide is a hygroscopic golden substance, a solution of which gives a blue coloration with sulphuric acid, probably due to the liberation of monothiomolybdic acid. *Dithiomolybdates* of general formula $M'_2MoO_2S_2$, obtained by passing hydrogen sulphide into concentrated solutions of the molybdates in the alkaline hydrates, crystallise in golden or reddish-golden needles. Derivable from them are the *pyrodithiomolydates* of general formula $M'HMo_2O_4S_3$, the salts of an acid, $H_2Mo_2O_4S_3$ ($2H_2Mo_2O_2S_2$ — H_2S), which stand in the same relation to dithiomolybdates as ortho- to pyro-phosphoric acid,* the ammonium salt of which, on treatment with ammonia, is reconverted into the ammonium salt of dithiomolybdic acid, thus: $NH_4HMo_2O_4S_3 + NH_3 = (NH_4)_2MoO_2S_2 + MoO_2S$. Solutions of the alkali pyromolybdates give brown or reddish-brown precipitates with solutions of salts of aluminium, chromium, manganese, copper, lead, silver, and uranium; and yellow precipitates with mercury, platinum, lanthanum, and cæsium salts. There is also described a potassium thiomolybdate, $K_8Mo_4S_9O_7$, prepared by dissolving potassium trimolybdate in potassium hydrosulphide, with addition of alcohol. A red oil is precipitated, from which golden-yellow monoclinic prisms can be separated. This salt can be distinguished from potassium thio- and dithio-molybdate by forming an immediate precipitate with solutions of barium salts.

---

* In the Abstract mentioned, the last two lines on p. 160 should read thus: Ammonium pyroxythiomolybdate is a reddish golden precipitate, having the composition $NH_4HMo_2O_4S_3$, the salt of an acid, $H_2Mo_2O_4S_2$ (= $2H_2MoO_2S_2 - H_2S$), &c.

Thiomolybdates, M_2MoS_4, obtained by passing hydrogen sulphide into solutions of the molybdates in concentrated alkalis, are brilliant red compounds, crystallising in the rhombic system. If the alkalis be more concentrated, salts are formed of the composition $M'_6Mo_3S_9$, called *basic thiomolybdates*, of which the potassium salt crystallises in red rectangular plates. Its aqueous solution gives yellow precipitates with calcium, strontium, and magnesium salts, golden-brown with manganese, and olive-green with cadmium salts.

The oxythio- and thio-molybdates give a golden-green coloration to a Bunsen flame; the absorption spectrum of aqueous solutions of the oxythiomolybdates is at the most refrangible end of the spectrum, but of the normal thiomolybdates at the red end.

Perthiomolybdates.—In the course of the preparation of molybdenum tetrasulphide, there was obtained a certain quantity of blood-red crystals of the composition $KHMoS_5$, probably formed by the action of hydrogen sulphide on potassium pyrothiomolybdate, an intermediate product of the reaction, thus: $K_2Mo_2O_7 + H_2S = KHMoS_5 + KHS + MoS_2$. In solutions of this salt, dilute acids cause a precipitation of perthiomolybdic acid, H_2MoS_5, insoluble in water and alcohol. It readily gives off hydrogen sulphide, and is converted into molybdenum tetrasulphide. This potassium salt forms the first case of an acid primary thio-salt; it may be reproduced from the acid by heating it with potassium hydrosulphide.

In conclusion, brief mention is made of sulphur-derivatives of vanadic and manganic acids. V. H. V.

Mineralogical Chemistry.

Presence of the Diamond in an Indian Pegmatite. By Chaper (*Ann. Chim. Phys.* [6], 2, 284—288).—After noticing the various theories as to the origin and formation of the diamond, the author announces that he has found diamonds *in situ* in a pegmatite, in Nizam, in the Presidency of Madras. The results of his observations show that the pegmatite contains epidote to a large amount, and also oligoclase and microcline, and it seems more than probable that it is this rock which has furnished the diamonds contained in the various deposits worked in Hindostan. There appears to be more than one mode of formation of the diamond, as it would be very difficult to show any analogy between the pegmatite and either the magnesian mud of the South African diamond beds, or the rock which has given rise to the latter by its disintegration, as it contains no granitic fragments.

As the diamond has been found in a rock as ancient as pegmatite, it may be found in all the products of the erosion or disintegration of pegmatite; that is to say, in the quartzites with or without mica, in the clays. in pudding-stones, &c. Moreover, the presence of the diamond in itacolumites and other secondary rocks, accompanied by crystallised quartz, apatite, rutile, oligist, &c., is no evidence that it has been formed in the sedimentary deposits. C. E. G.

Origin and Distribution of Phosphorus in Coal and Cannel Coal. By A. Carnot (*Compt. rend.*, 99, 154—156).—The presence of phosphorus in coal ash has already been observed by several chemists. The author has determined the amount of this element in various fossil plants, and in different samples of coal, with the following results:—

	P per cent.	
	I.	II.
Fossil calamodendrom..........	0·00195	0·00245
„ cordaites................	0·00082	traces
„ lepidodendron	traces	traces
„ psaronius (fern)	0·00271	0·00712
Mineral charcoal	0·00399	
Coal from Commentry..........	0·00163	
„ Ferrières	0·01385	
Anthracite....................	0·01467	
Cannel from Commentry........	0·04260	0·03912
„ Lancashire	0·02852	
„ Wigan............	0·02246	
„ Newcastle	traces	
„ Glasgow	0·00572	
„ Virginia	0 02771	
Paraffin shale from New South Wales......................	0·01956	
Boghead cannel from Autun	traces	
„ „ Frioul	0·06275	

Microscopic examination shows that cannel is composed of decomposed vegetable fragments of very various character, but generally contains a large number of spores or pollen grains very irregularly distributed (Renault). The two specimens which were almost free from phosphorus were found to be equally free from spores. Analysis of the spores and pollen of the modern representatives of carboniferous plants (*Lastræa*, *Polystichum*, *Osmunda*, *Lycopodium*, &c.) shows that these parts are very much richer in phosphorus than the other organs of the plants. It follows that the greater part of the phosphorus present in coal has been derived from the spores and the pollen of the plants from which it has been formed.

In the same piece of coal, there are frequently alternate brilliant and dull layers, the former having been derived from the wood, bark, and roots, the latter from the leaves and other *débris*. In a sample from Commentry the dull layers gave 10·5 per cent. of ash, and contained 0·00815 per cent. of phosphorus; the bright layers contained 3·8 per cent. of ash and 0·00326 of phosphorus. C. H. B.

Deposit of Saltpetre (Potassium Nitrate) at Cochabamba, Bolivia. By SACC (*Compt. rend.*, **99**, 84—85).—To the east of Cochabamba, near the village of Arané, there is an immense saline deposit of the composition: Potassium nitrate, 60 7; borax, traces of sodium chloride and water, 30·7; organic matter, 8·6 = 100. The soil on which this deposit rests is brown and inodorous when dry, but when moistened it evolves ammonium carbonate and hydrosulphide. It has the composition:—incombustible residue, 74·2; borax and salts, 15·5; organic matter, water, and ammonium salts, 10·3 = 100. The incombustible residue consists of very fine sand, and a very large proportion of calcium, iron, and magnesium phosphates. The saltpetre has been formed by the oxidation of the ammoniacal salts in the soil in presence of potash and soda derived from the decomposition of the slates on which the soil rests. The potassium nitrate has reached the surface by capillary action, whilst the more soluble sodium nitrate has been washed down by the rains to the drier and hotter districts along the coast. Fossil bones are very common in the district, and it is possible that this deposit at Arané, which is sufficient to supply saltpetre to the whole world, is the product of the decomposition of a gigantic deposit of prehistoric animals. C. H. B.

Pinnoite, a New Borate from Stassfurt. By H. STAUTE (*Ber.*, **17**, 1584—1586).—This mineral differs in its chemical and physical properties from the borates previously found at Stassfurt. It has a sulphur or straw-yellow colour, but is sometimes green, with a shade of red or grey. Hardness is 3—4; sp. gr. = 2·27. Its formula is $MgB_2O_4,3H_2O$. When heated, it decrepitates, becomes white, and melts with some difficulty, imparting a green coloration to the flame. Mineral acids dissolve it readily on heating. When boiled with water, an alkaline liquid is obtained, from which a flocculent precipitate separates, but redissolves as the solution cools. A. K. M.

Haydenite. By H. N. MORSE and W. S. BAYLEY (*Amer. Chem. J.*, **6**, 24—25).—This mineral from Baltimore was first described as an independent species by Cleaveland, and confirmed by Levy's assertion of its monosymmetric form. J. D. Dana and Des Cloizeau have, however, found the mineral to be really rhombohedral, like chabazite; but the only two published analyses by B. Silliman and Delesse do not agree with each other, or with Rammelsberg's formula for chabazite. The author has analysed an apparently undecomposed material, with the result that its composition agrees with the chabazite formula, and haydenite is, therefore, chemically and physically identical with chabazite.

SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.	BaO.	K_2O.	H_2O.		
49·29	18·06	0·79	5·13	0·86	1·46	3·16	21·31	=	100·07
49·19	18·07	0·88	5·19	0·86	1·48	2·84	21·31	=	99·81

H. B.

Avalite. By S. M. Losanitsch (*Ber.*, **17**, 1774—1775).—Avalite is the name the author gives to a new chromium-mineral which he has obtained from the neighbourhood of Mount Avala, near Belgrade. This mineral occurs in clay, and many minerals from that district, in the form of small green scales. The author freed it from clay, &c., by levigation, the mineral being specifically lighter than the clay. This mineral is not attacked by the ordinary acids, but is easily decomposed by means of hydrofluoric acid, or by fusion with alkaline carbonates. The analyses gave the following results:—

	I.	II.	III.
SiO_2	56·13	55·59	61·52
Cr_2O_3	14·59	10·39	9·82
Al_2O_3	14·37	16·60	14·14
K_2O	3·54	3·69	2·51
Fe_2O_3	1·10	2·55	1·28
MgO	0·43	1·74	1·20
Chromite	1·68	1·80	3·43
H_2O (hygroscopic)	2·39	1·39	0·73
Loss on ignition	5·38	5·42	4·48
	99·61	99·17	99·11

The author considers the water, chromite, iron, and magnesium to be impurities. The green colour of much of the quarzite occurring in serpentine from the district of Belgrade is due to the presence of avalite. L. T. T.

Origin of Phosphorites and Ferruginous Clays in Limestone Districts. By Dieulafait (*Compt. rend.*, **99**, 259—262).—From numerous analyses of phosphorites and the associated rocks, the author concludes that the calcium phosphate existing in the caverns in the south-west of France does not represent one-tenth of that which existed in the limestone which has been removed during the formation of the caverns. The ferruginous clays which accompany and often cover the phosphates have the same composition as the residue obtained when the rocks forming the walls of the cavern are treated with a dilute oxidising acid. Substances such as manganese, nickel, cobalt, zinc, copper, and iodine, which exist in very small quantities in the ordinary rocks of the phosphatic districts, are found in relatively high proportion in the phosphorite and the clays associated with it. It is possible, therefore, that the phosphorites in the southwest of France have been extracted from the surrounding rocks by chemical reactions in the wet way. C. H. B.

The Granite District of the Black Forest. By J. H. KLOOS (*Jahrb. f. Min.*, 1884, 1, 66).—The principal rock of the middle portion of the Wiesen Valley is a coarsely granular biotite-granite, which differs from the ordinary granite of the Black Forest in that muscovite is always absent. In this granitic mass, other crystalline rocks are frequently met with, both in veins and in irregular masses. The description of these rocks in the neighbourhood of the Wiesen Valley, forms the subject of this paper, special attention being paid to the diorites and gabbro of Ehrsberg, Waldmatt, and Kastel.

This granitic district of the southern portion of the Black Forest presents remarkable examples of the structural and physical differences between minerals of the same or similar composition from the older and more recent massive rocks, and also of the alterations and decompositions to which these minerals have been subjected after they have built up the rocks. The structure and physical properties of the orthoclase, the principal mineral in the predominating biotite-granite, are totally different from those of the potash felspar usually met with in similar districts of the more recent crystalline rocks. A labradorite, perfectly and uniformly filled with a powder rich in manganese, like that presented in the Ehrsberg gabbro, is unknown in more recent eruptive rocks. Diallage and the green radiated hornblende occur in this district in a form totally different from that usual in trachytes, basalts, and other more recent rocks. The occurrence of the quartz proves that it has crystallised out under unusual conditions, or that subsequent metamorphism has, to a great extent, taken place. An excellent example of the subsequent alteration of a mineral by the action of water is presented by the conversion of labradorite into an albite and zeolitic mineral. The various stages of this alteration may be seen both in the granite itself and in the rock masses subordinate to it. As examples may be mentioned the alteration of the plagioclase from the granitic and dioritic rocks into mica-like minerals, finally resulting in perfect pseudomorphs; and secondly, the alteration of the biotite of the finely granular granites into mica, which occurs to a small extent in the Ehrsberg diorite, and in a very well-marked manner in the Kastel gabbro; the alteration of the biotite of the finely granular granites into a soft scaly unelastic substance; the alteration of olivine into serpentine in the Ehrsberg picrite; the alteration of augite or hornblende in the minettes into a new fibrous yellow mineral, the exact nature of which has not yet been determined; and the alteration of the pinite and other constituents in the pinite-porphyry, are further examples.

B. H. B.

Mica-diorites and Kersantites of Southern Thuringia and the Frankenwald. By R. PÖHLMANN (*Jahrb. f. Min.*, 1884, *Beilage*, 67—160).—The vein rocks, rich in mica, occurring in the northern flank of the Fichtelgebirge, described by Gümbel as "lamprophyry," are, for the most part, kersantites; mica-diorites and minettes occur to a smaller extent. The kersantites are porphyritic rocks, and contain as constituents brown magnesium mica, felspar, augite partially replaced by hornblende, quartz, calcite, titanite, apatite, magnetite, and chromite. The magnesium mica was always found to be optically biaxial. It probably belongs partly to anomite, and partly to meroxene. In order to determine the chemical nature of the magnesium mica, that from the Bärenstein rock was analysed, giving the following results:—

SiO_2.	TiO_2.	Al_2O_3.	Mn_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.
38·72	0·75	16·26	trace	7·40	5·25	1·86	18·74

K_2O.	Na_2O.	F.	H_2O.	Total.	Sp. gr.
8·89	trace	trace	2·60	100·47	2·88

The felspar is, for the most part, triclinic (oligoclase, labradorite); but orthoclase is also present. The rather light coloured monoclinic augite on decomposing hardly ever passes into uralite, but into chloritic products. The presence of chromite crystals is worthy of note. The calcite is always of a secondary nature. The same is, to a certain extent, true of the quartz, if the porphyritic crystals are not taken into account.

The mica diorites are sometimes rich in augite and hornblende, as, for example, in the rock from Marlesreuth; at other times these bisilicates are entirely wanting, as is the case in the rock from Ködelschutz.

Contact alterations of the kersantite were observed, both in the rock itself and in the limestones and slates, but they are of slight importance. The kersantites do not essentially differ in structure and mineralogical composition from those known in other districts. The term "lamprophyre" is consequently incorrect from a petrographical point of view, more especially as it was used as a collective name for rocks of different classes. B. H. B.

Composition of the Water of the New Mineral Springs at Freyersbach. By K. BIRNBAUM (*Ber.*, 17, 1614—1615).—The com-

Parts per 10,000.

Organic Chemistry.

Properties of Liquid Methane and its Use as a Refrigerator. By S. WROBLEWSKI (*Compt. rend.*, **99**, 136—137).—The methane employed was obtained by heating sodium acetate with soda-lime, and was liquefied by means of liquid ethylene. Its critical temperature is −73·5° and the critical pressure 56·8 atmos. The following table shows the relation between the boiling point and the pressure:—

Atmos.	Boiling point.
56·8	− 73·5°
52·5	− 75·9
24·9	− 98·2
16·4	− 113·4
6·7	− 130·9

At atmospheric pressure, methane does not solidify, but boils between −155 and −160°, and thus gives a temperature intermediate between those obtained with liquid oxygen and liquid ethylene respectively.

C. H. B.

Behaviour of Ethylidene Chloride with Ethylamine and Amylamine. By A. W. HOFMANN (*Ber.*, **17**, 1907—1908).—When ethylidene chloride is heated with ethylamine, collidine and ethyl chloride are formed, together with small quantities of ammonia and triethylamine:—

I. $4C_2H_4Cl_2 + 7NH_2Et = C_8H_{11}N,HCl + 6NH_2Et,HCl + EtCl$.
II. $3(NH_2Et,HCl) = 2NH_4Cl + NEt_3HCl$.

Amylamine yields collidine, diamylamine, triamylamine, and ammonium chloride.

Acetamide also yields collidine, together with acetic chloride.

L. T. T.

Action of Chlorine on Isobutylene. By CHÉCHOUKOFF (*Bull. Soc. Chim.*, **41**, 253—254).—The action of chlorine on isobutylene does not give rise to a chloride of that hydrocarbon, but to two isomeric chlorisobutylenes. The first, *isocrotyl chloride*, $CMe_2{:}CHCl$, forms isobutaldehyde when the aqueous solution is heated; and when warmed with sodium ethylate, it yields *ethyl isocrotyl ether*. The second *chlorisobutylene* distils at 72—78°, and is insoluble in water. On heating it with a solution of potassium carbonate, it yields an alcohol boiling at 111—115°. This combines with bromine, forms a crystalline alcoholate, and evolves hydrogen chloride when treated with phosphorus pentachloride. The corresponding ethereal acetate boils at 119—121°. The constitution of this chlorisobutylene is probably $CH_2{:}CMe.CH_2Cl$, and that of the alcohol $CH_2{:}CMe.CH_2.OH$.

W. R. D.

Caucasian Petroleum. By MARKOWNIKOFF and OGLOBINE (*Bull. Soc. Chim.*, **41**, 258).—Hydrocarbons of the C_nH_{2n} series, called by the authors *naphthenes*, constitute the principal part of Caucasian petroleum. The members of this group of hydrocarbons do not form nitro-derivatives, and resemble the paraffins in not yielding additive compounds, and also in the formation of alcohols from the chlorinated derivatives. Certain of the chlorinated derivatives are convertible, by abstraction of hydrogen chloride, into hydrocarbons of the C_nH_{2n-2} series, which behave like unsaturated compounds, and may be termed *naphthylenes*.* When oxidised, the naphthenes form oxidation-products or are converted into higher isologues, and thus possess all the characters of closed-chain hydrocarbons. The portion of Caucasian petroleum having a higher boiling point, probably contains hydrocarbons of the C_nH_{2n-2} and C_nH_{2n-4} series, whilst 10 per cent. of the petroleum consists of benzenoïd hydrocarbons belonging to known series, and also to a series of hydrocarbons isomeric with styrolene and its isologues. These compounds furnish brominated derivatives, but no additive compounds. Their benzenoïd character is exhibited in the formation of nitro- and sulpho-derivatives. The petroleum also contains acid and neutral compounds containing oxygen.

W. R. D.

Preparation of Cyanides and Ferrocyanides from Trimethylamine. By E. WILLM (*Bull. Soc. Chim.*, **41**, 449—451).—This paper describes the commercial application of the decomposition of trimethylamine at a red heat by which the whole of the nitrogen is obtained as hydrocyanic acid and ammonium cyanide, together with gaseous hydrocarbons. The vapour of trimethylamine is passed into a retort heated to bright redness, and the products are passed first into sulphuric acid, where the ammonium cyanide is converted into hydrocyanic acid; and secondly into a solution of soda, potash, or calcium hydroxide, where the acid is converted into the corresponding cyanide. In this way, concentrated solutions of the cyanides are obtained, while the gaseous hydrocarbons, free from ammonia and hydrogen cyanide, pass on and are collected for use in lighting the works. From the solution of alkaline cyanide, the corresponding ferrocyanide is obtained by adding ferrous oxide, freshly precipitated from a solution of ferrous chloride by milk of lime, and this liquid after filtering yields, without further concentration, crystals of ferrocyanide, which are as pure as those obtained after the third crystallisation by the older method. The process appears to have an important bearing on the economical utilisation of the residues from molasses. W. R. D.

---

* It would be better, perhaps, to call these hydrocarbons naphthines (analogous to ethine), seeing that the term naphthyl has long been used to signify the hypothetical radical $C_{10}H_7$.—C. E. G.

Constitution of some Simple Cyanogen-compounds. By G. Calmels (*Compt. rend*, **99**, 239—241).—When finely powdered mercuric cyanide is heated with an equal weight of methyl iodide in sealed tubes at 110°, the products are mercuric iodide, methylcarbamine, and a tarry substance formed by the polymerisation of the carbamine at the moment of its formation. Zinc cyanide must be boiled for at least two days with ethyl iodide (in a flask with an inverted condenser), in order to obtain an appreciable quantity of ethylcarbamine. The failure of this reaction with certain cyanides is due to the fact that the conversion of these cyanides into iodides requires a temperature at which the carbamine is decomposed.

When an ethereal solution of zinc-ethyl is mixed with an ethereal solution of cyanogen iodide, zinc cyanide is precipitated and ethyl iodide is formed. The addition of an ethereal solution of cyanogen iodide to dry zinc methyl iodide, however, produces a considerable development of heat, and zinc iodide, zinc cyanide, methyl iodide, and methylcarbamine are formed. When an ethereal solution of mercuric methide is heated with an equivalent quantity of cyanogen iodide in a sealed tube at 50°, mercuric cyanide is formed; but if the temperature is raised to 100°, the inverse reaction takes place and ethylcarbamine is produced. The action of cyanogen iodide in ethereal solution on metallic zinc yields zinc cyanide and free iodine, the latter slowly combining with the excess of zinc. It is evident that in these reactions the metallic cyanide is formed in preference to the iodide, but this fact does not determine the constitution of cyanogen iodide, for a metallic cyanide is always an intermediate product of the action of this substance on organo-metallic radicles. When, however, an ethereal solution of aluminium-ethyl is mixed with a similar solution of cyanogen iodide, aluminium iodide and acetonitrile are produced, but no trace of ethylcarbamine is formed. It follows that the constitution of cyanogen iodide is represented by the formula $N\equiv C-I$, and is strictly analogous to the constitution of the chloride and bromide.

These reactions confirm the existence of two distinct groups,

cyanides and isocyanides, amongst the most simple compounds of cyanogen.
C. H. B.

Ethereal Salts of Cyanuric Acid. By PONOMAREFF (*Bull. Soc. Chim.*, **41**, 315).—The ethereal salts of cyanuric acid were obtained by the action of sodium methoxide and ethoxide on cyanogen iodide or bromide, or on the polymerides of the latter. These compounds combine with mercuric chloride, and when ethyl cyanurate is heated at 180—200°, it is converted into ethyl isocyanurate. Heated to a moderate extent with baryta-water, *barium diethyl isocyanurate* is formed; the corresponding acid is isomeric with that obtained by Limpricht. The ethereal salt can be reformed by heating the lead salt of the acid with ethyl iodide. The acid obtained by decomposing the ethereal salts of cyanuric acid with potash is identical with that derived from carbamide. The same ethereal salts can be obtained by heating the silver salt of cyanuric acid with ethyl or methyl iodide, but there are also produced the corresponding salts of isocyanuric acid. When monopotassium and dipotassium cyanurates are treated in a similar manner at 180°, the first salt gives rise to the diethyl-derivative, and the second salt to the triethyl-derivative of cyanic acid. The author concludes that the salts of the formula $(CONEt)_3$ are more stable than those of the formula $(CNOEt)_3$.

W. C. W.

Action of Aluminium Chloride on a Mixture of Alcohols of the Paraffin Series with Ethyl Chlorocarbonate. By B. Pawlewski (*Ber.*, **17**, 1606—1607).—The author finds this reaction is similar to that recently described by him in which ethyl phenylcarbonate is produced (this vol., p. 1005). Aluminium chloride, in considerable excess, is added gradually to a mixture of propyl alcohol with ethyl chlorocarbonate, and the whole allowed to remain for several hours; the mass is then warmed, when a violent action sets in accompanied by an abundant evolution of hydrochloric acid. The product is treated with water and a 10 per cent. solution of hydrochloric acid, then dried and fractioned. The ethylic propylcarbonate, PrO.COOEt, obtained boils at 145·6° (corr.); its sp. gr. is 0·9532 at 20°.
A. K. M.

Purification of Methyl Alcohol. By J. Regnauld and Villejean (*Compt. rend.*, **99**, 82—84).—Methyl alcohol prepared from methyl oxalate almost always contains small quantities of some substance, possibly either acetone or ethyl alcohol, which yields iodoform when treated with iodine. To obtain perfectly pure methyl alcohol, the alcohol prepared from the oxalate is mixed with 10 per cent. of iodine, and sodium hydroxide added gradually until the reaction is distinctly alkaline. The liquid is then carefully distilled. In this process the foreign organic substances are converted into iodoform, and the latter is decomposed by the alkali into an iodide and a formate.

The peculiar saffron-like odour observed when iodine is mixed with an aqueous solution of potash or soda was obtained by the authors with iodine liberated by the action of chlorine on a solution of fused potassium iodide in water distilled with potassium permanganate, and recently fused sodium hydroxide. The glass vessels containing these substances had previously been strongly heated, and were exposed to the air as little as possible. It is evident therefore that if the odour is due to iodoform formed from traces of organic matter, the quantity of iodoform must be infinitesimal. C. H. B.

Action of Zinc Propyl on Acetic Chloride. By MARKOWNIKOFF (*Bull. Soc. Chim.*, **41**, 259—260). From analogy, it was expected that the reaction of zinc propyl with acetic chloride would give the tertiary alcohol, *methyl dipropyl carbinol*, but it is found to yield the secondary alcohol, *methyl propyl carbinol*, and propylene. This is explained by the action of water on the unstable compound $CMePr_2.ZnOPr$, thus:—

$$CMe(C_3H_7)_2.ZnOC_3H_7 + 2H_2O = C_3H_6 + Zn(OH)_2 + CHMe(C_3H_7).OH.^*$$

W. R. D.

Cetyl Alcohol and Cetylacetic Acid. By F. KRAFFT (*Ber.*, **17**, 1627—1631). In a previous paper (Abstr., 1883, 1075) the author described the preparation of hexadecyl alcohol by the reduction of palmitaldehyde, and proved its identity with the chief constituent of "cetyl alcohol" from spermaceti. Commercial cetyl alcohol (m. p. 45—47·5°) contains also *octodecyl alcohol*, $C_{18}H_{38}O$, and probably some lower homologues. The hexadecyl alcohol and octodecyl alcohol may be separated by converting the mixture into the acetic ethers and fractioning. The purified octodecyl alcohol crystallises in white scales, melts at 5·9°, and boils at 210° (15 m.m.), agreeing with the alcohol obtained from stearaldehyde (*loc. cit.*). To obtain cetylacetic acid, cetylmalonic acid is first prepared by the action of sodium ethylate on ethyl malonate and cetyl iodide. Cetylmalonic acid, $C_{19}H_{36}O_4$, melts at 120—121°, and begins to decompose at about this temperature, whilst at 150—180° it rapidly breaks up into carbonic anhydride and *cetylacetic acid*, $C_{18}H_{36}O_2$. After purification this melts at 69·2°, crystallises in large nacreous plates, and is identical with ordinary (normal) stearic acid. Guthzeit states that the two are isomeric (Abstr., 1881, 408). A. K. M.

Chemical Composition of Carnauba Wax. By H. STÜRCKE (*Annalen*, **223**, 283—314).—Carnauba wax is obtained from *Copernica cerifera*, a Brazilian palm. It has been investigated by Berard (*Bull. Soc. Chim.* [1], **9**, 41), Story-Maskelyne (this Journal, 1869, 87), and

---

* This equation is obviously incorrect. Arguing from Butlerow's results, the reaction should probably be represented, $CMe(C_3H_7)_2.ZnOC_3H_7 + 2H_2O = C_3H_6 + C_3H_8 + Zn(OH)_2 + CHMe(C_3H_7).OH.$—W. R. D.

Piverling, who all find it to consist mainly of myristyl cerotate. In the alcoholic extract of the wax, Berard found free cerotic acid; Story-Maskelyne, on the contrary, found free myricyl alcohol, whilst Piverling found the substance soluble in boiling alcohol to be distinguished from myricyl alcohol by its melting point and elementary composition.

Carnauba wax forms a hard, brittle, amorphous, straw-yellow mass, melting at 83—83·5°. In confirmation of Story-Maskelyne's statement, myricyl alcohol dissolves out on boiling with alcohol; it is accompanied by a small quantity of myricyl cerotate, which is soluble in boiling alcohol to the extent of about 0·82 gram per litre. The wax was saponified by boiling it with alcoholic soda. The non-acid constituents were separated by fractional solution in and crystallisation from light petroleum and subsequently from alcohol. There were thus obtained: 1. A crystalline hydrocarbon of paraffin-like nature, melting at 59—59·5°, and resolidifying at 58·7; 2. A crystalline alcohol of the formula $C_{27}H_{56}O$, melting at 76°; on heating this with soda-lime, &c., it is converted into an acid melting at 78·1—78·4°; 3. Myricyl alcohol, $C_{30}H_{62}O$, free and in combination (as myricyl cerotate), forming about 45 per cent. of the wax employed. It crystallises in lustrous white tables, melts at 85·5—85·7°, resolidifies at 85·3°, is sparingly soluble in the cold, but readily in hot alcohol, ether, benzene, light petroleum, and chloroform. By heating it with soda-lime, it is converted into *melissic acid;* the formula $C_{30}H_{60}O_2$ for this acid is confirmed by fresh analyses of the acid, and of its lead and silver salts. It crystallises in lustrous white plates or needles, melts at 89·9—90·2°, resolidifies at 89·2°, is readily soluble in hot alcohol, light petroleum, chloroform, and carbon bisulphide, sparingly in boiling ether. The *lead* salt melts at 118—119°, and resolidifies at 117·5°, it is sparingly soluble in boiling toluene and glacial acetic acid, insoluble in alcohol and ether; 4. A *dihydric alcohol* of the formula $C_{23}H_{46}(CH_2.OH)_2$. It forms a pure white microcrystalline powder or fine needles, melts at 103·5—103·8°, resolidifies at 102·5°, is sparingly soluble in light petroleum, more readily in a mixture of benzene and ether. By heating it with soda-lime, &c., it is converted into a *bibasic acid*, which forms white crystalline flocks, melts at 102·5°, and resolidifies at 100·2°; it is soluble in boiling alcohol, benzene, and a mixture of ether and light petroleum. The *lead* salt, $C_{23}H_{46}(COO)_2Pb$, is insoluble in boiling ether, alcohol, and benzene, scarcely soluble in boiling toluene, readily in boiling glacial acetic acid. It is decomposed when heated to 125°.

The separation of the acids obtained by the saponification proved exceedingly troublesome, and was effected by a combined process of fractional solution in light petroleum, and fractional precipitation with magnesium acetate. The products obtained were: 1. An acid of the formula $C_{23}H_{47}.COOH$, isomeric with lignoceric acid, and occurring only in small quantity. It forms a fine crystalline powder, melts at 72·5°, resolidifies at 71·8°, is readily soluble in boiling alcohol, ether, light petroleum, and benzene. The lead salt, $(C_{25}H_{49}O_2)_2Pb$, melts at 110—111°, and resolidifies at 108—109°; 2. The main acid constituent is either identical or isomeric with cerotic acid, $C_{27}H_{54}O$.

It agrees with cerotic acid from bees-wax in all its properties, except that after fusion the resolidified acid exhibits no trace of crystalline structure; 3. A substance of lactone-like nature presumably of the formula $C_{19}H_{38}<\genfrac{}{}{0pt}{}{CH_2}{CO}>O$. It forms a white crystalline powder, melts at 103·5°, is sparingly soluble in boiling 90 per cent. alcohol, somewhat more soluble in absolute alcohol, benzene, and toluene, readily in boiling isobutyl alcohol. When heated with soda-lime, &c., it yields a bibasic acid, melting at 89·5—90°, whose lead salt on analysis gave numbers agreeing with the formula $C_{19}H_{35}(COO)_2Pb$.

A. J. G.

Action of Sulphur on Sodium Mercaptide. By H. BÖTTGER (*Annalen*, **223**, 346—348).—Sulphur when heated at 100° with sodium mercaptide in presence of absolute alcohol yields ethyl bisulphide and sodium polysulphides. Experiments were made to find a readier method of preparing sodium mercaptide; by the action of ethyl sulphide on sodium sulphide; of mercaptan on sodium hydrosulphide; of ethyl sulphide on sodium hydrosulphide; and of sodium sulphide on mercaptan, but in each case with negative results.

A. J. G.

Ethyl Sulphides. By H. BÖTTGER (*Annalen*, **223**, 348—354). According to Müller (this Journal, 1871, 904), sulphur does not act on ethyl sulphide even on heating the mixture for four days at 150°. The author finds that by heating the mixture for 24 hours at 180°, the monosulphide is in part converted into di-, tri-, tetra-, and probably also penta-sulphide.

Sulphur chloride acts violently on ethyl sulphide, hydrochloric acid being evolved, carbon separating, and ethyl polysulphides being formed.

Sulphurous dichloride when mixed with ethyl sulphide, and gently heated, reacts with it to form hydrochloric acid, sulphurous anhydride, carbon, and ethyl polysulphides. Sulphuric dichloride reacts in a similar manner.

By the action of sulphuric hydroxychloride on ethyl sulphide, there are formed sulphuric acid, sulphurous anhydride, hydrochloric acid, and water, whilst carbon separates.

A. J. G.

A New Ethylic Phosphate. By A. GEUTHER (*Annalen*, **224**, 274—282).—An ethylic phosphate of the composition $(EtO)_3H.PO.P(OEt)_4$, is obtained when phosphorous trichloride acts on an excess of sodium ethylate (which has been dried at 180° in an atmosphere of hydrogen) in the presence of absolute ether. Alcohol, ethylene, and ethyl phosphine, are also formed during the reaction. The new phosphate is a colourless liquid lighter than water. It boils between 150° and 160°, with gradual decomposition into alcohol and ethyl phosphite and phosphate.

W. C. W.

Dichlorovinyl Methyl Ether. By A. DENARO (*Gazzetta*, **14**, 117—120).—The four known vinyl ethers are, vinyl ethyl ether, $C_2H_3.OEt$; monochlorovinyl ethyl ether, $C_2H_2Cl.OEt$; dichlorovinyl ethyl ether, $C_2HCl_2.OEt$; and trichlorovinyl ethyl ether, $CCl_3.OEt$, but up to the present time vinyl methyl ether and its derivatives have not been examined.

Dichlorovinyl methyl ether, $C_2HCl_2.OMe$, is prepared by heating potassium methylate (144 grams) with trichlorethylene (104 grams) for 16 hours at 50—60°, in a flask furnished with a reflux condenser; water is then added, and the ether which separates is dried over calcium chloride, and fractionally distilled to separate the small portion of unattacked trichlorethylene. The ether is a colourless liquid of agreeable odour, recalling that of acetal. It boils at 109—110°, and its sp. gr. is 1·2934 at 0° and 1·1574 at 100°. When exposed to the air, it slowly decomposes with evolution of hydrochloric acid.

When the ether is boiled with sulphuric acid diluted with four parts of water in a reflux apparatus, it is decomposed with formation of a crystalline substance, which may be extracted from the product by skaking it with ether: this melts at 56—57°, distils at 118—121°, and appears to be identical with Paternò's dichloraldehyde; the reaction in which it is formed being

$$CCl_2 : CH.OMe + SO_2(OH)_2 = CHCl_2.CHO + SO_2(OH).OMe.$$

From its mode of formation and the action of sulphuric acid on it, there can be no doubt that the constitutional formula of the ether is $CCl_2 : CH.OMe$. C. E. G.

Allyl Dimethyl Carbinol. By POUTOKINE (*Bull. Soc. Chim.*, **41**, 268).—The fractional distillation of crude allyl dimethyl carbinol yields an alcohol boiling at 174°, which is attacked by bromine, hydrobromic acid being evolved, and when oxidised it yields acetic and butyric acids. It probably, therefore, contains the isopropyl-group, and may be represented as $C_3H_7.CH : CH.CH_2.CMe_2.OH$.

W. R. D.

Dipropyl Propylidenic Oxide. By B. SCHUDEL (*Monatsh. Chem.*, 5, 245—250).—This compound is formed by the action of phosphine on a mixture of normal propyl alcohol and propaldehyde, but only in small quantities. A much better yield is obtained by heating a mixture of the alcohol and aldehyde with acetic acid in sealed tubes at 100°. The product is fractionated until the thermometer rises to 110°, and the residue is then heated with potash in a silver flask connected with a reflux condenser, for some hours; it is finally washed with water and dried over calcium chloride. In this manner a liquid is obtained, the chief portion of which boils at 163—164°, and consists of dipropyl propylidenic oxide, $CHEt(OPr)_2$. It is a liquid of sp. gr. = 0·8495 at 0°, and boils at 165·6° (corr.), and barometer at 747 mm. The determinations of its vapour-density gave the numbers 81·78 and 80·14 ($H = 1$).

That the oxide is in reality dipropyl propylidenic oxide is shown by the fact that, when heated with acetic anhydride in sealed tubes at 180°, it yields propyl acetate and the compound $CHEt(O\overline{Ac})_2$, as represented by the following equation:—

$$CHEt(OPr)_2 + 2\overline{Ac}_2O = 2Pr.O\overline{Ac} + CHEt(O\overline{Ac})_2.$$

P. P. B.

Action of Ammonium Chloride on Glycol at High Temperatures. By A. W. HOFMANN (*Ber.*, **17**, 1905—1906).—No trace of ethylenediamine is formed, but a pyridine base which proved to be collidine. The reaction must take place according to the equation

$$4C_2H_6O_2 + H_3N,HCl = C_8H_{11}N,HCl + 8H_2O.$$

The temperature employed was 300—400°. L. T. T.

Butylic Glycerol Triacetin. By L. PRUNIER (*Compt. rend.*, **99**, 193—195).—The butylic glycerol previously described (*Compt. rend.*, **80**, 1603), when heated with acetic anhydride in sealed tubes at 140°, yields a triacetin which can be obtained almost solid by evaporation over sulphuric acid and lime. It is a neutral substance with a bitter taste. C. H. B.

A General Reaction of Polyhydride Alcohols in Presence of Borax and Paratungstates. By D. KLEIN (*Compt. rend.*, **99**, 144—147).—In presence of an aqueous solution of borax, dulcitol behaves in the same manner as mannitol (*Compt. rend.*, **86**, 826). Dulcitol is neutral to litmus, and borax is distinctly alkaline, but a solution containing less than 0·5 mol. of borax for each molecule of dulcitol is strongly acid, the acidity being greater the smaller the proportion of borax; a solution containing 0·5 mol. of borax for each mol. of dulcitol is neutral; and a solution containing a higher proportion of borax is alkaline, the alkalinity increasing with the amount of borax present. These results were obtained by mixing saturated solutions of the two substances at about 15°. None of the solutions showed any rotatory power. The acid solution first mentioned acquires an alkaline reaction when diluted with a large quantity of water.

With solutions of sodium paratungstate, dulcitol also behaves in the same way as mannitol. A mixture of concentrated solutions of the two substances has an acid reaction after boiling. The dulcitol solution, however, has no rotatory power. The solubility of dulcitol is largely increased by the presence of sodium paratungstate, and to a still greater extent by the presence of borax.

These reactions are perfectly general, and are produced by all biborates, soluble paratungstates, and all non-condensed polyhydric alcohols, the proportion of the alcohol required to produce an acid reaction being lower the higher the hydricity of the alcohol. Hydroxy acids, such as mucic acid, which contain a large number of OH groups, give similar reactions. An increase of rotatory power only takes place when the alcohol itself is optically active. Saccharose and dextrin do not give these reactions.

The reactions admit of very simple explanation. Ethereal salts of the alcohol employed are formed, and play the part of acids having a greater saturating capacity than the inorganic acid. They require for the formation of neutral salts a higher proportion of the base than was combined with the inorganic acid, and consequently give acid solutions. C. H. B.

Persite, a Sugar analogous to Mannitol. By A. MUNTZ and V. MARCANO (*Compt. rend.*, **99**, 38—40).—*Laurus persea*, a tree of moderate height, very abundant in the tropics, bears a fruit with a fleshy pericarp, rich in oil, and a ligneous-looking seed. In 1831 Avequin stated that this seed contained a large quantity of mannitol, and Melsens found that this mannitol has the same percentage composition as that derived from manna.

The sugar is easily extracted from the seeds by triturating them with boiling alcohol, or water containing a little basic lead acetate. It crystallises rapidly, and can be purified by repeated crystallisation from alcohol. It has the composition $C_6H_{14}O_6$, and melts at 183·5—184°, like dulcitol, whereas the melting point of mannitol is 164—164·5°. Unlike dulcitol, however, it yields oxalic acid without any mucic acid when oxidised with boiling nitric acid. This sugar, to which the author gives the name *persite*, is, in fact, analogous to but not identical with mannitol.

Persite is comparatively insoluble in cold water, a saturated solution at 15° containing only 6 per cent., but it is very soluble in hot water, from which it separates in a farinaceous mass on cooling. It is only very slightly soluble in cold alcohol, but its solubility increases with the temperature: a boiling saturated alcoholic solution, as it cools, deposits persite in a bulky mass of very slender needles. Persite even in concentrated solutions has no action on polarised light, but it acquires a distinct dextrorotatory power on adding borax to the solution. It has no action on an alkaline copper solution even after boiling with dilute inorganic acids, and it does not undergo true alcoholic fermentation.

When treated with a mixture of fuming nitric acid and sulphuric acid, persite yields a trinitro-derivative which detonates violently on percussion. Nitropersite is only slightly soluble in cold alcohol, but is somewhat soluble in boiling alcohol, from which it is deposited in a bulky crystalline mass. It is also somewhat soluble in ether. A solution in a mixture of alcohol and ether has a dextrorotatory power of + 2·1.

When heated at about 250°, persite gives off water without becoming dark-coloured, and yields a substance analogous to mannitan.

Persite occurs in the seeds of *Laurus persea* to the extent of 6 to 8 per cent.; in the pericarp from 1·8 to 6·3 per cent. according to the stage of maturity; and in the dry leaves about 2 per cent. When the fruit is completely ripe, the proportion of persite has considerably diminished, whilst that of oil has increased, and hence it would seem that persite, like mannitol in the olive, contributes to the formation of the fatty bodies. During the germination of the seeds the persite disappears. C. H. B.

Circular Polarisation of Cane-sugar. By B. TOLLENS (*Ber.*, **17**, 1751—1758).—About eight years ago, the author and Schmitz, working independently, both came to the conclusion, now generally accepted, that cane-sugar, as well as dextrose and some other substances investigated by Landolt, have no unchangeable specific rotation, but that this decreases slowly as the concentration increases. Hesse's investigation of the rotation of very dilute solutions (*Annalen*, **176**, 89 and 189) seemed to show, however, that in solutions containing only 1 to 3 per cent. sugar, the rotation ($[\alpha]_D = 68°$ about) was much higher than those containing 10 per cent. and upwards ($[\alpha]_D = 66·5—64°$). The author has now made a careful series of determinations with very dilute solutions; he used a Landolt-Laurent instrument, and believes the results to be correct to within 2′. He has found no such increase of rotation for dilute solutions, but if anything a *very slight* decrease; and concludes, therefore, that "the specific rotation of very dilute solutions of cane-sugar follows the same law as that of concentrated solutions," and that "only one equation is needed for calculating the specific rotation of cane-sugar solutions whatever their concentrations." The formula he previously gave (*Ber.*, **10**, 1410) for the specific rotation of concentrated solutions, $[\alpha]_D = 66·386° + 0·015035°P - 0·0003986°P^2$, where P = percentage concentration of the solution, is applicable to all concentrations. The following table shows the results obtained compared with those calculated by means of the above formula.

Weight of sugar in 100 grams solution or P.	Rotation for $[\alpha]_D$.		Difference.
	Found.	Calculated.

The sugar employed was carefully purified by repeated crystallisation from water, and finally by precipitation from its aqueous solution by alcohol.

The author is at present carrying out similar investigations with dextrose, and already finds that the specific rotation decreases with dilution of the solution rather than increases. L. T. T.

Melitose from Cotton-seed. By H. Ritthausen (*J. pr. Chem.* [2], **29**, 351—357).—This sugar, which was discovered by Johnston in 1843, and further examined by Berthelot, has hitherto been found only in Tasmanian manna. The author finds that it is contained in large quantity in cotton-seed, and has prepared it from cotton-cake.

The cake is extracted with hot alcohol (sp gr. 0·848), and the extract is concentrated, when it deposits crystalline lumps; these are washed with cold alcohol (80 per cent.) and then dissolved in alcohol heated to 70°; the solution is treated with animal charcoal and allowed to remain 3 to 5 days, when it deposits tufts of lustrous acicular crystals. The yield of pure melitose is 3 per cent. of the raw material. Melitose dissolves in 6 parts of water at 16°, and is almost insoluble in absolute alcohol. The aqueous solution has a higher dextrorotatory power than cane-sugar: $[\alpha]_j = 117·4°$ (Berthelot gives $[\alpha]_j = 88°$ for the hydrates, and $[\alpha]_j = 102°$ for anhydrous melitose). It does not reduce Fehling's solution even on boiling. After boiling with dilute sulphuric acid, the rotatory power is reduced to about one-half the original, $[\alpha]_j = 61·8°$, whilst Berthelot states that it is only reduced by one-third. The analysis agrees with the formula $C_{12}H_{22}O_{11},3H_2O$. It undergoes partial fusion below 90°, and only loses the last traces of water very slowly, but if heated without fusion, the greater part of the water passes off at 84—85°, and the remainder is then readily removed at 104—108° without fusion.

P. F. F.

Non-identity of Arabinose and Lactose. By C. Scheibler (*Ber.*, 17, 1729—1732).—Claesson (Abstr., 1881, 795) has disproved Kiliani's view of the identity of arabinose and lactose (Abstr., 1881, 243). C. O'Sullivan (Trans., 1884, 41 *et seq.*) has described four different arabinoses obtained from gum arabic, and which he designates α, β, γ, and δ arabinose. The author is inclined to think that O'Sullivan's α-compound is identical with his arabinose, the γ-compound with lactose (galactose), and the β-compound a mixture of the two.

The author has prepared the phenylhydrazine compounds of arabinose and lactose. *Phenylarabinosazone* is precipitated in the form of oily drops which soon solidify, it melts at 157—158°. *Phenylgalactosazone* is precipitated at once in crystalline form and melts at 170—171°. E. Fischer found the melting point of the latter to be 182°. L. T. T.

New Method for Preparing and Estimating Glycogen. By A. Landwehr (*Zeit. Physiol. Chem.*, 8, 165—174).—The extract of the liver, made in the ordinary way, is boiled with a small quantity of zinc acetate, to coagulate all the albumin. The filtrate from this precipitate is placed on the water-bath with an excess of ferric chloride, and, after heating, the whole of the iron is precipitated with soda. This precipitate is collected, washed with hot water, and dissolved in hydrochloric or acetic acid; the latter is preferable (in this case hydrochloric acid must also be added after solution): it is then poured into three times its volume of alcohol. The glycogen thus prepared is free both from ash and from nitrogen.

The quantitative determination can be made either by weighing the pure precipitated glycogen, after drying in a vacuum over sulphuric acid and in the water-oven at 120°, or by calculating as glycogen the difference between the iron precipitate weighed after drying at 120° and the oxide of iron left after ignition. This, however, is open to objection, as the percentage of water is very variable in the excess of oxide of iron that must necessarily always be present.

Polarimetric Investigation of Various Forms of Cellulose. By A. Levallois (*Compt. rend.*, 99, 43—45).—Cellulose prepared by the action of ferrous chloride solution on guncotton and on collodion pyroxylin was dissolved in an ammonio-copper solution, and the rotatory power of this solution compared with that of a similar solution of pure cellulose from paper, with the following results:—

	Deviation.
Pure cellulose	9·5°
Cellulose from trinitro-cellulose .	8·5
Cellulose ,, pyroxylin.......	8·5

The differences observed may be attributed to hydration produced by prolonged washing of the reduced cellulose with hydrochloric acid. The product, in fact, had the appearance of hydrocellulose.

Similar determinations were made with a cuprammonium solution of cellulose which had been immersed in sulphuric acid of a definite strength for different periods of time. In the first series, the acid employed was sulphuric acid of 66°, diluted with its own volume of water, and in the second series the same acid diluted with only half its volume of water.

1st Series.		2nd Series.	
——		Immersed 10 seconds..	8·8
——		,, 30 ,, ..	9·5
Immersed 1 minute ..	9·5	,, 1 minute ..	9·0
,, 5 minutes..	8·7	,, 5 minutes..	9·0
,, 15 ,, ..	8·7	,, 15 ,, ..	8·8

These results are practically identical. As Bechamp has shown, the acid converts the cellulose into a pasty mass, which is entirely dissolved in about five minutes. The acid solution, when poured gradually into a large volume of water, yields very heavy translucid cellules, which are only freed from acid with some difficulty. If the action of the acid is prolonged, the solution is only precipitated when poured into a very large volume of water, and the precipitate does not form instantly. If, however, the solution is poured into alcohol, it is at once precipitated. The precipitate in either case is subjected to prolonged washing with alcohol, and when dried forms a friable substance, slightly soluble in water, and very soluble in a cuprammonium solution; but the latter solution has only about half the rotatory power of a solution of pure cellulose. C. H. B.

Conversion of Primary Amines into Nitriles. By A. W. Hofmann (*Ber.*, 17, 1920—1921).—In a previous communication (this vol., p. 1114), the author showed that the amide of an acid of the fatty series may be converted into the nitrile of the next lower member of the series. The occurrence of the amines of the lower homologue in this reaction point to the fact of the intermediate formation of amines. Taking into account the conversion of amines into mono-derivatives of nitrogen bromide (Abstr., 1883, 789), the author thinks the reaction must be looked upon as taking place in three stages:—

$$\text{I. } C_8H_{17}.CONH_2 + Br_2 + 4NaOH = C_8H_{17}.NH_2 + 2NaBr + Na_2CO_3 + 2H_2O$$

$$\text{II. } C_8H_{17}.NH_2 + 2Br_2 + 2NaOH = C_8H_{17}.NBr_2 + 2NaBr + 2H_2O.$$

$$\text{III. } C_8H_{17}.NBr_2 + 2NaOH = C_7H_{15}.CN + 2NaBr + 2H_2O.$$

L. T. T.

Trimethylenediamine. By E Fischer and H. Koch (*Ber.*, 17, 1799—1801).—The authors have prepared and examined this compound, as it seems to be a suitable starting point for the preparation of the less oxygenised members of the uric acid group.

It was prepared by the action of alcoholic ammonia on trimethylene bromide. Niederist studied the reaction of these bodies on one another, obtaining a number of complicated derivatives (*Monatsh. Chem.*, 1880, 838), but appears to have overlooked the formation of the amine. Trimethylene bromide was mixed with 8 to 9 times its weight of an alcoholic solution of ammonia saturated at 0°, and the mixture was allowed to remain for two or three days in well-closed vessels, at the ordinary temperature. The liquid was then evaporated to dryness, when the hydrobromide of the base was left mixed with bye-products, which appeared similar to those of Niederist, but were not further examined. *Trimethylenediamine*, $C_3H_6(NH_2)_2$, is a colourless mobile liquid resembling ethylene and propylene diamines. It distils at 135—136°, and forms a cloud when brought in contact with moist air. When mixed with water, considerable development of heat takes place; when exposed to the atmosphere it absorbs carbonic anhydride, and is converted into the carbonate. It is miscible in all proportions with alcohol, ether, benzene, and chloroform; the anhydrous compound attacks cork and indiarubber readily. The hydrochloride, $C_3H_6(NH_3Cl)_2$, crystallises in well-formed colourless prisms, easily soluble in water. The hydrobromide, sulphate, and nitrate are all crystalline, but the two latter exceedingly deliquescent. The platinochloride forms pale red glittering crystals, sparingly soluble in water. L. T. T.

Acediamine. By A. W. Hofmann (*Ber.*, 17, 1924—1926).—Strecker showed (*Annalen*, **103**, 328) that when acetamide was acted on by dry hydrochloric acid gas, acediamine, $C_2H_6N_2$, was formed. Tawilderow (*Ber*, **5**, 477) could not obtain acediamine by Strecker's process, and contended that the substance Strecker had obtained was really a mixture of diacetamide hydrochloride, and ammonium chloride. Whilst working at some allied compounds, the author has repeated Strecker's work, with perfectly satisfactory results, obtained a good yield of acediamine, and found none of Tawilderow's difficulties.

In order to assimilate the nomenclature to that he employed for the phenyl-derivative he prepared (*Monatsber. Berl. Akad.*, 1865, 640), the author proposes to substitute the name ethenyldiamine for Strecker's acediamine. L. T. T.

Triacetonamine and its Homologues. By E. Fischer (*Ber.*, **17**, 1788—1799).—In continuation of former communications on this subject (Abstr., 1883, 790 and 1153), the author describes a number of derivatives of triacetonamine which he has investigated.

Triacetonalkamine is best prepared by the reduction of triacetonamine in slightly acid solution by sodium-amalgam. A much better yield is obtained than if the reduction is carried out in alkaline solutions. Triacetonine, already described (*loc. cit.*), is best purified by the help of its hydrobromide; this salt crystallises from boiling water in large prisms. The free base distils at 146—147° under 740 mm. pressure; it is poisonous, and inhalation of its vapour causes giddiness, head-ache, and sickness. It forms an unstable but crystalline hydroxide. The hydriodide and aurochloride are both sparingly soluble in cold water. A solution of the sulphate, when warmed with sodium nitrite, yields *nitrosotriacetonine*, $C_9H_{16}N.NO$, which has a strong odour of camphor, and crystallises in yellowish plates, soluble in alcohol, ether, and benzene, very sparingly so in water. When it is boiled with hydrochloric acid, a base is formed which very closely resembles triacetonine. When reduced with zinc and acetic acid, nitrosotriacetonine yields a base which reduces Fehling's solution strongly, and is probably a secondary hydrazine. When heated with methyl iodide, triacetonine yields *methyltriacetonine*, which, however, is better obtained by the action of sulphuric acid on methyltriacetonalkamine at 100°. Methyltriacetonine is a colourless oil, sparingly soluble in water, and easily volatile in a current of steam. Its hydrobromide and hydriodide are easily soluble, and it does not form a hydrate. Its aurochloride crystallises in small, characteristic yellow prisms. It is not attacked by nitrous acid, and is probably a tertiary base.

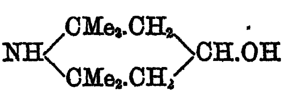
Triacetonine is an unsaturated compound, and if its hydriodide is heated at 150° with excess of hydriodic acid, the sparingly soluble hydriodide of an iodated base, $C_9H_{16}NI,HI$, is formed. Moniodotetramethylpiperidine, $C_9H_{18}NI$, is liberated from this hydriodide by the action of potash, and crystallises in colourless plates, easily soluble in alcohol, ether, and chloroform, insoluble in water. It melts at 90°. The hydrochloride is more soluble than the hydriodide. When reduced with sodium-amalgam in aqueous solution, it yields a base very similar in properties to triacetonine. The quantity of this base obtained was too small for the author to determine whether it was tetramethylpiperidine.

Pseudo-triacetonalkamine, described by Heintz (this Journal, 1877, i, 592) as a bye-product in the preparation of triacetonalkamine, was also obtained by the author. He believes, however, that Heintz's formula, $C_9H_{19}NO$, is not correct, and that $C_8H_{16}NO$, or some multiple thereof, more probably expresses its true composition. It probably is not a simple acetone-base, but is of higher molecular weight. It is undoubtedly related to the alkamines, as when treated with sulphuric acid at 100° it yields *pseudotriacetonine*, easily soluble in alcohol, and volatile in a current of steam. It melts at 128°, and forms sparingly soluble hydrobromide and hydriodide. It was only obtained in small quantity, and did not yield satisfactory analytical results, but its formula appears to be $C_6H_{14}N$.

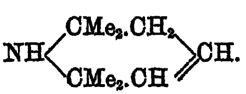
Vinyldiacetonamine, $C_8H_{15}NO$, already described by Heintz (this Journal, 1877, ii, 878), is best obtained by the action of paraldehyde on diacetonamine oxalate. When reduced by sodium-amalgam in acid solution, it yields *vinyldiacetonalkamine*, $C_8H_{17}NO$, which melts at 123°, and is easily soluble in water and alcohol, very sparingly so in ether. It yields easily soluble salts with mineral acids and with gold and platinum chlorides. Its composition is the same as Wertheim's conhydrine, which it resembles so closely that the author is inclined to look upon the two bases as identical. When heated with concentrated sulphuric acid, vinyldiacetalkamine yields *vinyldiacetonine*, $C_8H_{15}N$, a colourless oil, which may be distilled in a current of steam, and has an odour resembling that of conine. When purified, this base distils at 137° under 741 mm. pressure. It is less soluble in boiling than in cold water, and is miscible in all proportions with alcohol, ether, and chloroform. Its hydriodide crystallises in sparingly soluble needles, the hydrochloride and hydrobromide are much more soluble. It forms a crystallisable hydroxide and a characteristic aurochloride. It is converted into a nitrosamine by the action of nitrous acid. It combines with hydriodic acid in a manner similar to triacetonine, forming *iodotrimethylpiperidine*, $C_8H_{16}NI$; this crystallises in regular colourless prisms which melt at 60°, and are easily soluble in ether, almost insoluble in water.

Benzaldiacetonamine, $C_{13}H_{17}NO$, was first prepared by Heintz (Abstr., 1879, 54), but the author, having overlooked Heintz's work, redescribed it (this vol., 54) under the name of benzodiacetonamine. He now proposes to revert to Heintz's nomenclature. This compound yields benzaldiacetonalkamine (this vol., p. 54) on reduction, which is converted into the corresponding acetonine by the action of strong sulphuric acid. *Benzaldiacetonine*, $C_{13}H_{17}N$, has an odour resembling at once that of piperidine and of benzaldehyde. It distils undecomposed, does not solidify at − 20°, and is volatile in steam. Its hydrochloride is easily soluble; its hydrobromide and hydriodide very sparingly so. It forms an aurochloride which crystallises in long yellow needles. When heated in acid solution with sodium nitrite, it yields a nitroso-compound.

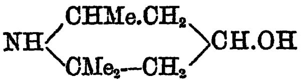
Heintz gave triacetonamine the formula  $NH{<}\begin{matrix}CMe_2.CH_2\\CMe_2.CH_2\end{matrix}{>}CO$. Accepting this formula as probably correct, the bodies just described will be represented by the following formulæ:—



Triacetonalkamine.

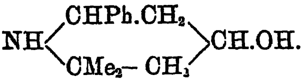


Triacetonine.



$$\mathrm{NH}\left\langle\begin{matrix}\mathrm{CHMe.CH_2}\\ \mathrm{CMe_2{-}CH_2}\end{matrix}\right\rangle\mathrm{CH.OH}$$

Vinyldiacetonalkamine.



$$\mathrm{NH}\left\langle\begin{matrix}\mathrm{CHPh.CH_2}\\ \mathrm{CMe_2{-}\ CH_2}\end{matrix}\right\rangle\mathrm{CH.OH.}$$

Benzaldiacetonalkamine.

Latterly the formula  $\mathrm{N}\left\langle\begin{array}{c}\mathrm{CH:CH}\\ \hline \mathrm{CH:CH}\end{array}\right\rangle\mathrm{N}$ for pyridine has been gaining ground. In the formation of acetonines from the corresponding alkamines the conditions seem to be very favourable for the bringing about of such a linking of carbon with nitrogen. In every case, however, the imide-group has remained intact, the elements of water having been split off from the carbon nucleus, and thus formed an unsaturated body. There seems, therefore, to be no inclination for the nitrogen in these bodies to unite with the carbon-atom occupying the para-position; and although the case may be different with the less hydrogenised pyridine nucleus, the author considers that, at present at least, the older formula for pyridine should be retained in preference to the new. L. T. T.

Imido-ethers from Acetone Cyanhydrin and Allyl Cyanide.

By A. PINNER (*Ber.*, **17**, 2007—2010).—*Chlorobutyrimido-ether hydrochloride*, $C_3H_6Cl.C(OEt):NH,HCl$, is prepared by saturating a mixture of equal molecular proportions of allyl cyanide and ethyl alcohol with hydrochloric acid gas. It crystallises in large, thick, colourless prisms. It dissolves readily in water, but the solution soon decomposes with separation of ethyl β-chlorobutyrate. Alcoholic potash appears to convert it into crotonic acid. On long standing, it becomes liquid, and the oil on distillation yields ethyl β-chlorobutyrate and an amide which crystallises in thin colourless needles, melts at 149—152°, and is readily soluble in alcohol and benzene, probably crotonamide. Ammonia converts the imido-ether hydrochloride into an uncrystallisable amidine hydrochloride.

Hydroxyisobutyrimido-ether hydrochloride,

$$CMe_2(OH).C(OEt):NH,HCl,$$

is obtained by the action of hydrochloric acid on a mixture of alcohol and acetone cyanhydrin. It can only be crystallised with difficulty. By treatment with ammonia, it is converted into *hydroxyisobutyramidine hydrochloride*, $CMe_2(OH).C(NH_2):NH.HCl$, which crystallises in large, thick, transparent plates, and is readily soluble in alcohol and water.

By allowing a mixture of cinnamon oil and dry hydrocyanic acid to stand for some weeks, *cinnamaldehyde cyanhydrin*, $C_9H_8O.HCN$, is obtained in white granular crystals melting at 80—81°, readily soluble in alcohol and benzene, sparingly soluble in light petroleum. Hydrochloric acid and alcohol convert it into a crystalline imido-ether.

Cyanbenzin, $C_{21}H_{21}N_3$, when pure, crystallises in slender interlaced needles, and melts at 221°. A. J. G.

Hydroxy-base of Cyanmethine, $C_6H_8N_2O$.

By R. WOLLNER (*J. pr. Chem.* [2], **29**, 131—134).—The hydroxy-base of cyanmethine obtained by the action of nitrous acid on cyanmethine in acetic acid solution (Abstr., 1883, 653), differs from the corresponding cyanethine-compound in being very soluble in water. The author has prepared it in a pure state by heating crude cyanmethine with concentrated hydrochloric acid in closed tubes at 180°, evaporating, neutralising with soda, and extracting the hydroxy-base with benzene. It forms very soluble crystalline salts with nitric and oxalic acids, and a platinochloride crystallising in plates.

The author has endeavoured to prepare the base $C_6H_8N_2$, analogous to cyanconine, $C_9H_{14}N_2$ (Abstr., 1883, 352) By the action of phosphorus pentachloride on the hydroxy-base an oil containing chlorine was obtained, soluble in ether, alcohol, and benzene, insoluble in water, and nearly insoluble in concentrated hydrochloric acid. With hydrochloric acid gas, this forms a solid compound, probably a hydrochloride, which is insoluble in alcohol and ether, but very hygro scopic; it is decomposed by water into the original oil and hydrochloric acid. On reducing this oil with hydrochloric acid and zinc, neutralising with soda, and distilling with steam, a distillate is obtained having an alkaline reaction, and giving a double salt with mercuric chloride. These compounds are probably analogous to chlorocyanconine and cyanconine, but were obtained in quantities too small for analysis.

On heating the hydroxy-base of cyanmethine with methyl iodide at 150°, iodides of methylated ammonias are obtained, chiefly tetramethylammonium iodide, and not a methylated hydroxy-base such as is formed by the action of iodide of methyl on the hydroxy-base of cyanethine. A. B.

Compound formed by Addition of Hydrochloric Acid to α-γ-Dichlorocrotonaldehyde. By K. NATTERER (*Monatsh. Chem.*, 5, 251—265).—In a former communication (Abstr., 1883, 964), the author has shown that *α-γ-dichlorocrotonaldehyde* unites directly with hydrochloric acid to form a compound isomeric with *butylchloral*, the constitution of which may be represented by either of the two following formulæ:—

$$CH_2Cl.CHCl.CHCl.CHO \text{ or } CH_2Cl.CH_2.CCl_2.CHO.$$

The object of this investigation has been to decide between these two formulæ, and the results obtained indicate that this additive compound of hydrochloric acid and α-γ-dichlorocrotonaldehyde is represented by the first of the above formulæ; for if it is boiled with water and barium carbonate, it yields a syrupy compound, which, when dry, forms an amorphous mass, not convertible into erythrol, as would be the case were the constitution represented by the second formula. The substance obtained resembles the carbohydrates, and most probably has the constitution $OH.CH_2.CH_2.CO.CHO$.

These conclusions find further support in the facts that the *trichlorobutyric acid*, formed by the oxidation of this additive compound, cannot be converted into an unsaturated acid by treatment with zinc-dust and water, or by heating it with an alcoholic solution of potassic iodide. The *trichlorobutyric acid*, which has the constitution,

$CH_2Cl.CH_2.CCl_2.COOH$, appears to form a lactone by replacement of one of the chlorine-atoms, and by long-continued boiling with water is converted into an acid free from chlorine, namely,

$$OH.CH_2.CH_2.CO.COOH,$$

which resembles pyroracemic acid. P. P. B.

Formation of Amides from Ammonium Salts. By N. MENSCHUTKIN (*J. pr. Chem.* [2], **29**, 422—436).—The greater part of this paper has already appeared in a shorter form (*Ber.*, **17**, 846, and this vol., p. 836). The author gives tables containing the rate (that is, the amount formed at the end of one hour) and limit of "amidation" of primary, secondary, and tertiary acids between 125° and 212·5°. The formation of amides follows the same law as that of etherification, and in the following table the values of different acids, compared with formic acid, are given. The temperature of the rate is 155°, and of the limit 125°:—

	Coefficient of etherification.		Coefficient of amidation.	
	Rate.	Limit.	Rate.	Limit.
Primary acids:—				
Formic acid	100	100	100	100
Acetic acid	71·9	104·8	88·5	143·8
Propionic acid	66·7	106·8	88·5	—
Butyric acid	53·9	108·2	74·8	149·1
Caproic acid	53·6	108·7	83·8	149·5
Phenylacetic acid	79·1	115	63·3	—
Secondary acid:—				
Isobutyric acid	43·4	108	64·5	149·1
Tertiary acid:—				
Benzoic acid	13·9	112·9	1·3	?
Anisic acid	8·6	110·4	6·6	?

For the purpose of comparison, the author gives a table (p. 1297) in which various results are shown in relation to the above acids. In Column I are given the results for the affinities of the acids ascertained by the decomposition of acetamide by dilute acids; in Column II the decomposition of methyl acetate by dilute acids; in Column III the value of the investigated acids on salts, the above being Oswald's results. In Column IV is given the thermal effect of the formation of the salts in the solid state by Berthelot.

	I.	II.	III.	IV.
Formic acid	100	100	100	100
Acetic acid	48·4	51·5	34·1	80·9
Propionic acid	—	48·3	26·6	—
Butyric acid	—	47·9	25·1	76·7
Isobutyric acid	—	45·4	23·6	—
Isovalerianic acid	—	—	—	64·2

In all the above reactions, the acids investigated show the same relations. In all the columns similar changes in the composition or isomerism of the acids show similar changes in the figures, so that in all the reactions the same series are obtained. A. B.

Influence of Temperature on the Rate of Certain Reactions. By N. Menschutkin (*J. pr. Chem.* [2], 29, 437—447).—In this paper are given the conclusions derived from the author's investigations on the formation of ethyl acetate from acetic acid and ethyl alcohol, acetamide from acetic acid and ammonia, and acetanilide from acetic acid and aniline. These reactions are not simple as are the combination of two compounds, or the decomposition of one compound into two, but are double decompositions and the more complicated as they are reciprocal. The estimations are not those of the rate of formation or decomposition, but the differential of the rate of the two reactions. Disregarding this disadvantage, it is found that the influence of temperature on the increase in the rate of the reaction is regular. The method of investigation has been to warm molecular weights of the substance for an hour at various temperatures, and then estimate the quantities of ethereal salt, anilide, or amide, as the case might be, which were formed.

The influence of the temperature on the increase of the rate of formation of ethyl acetate is given in the following table. In the first column is given the temperature of the experiment; in the second the percentage of ethyl acetate formed; and in the third the difference in the increase, usually between 10°.

Temperature.	Amount of ethyl acetate formed.	Difference.
90°	7·50	6·0
102	13·50	5·52
112	19·02	5·76
122	24·78	7·82
132	32·60	8·05
142	40·65	6·17
152	46·82	6·17
162	52·99	4·46
172	57·45	3·54
182·5	60·99	2·99
212·5	63·98	—

In the formation of the ethereal salt, the rate increases with the rise of temperature throughout, but the amount of increase has a maximum and then diminishes. This maximum lies between 125° and 145°, when the formation is about half completed. The rate at 212·5° approaches the limit of the reaction (66·6 per cent.). The author represents these reactions by means of curves, of which the abscissa is the temperature and the ordinate the percentage of ethereal salt, anilide, or amide formed. The curve of the rate of formation of ethyl acetate has the appearance of an elongated letter S.

The influence of temperature in the formation of acetanilide is shown in the following table:—

Temperature.	Amount of acetanilide formed.	Difference.
82°	6·08	2·42
90	8·50	6·09
102	14·59	6·92
112	21·51	9·2
122	30·71	9·2
132	39·91	7·74
142	47·65	7·84
152	55·49	6·08
162	61·57	4·82
172	66·39	2·48
182·5	68·87	3·32
212·5	72·19	—

In this and in the preceding case, the commencement of the formation begins at the ordinary temperature, but the amount is small. The maximum of the increase in the rate is between 122° and 132°, and in this case it is again half completed. The curve in these reactions is of the same form as the ethyl acetate curve.

Finally, in the case of acetamide, the following results have been obtained:—

Temperature.	Amount of acetamide formed.	Difference.
100°	0	1·27
110	1·27	3·14
121	4·41	4·61
130	9·02	12·34
140	21·36	15·60
150	36·96	—
152	40·66	—
155	50·90	21·71
160	58·67	13·66
172	72·33	5·98
182·5	78·31	4·52
212·5	82·83	—

In this increase, the maximum of increase in rate is sharper and much greater than in the two former cases. At 212·5 the rate is almost equal to the limit (84·0 per cent.). The curve is like an upright S, and the maximum in the increase in the rate is about half of the total decomposition.

In these reciprocal reactions the limit depends on the rate of both reactions being the same. Berthelot has shown that temperature has no influence on the limit in the cases of different systems of alcohols and acids, and the author has confirmed this. In the formation of acetanilide, the author shows that a decrease in the limit takes place by rise of temperature, and in the formation of acetamide, an increase. The following table shows this:—

Acetamide.		Acetanilide	
Temperature.	Limit.	Temperature.	Limit.
100°	85·05 per cent.		—
125	83·11 ,,	125°	75·10 per cent.
135	82·39 ,,	140	78·18 ,,
145	81·22 ,,	155	81·46 ,,
155	79·68 ,,	182·5	82·82 ,,
182·5	78·85 ,,	212·5	84·04 ,,
212·5	77·75 ,,		—

Probably in these cases the limit may become constant at higher temperatures.

In these reactions, the differences are small as compared with the differences in the chemical properties of the substances, and it seems probable that the above experiments show the general character of the influence of temperature in such reactions, which imply double decomposition. A. B.

Acids contained in Beeswax. By F. NAFZGER (*Annalen*, **224**, 225—258).—Brodie's formula for cerotic acid (*Annalen*, **67**, 180; **71**, 144), $C_{27}H_{51}O_2$ has been called in question by Heintz (*J. pr. Chem*, **66**, 1) and others. Schalfejeff (*Ber.*, **9**, 278 and 1688) denies that it is a homogeneous product, and states that it is a mixture of the acid $C_{34}H_{68}O_2$, melting at 91°, with other acids of the same series.

The author finds that the cerine of beeswax consists chiefly of free cerotic acid, melting at 78·5°, mixed with a small quantity of acids of the oleic series. By fractional precipitation of the alcoholic solution with magnesium acetate, a small quantity of an acid melting at 89° was isolated. It has the formula $C_{30}H_{60}O_2$ or $C_{31}H_{62}O_2$.

Analyses of cerotic acid and its lead and silver salts failed to decide whether the acid has the composition $C_{26}H_{52}O_2$ or $C_{27}H_{54}O_2$. They prove, however, that this acid is not identical with the lignoceric acid of Hell and Hermann (Abstr., 1881, 249).

Myricin is chiefly composed of myricyl palmitate and the myricyl salt of an acid of the oleic series. W. C. W.

Action of Bromine on Levulinic Acid (β-Acetopropionic Acid). By C. HELL and E. A. KEHRER (*Ber.*, **17**, 1981—1984)—*Dibromlevulinic acid*, $C_5H_6Br_2O_3$, is obtained by gradually adding bromine to an ethereal solution of levulinic acid, the reaction being very vigorous. It is also formed by adding bromine to an aqueous solution of levulinic acid and allowing the mixture to stand for some days, best in sunlight. It crystallises in tufts of needles, or in thick, apparently rhombic, prisms, melts at 112—113°, and is decomposed at 130—140°. It is readily soluble in ether, alcohol, acetic acid, ethyl acetate, and acetone, sparingly soluble in cold water, chloroform, and benzene, practically insoluble in light petroleum. It is not decomposed by cold water, whilst hot water decomposes it with elimination of all its bromine as hydrobromic acid, and an amount of carbonic anhydride equal to a little less than one-fifth of the carbon present as COOH; the other decomposition-products have not been isolated. The bromine-derivative was also prepared from synthetical β-acetopropionic acid, and agreed in all particulars with that above described, confirming the statement of Conrad (Abstr., 1879, 453) and Tollens (*ibid.*, 523), as to the identity of levulinic and β-acetopropionic acid.

A. J. G.

Preparation of Glyoxal Derivatives from Trichlorlactic Acid. By A. PINNER (*Ber.*, **17**, 1997—2002).—On heating a mixture of trichlorlactic acid and carbamide dissolved in a little water, on the water-bath for 10—12 hours, acetylene-carbamide is formed. If the water be omitted, dichlorovinyl-carbamide is obtained in addition. By the action of excess of ammonia on trichlorlactic acid, glycosine is formed, one of the nitrogenous bases obtained by Debus by action of ammonia on glyoxal. A mixture of trichlorlactic acid, hydroxylamine hydrochloride, and sodium carbonate yields glyoxime. Phenylhydrazine acting on sodium trichlorlactate converts it into the compound $C_{14}H_{14}N_4$, previously obtained by E. Fischer (this vol., p. 1151) from glyoxal and phenylhydrazine. Sodium amalgam converts trichlorlactic acid into a crystalline chlorinated acid, probably monochlorlactic acid.

A. J. G.

Thiolactic and Thiodilactylic Acids. By J. M. LOVÉN (*J. pr. Chem.* [2], **29**, 366—378).—An acid of the supposed formula $C_2H_4(SH).COOH$, is described by Schacht (*Annalen*, **129**, 1), and Böttinger (Abstr., 1876, 624); the same chemists also briefly mention a thiodilactylic acid, but the author considering it very doubtful whether the acids described by them were really those in question, has subjected these acids to a detailed investigation.

Action of α-Chloropropionic acid on Potassium Sulphhydrate.—When pure chloropropionic acid is gradually added to a concentrated solution of potassium sulphhydrate, sulphuretted hydrogen is evolved, and potassium chloride, thiolactate, and thiodilactylate are formed according to the equations:—

$$2KSH + C_2H_4Cl.COOH = KCl + C_2H_4(SH).COOK + H_2S.$$
$$C_2H_4(SH).COOK + KSH = C_2H_4(SK).COOK + H_2S.$$
$$C_2H_4(SK).COOK + C_2H_4Cl.COOK = KCl + (C_2H_4.COOK)_2S.$$

The thiodilactylate was precipitated by means of barium chloride, and the thiolactic acid obtained from the filtrate by acidulating with sulphuric acid and shaking with ether.

α-Thiolactic acid, $CHMe(SH).COOH$, may be prepared more easily by saturating an aqueous solution of pyruvic acid with sulphuretted hydrogen at a gentle heat, strong hydrochloric acid and zinc are then added; on cooling, the thiolactic acid is extracted with ether. The acid is a colourless oily liquid of unpleasant odour, and miscible with water and alcohol in all proportions. Ferric chloride gives a transient indigo-blue colour, after which alkalis give an intense purple-red coloration which gradually disappears in contact with the air. Excess of ferric chloride converts it into dithiolactylic acid. Cupric salts added in excess produce a deep-violet solution (distinction from β-thiolactic and thioglycollic acids, which give precipitates). A number of salts derived from thiolactic acid are described; those metals which are precipitated from an acid solution by sulphuretted hydrogen form acid compounds, by displacement of the hydrogen which is combined with sulphur, of the type $C_2H_4(SR).COOH$. Ethylic thiolactate, prepared by heating a mixture of thiolactic acid with alcohol and a little sulphuric acid, is a mobile liquid of intensely disagreeable odour, and only slightly soluble in water; with solutions of the heavy metals, it behaves like mercaptan; thus with copper it forms a compound $[C_2H_4(COOEt)S]_2Cu_2$.

Dithiodilactylic acid, $(C_2H_4.COOH)_2S_2$, is prepared by the oxidation of thiolactic acid with iodine or ferric chloride; it crystallises in shining needles or hard cakes, which melt at 142°, and are sparingly soluble in cold but readily in hot water, alcohol, or ether. It gives no reactions with either copper or iron salts; zinc and hydrochloric acid convert it into thiolactic acid, which is thus most readily obtained in a pure state. The author regards it as almost beyond doubt that the acid prepared by Schacht and Böttinger was really dithiolactylic acid, the percentage composition being but slightly different from that of thiolactic acid.

Thiodilactylic acid, $(C_2H_4.COOH)_2S$.—As already mentioned, this acid is obtained as a bye-product in the preparation of thiolactic acid. It is formed as the principal product by the action of potassium α-chloropropionate either on potassium sulphide or on basic potassium thiolactate. The free acid is obtained from its barium salt by acidulation with sulphuric acid; it crystallises in large well-formed monoclinic prisms melting at 125°. The acid is very soluble in water, alcohol, and ether; it suffers no change from contact with the air, and is not acted on by nascent hydrogen or sulphuretted hydrogen.

β-Thiolactic acid (thiohydracrylic acid), $CH_2(SH).CH_2.COOH$, is obtained by the action of β-iodopropionic acid on potassium sulphhydrate; there is no second acid formed in this reaction. It is best prepared in a state of purity by reducing β-dithiodilactylic acid. It is a colourless liquid of a disagreeable, penetrating odour, differing from that of α-thiolactic acid; with the latter acid, however, it agrees in most respects, but is more readily oxidised in contact with the air to β-dithiolactylic acid, and with cupric salts gives a light-violet precipitate, which soon turns to a dirty green colour. The compounds with the heavy metals are similar to those of α-thiolactic acid, thus: $[CH_2(COOH).CH_2.S]_2Hg$.

β-Dithiodilactylic acid, $[CH_2(COOH).CH_2]_2S_2$, is obtained by treating crude thiohydracrylic acid with ferric chloride as long as a transient blue colour is produced, a voluminous crystalline precipitate is obtained, which is washed with cold and recrystallised from hot water. The acid forms thin silvery plates almost insoluble in cold water. It is reduced to thiohydracrylic acid by nascent hydrogen.

P. F. F.

Action of Ethyl Dibromosuccinate on Ethyl Malonate. By W. H. PERKIN, jun. (*Ber.*, **17**, 1652—1658).—Sodium (4 grams) is dissolved in absolute alcohol (50 grams), ethyl malonate (14 grams) added, and then gradually an alcoholic solution of ethyl dibromosuccinate, the whole being well cooled after each addition. The product is heated on a water-bath until it becomes neutral, diluted with water, and the oil extracted with ether. The *ethylic trimethylenetetracarboxylate*,  $(COOEt)_2C\left<\begin{matrix}CH.COOEt\\ |\\ CH.COOEt\end{matrix}\right.$, obtained, is a very thick, colourless oil of agreeable odour; it boils at 245—247°, and does not solidify in a freezing mixture. In order to obtain the free acid, the ethyl salt is boiled with an excess of soda solution, the whole evaporated nearly to dryness, acidulated with dilute sulphuric acid, and extracted with ether. *Trimethylenetetracarboxylic acid* forms a hard, colourless crystalline mass, and melts at 95—100° with evolution of carbonic anhydride. It is a strong acid, dissolves readily in water, ether, alcohol, and acetone, sparingly in light petroleum, benzene, and toluene. The silver salt, $C_7H_2O_8Ag_4$, is obtained by precipitation from the ammonium salt as a white amorphous precipitate; it decomposes suddenly on heating. The ammonium salt is not precipitated by copper sulphate, whilst with barium chloride it yields a white gelatinous precipitate very sparingly soluble in water. The *calcium salt*, $C_7H_2O_8Ca_2,H_2O$, separates on warming a solution of the ammonium salt to which calcium chloride has been added; it is much more soluble in cold than in hot water. When trimethylenetetracarboxylic acid is heated at 190—200°, carbonic anhydride is evolved, and *trimethylenetricarboxylic acid*,  $COOH.CH\left<\begin{matrix}CH.COOH\\ |\\ CH.COOH\end{matrix}\right.$, is obtained as in an oil. When purified it is crystalline, melts at about 145—150°, dissolves readily in water, alcohol, and acetone, and sparingly in light petroleum, benzene, carbon bisulphide, and chloroform. When it is heated, it first gives off water, partially carbonises and yields a small quantity of distillate; this solidifies on cooling, is sparingly soluble in ether, and is probably the anhydride of the acid. The *silver salt*, $C_6H_3O_6Ag_3$, forms a white granular precipitate, and does not explode when heated. The ammonium salt yields a bright-green sparingly soluble precipitate with cupric sulphate, and very sparingly soluble white precipitates with barium chloride and lead acetate, whilst with calcium chloride no precipitate is formed except on warming, the calcium salt being much more soluble in cold than in hot water, and apparently almost insoluble in boiling water. The trimethylenetricarboxylic acid is isomeric with the acid described by Conrad and Guthzeit (this vol., p. 991), with aconitic and carboxylglutaconic acids, and is perhaps identical with Baeyer's aceconitic acid (*Annalen*, **135**, 206).

At the end of the paper, a table is given containing all the trimethylene- and tetramethylene-derivatives hitherto prepared.

A. K. M.

Homologues of Glycidic Acid. By Melikoff (*Bull. Soc. Chim.*, 41, 311).—When crotonic acid is acted on by hypochlorous acid, *chloroxybutyric acid* is obtained which melts at 62—63°, and this when treated with alcoholic potash gives the potassium salt of *propyleneoxycarboxylic acid*,  $O\left\langle\begin{matrix}CHMe\\ |\\ CH.COOK,\frac{1}{2}H_2O\end{matrix}\right.$, which crystallises in small prisms. The silver salt likewise crystallises in prisms, and its aqueous solution forms a silver mirror when boiled. The acid melts at 84° and evolves suffocating vapours; it forms additive compounds, and combines with hydrochloric acid, evolving heat and producing an isomeric chloroxybutyric acid, melting at 85°. The acid is distinguished from glycidic acid by absorbing water when exposed to the air, with formation of glyceric acid. When heated with water at 120°, *propyleneglycolcarboxylic acid* is obtained, of which the barium and silver salts were examined. Treated with ammonia, the acid yields *amidoxybutyric acid*, which crystallises in prisms and combines with both acids and bases. Metacrylic acid is converted by hypochlorous acid into *chlorisobutyric acid;* this melts at 106—107°, and boils at 230—235° with partial decomposition. It is decomposed by alcoholic potash, yielding *metoxyacrylic acid*, $C_4H_6O_3,\frac{1}{2}H_2O$. The potassium salt of this acid crystallises in prismatic plates, and the silver salt in needles. The free acid is a viscous liquid, which combines with hydrochloric acid, forming *chloroxyisobutyric acid*. The acids containing the ethylene oxide residue are distinguished by combining directly with other bodies.

W. R. D.

Isomerism of Fumaric and Maleic Acids. By Pétrieff (*Bull. Soc. Chim.*, 41, 309).—The additive compounds of fumaric and maleic acids are distinguished by different boiling and fusing points; when they are saponified, fumaric acid is formed. The action of chlorine on fumaric acid gives rise to dichlorosuccinic and trichloracetic acids. Under the same conditions, maleic acid also forms a dichlorosuccinic acid which differs in solubility and fusing point from that obtained from fumaric acid. Fumaric acid combines with hypochlorous acid, forming a liquid which yields inactive maleic acid when reduced by sodium-amalgam. Maleic acid when treated in the same way also gives inactive maleic acid together with an acid of the formula $C_4H_4O_5$, which is probably oxymaleic acid, and an acid liquid having the composition of maleic acid, but which, when heated, is decomposed into carbonic anhydride and a substance having the formula $C_6H_{10}O_5$. By the action of zinc ethyl on the neutral ether of fumaric acid ethylsuccinic acid was obtained. The author considers that the formula for fumaric acid which has been proposed by Fittig, accurately represents the constitution of the acid, but does not admit the formula for maleic acid which has been suggested by the same chemist.

W. R. D.

Action of Hydroxylamine on Meconic, Comenic, and Pyromeconic Acids. By E. ODERNHEIMER (*Ber.*, **17**, 2081—2088).—By the action of hydroxylamine hydrochloride on an alcoholic solution of meconic acid, there is obtained a compound of the formula $C_7H_5O_7N + H_2O$. It crystallises in colourless rosettes of small needles, readily soluble in water, sparingly soluble in alcohol, ether, and chloroform, insoluble in light petroleum; it decomposes suddenly when heated to about 190°. Heated with strong hydrochloric acid hydroxylamine is separated. The aqueous solution has a strongly acid reaction and reduces Fehling's solution at the ordinary temperature. With both the acid and salts, ferric chloride gives a characteristic red coloration similar to that produced by meconic acid. Two silver salts were obtained, the first a yellow salt by the addition of silver nitrate to a neutral solution of the ammonium salt, it is very unstable; on adding ammonia a silver mirror is deposited; the second is a white salt, $C_7H_3O_7NAg_2 + H_2O$, formed on adding silver nitrate to a cold aqueous solution of the free acid; it is sparingly soluble in hot water, insoluble in alcohol. The normal calcium salt, $C_7H_3O_7NCa + 4H_2O$, forms thin transparent plates. The acid salt, $(C_7H_3O_7N)_2Ca + 2H_2O$, is obtained by addition of calcium chloride to the free acid; it crystallises in white needles. The sodium salt, $C_7H_3O_7NNa$, is crystalline and insoluble in alcohol. The barium salt, $(C_7H_3O_7N)_2Ba + 10H_2O$, crystallises in feathery groups of needles. These results show that there is only a single oxygen-atom in meconic acid capable of entering into reaction with hydroxylamine, and renders it very probable that meconic acid is a ketonic acid of the formula $C_4HO(CO)(OH).COOH$, the isonitroso-derivative having the formula $C_4HO(C:NOH)(OH).COOH$. The author's experiments with hydroxylamine hydrochloride and comenic and pyromeconic acids yielded negative results. The author has investigated the action of hydroxylamine on dehydracetic acid, and obtained results confirming those of Perkin and Bernhart (this vol., p. 1121).

A. J. G.

Action of Hydroxylamine and Ethylamine on Comanic Acid. By H. OST (*J. pr. Chem.* [2], **29**, 378—380).—This is a preliminary note published in consequence of the appearance of a paper by V. Meyer (Abstr., this vol., p. 993), on the action of hydroxylamine on chelidonic and meconic acids. On mixing equivalent weights of comanic acid, $C_5H_3O_2.COOH$, hydroxylamine hydrochloride, and sodium carbonate with water, and heating, the whole dissolves, but soon a body separates having the composition of an oximido-comanic acid, $C_5H_3O(NOH).COOH$. This substance, however, does not behave like an oximido-compound, for the nitrogen is not loosely combined, and when heated with fuming hydrochloric acid no hydroxylamine is eliminated, but at 200° carbonic anhydride is evolved with formation of a compound $C_5H_5NO_2$. Tin and hydrochloric acid convert the oximido-compound into β-hydroxypicolinic acid, which is also readily formed from comanic acid and ammonia. It would thus appear that the hydroxylamine acts similarly to ammonia, and that the above compound is a dihydroxypyridinecarboxylic acid. Ethylamine converts comanic acid into an acid, $C_8H_9NO_3$ +

$\frac{1}{2}H_2O$, which appears to be ethylpyridinehydroxycarboxylic acid, $C_5H_2EtN(OH).COOH$. Similarly comenic acid and ethylamine give $C_4H_9NO_4$, which is probably dihydroxy-ethylpyridinecarboxylic acid, whilst aniline and comenic acid give a corresponding phenyl-compound, $C_{12}H_9NO_4$. P. F. F.

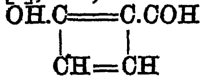
Decomposition of Optically Inactive Compounds. By E. JUNGFLEISCH (*Bull. Soc. Chim.*, **41**, 222—226).—The author considers that the separation or non-separation of inactive compounds by "compensation" is determined by the relative solubility of the inactive compound, and of the two compounds into which it is capable of being separated. If the original compound is less soluble than either of the compounds of which it is constituted, no separation is effected by crystallisation; but if either of the constituent compounds is less soluble than the original compound, separation occurs under certain conditions when crystallisation is attempted. This being the case, the result will vary at different temperatures; thus it has been noticed that sodium potassium tartrate can be crystallised without decomposition near 0°, the salt at this temperature being less soluble than either the dextrorotatory or lævorotatory salts which compose it. The unequal solubility of the two products of the decomposition also appears to be an important factor in producing the result. This has been investigated in the case of sodium ammonium racemate, a process for the separation of which into dextrorotatory and lævorotatory sodium ammonium tartrates has been devised by the author, and fully described in a previous Abstract (Abstr., 1882, 602). As the result of a number of experiments, it is noticed that in the first crystallisation the dextrorotatory salt is deposited in greater quantity than the lævorotatory, but in the second crystallisation the reverse is the case. Further, a supersaturated solution of ammonium sodium racemate, from which the dextrorotatory and lævorotatory salts have been, as far as possible, separated by crystallisation, when examined by the polariscope is feebly lævorotatory, and on the addition of boric acid becomes markedly so. These facts indicate the greater solubility of the lævorotatory salt in the saline liquid. The decomposition of cinchonine racemate into dextrorotatory and lævorotatory cinchonine tartrate, and of cinchonine paraphenylglycollate into the two active cinchonine phenylglycollates, may be explained by the wide difference in the solubilities of the constituent salts. The behaviour of paracamphoric acid also supports this view. When a hot concentrated solution of this acid is cooled and fractionally crystallised, the crystals which separate between 80° and 40° are strongly lævorotatory, whilst those formed below 40° are dextrorotatory. By recrystallising these fractions they become more and more strongly lævo- or dextro-rotatory. In this way crystals were obtained containing 75 per cent. of the lævorotatory acid. When a solution of paracamphoric acid is crystallised, and the crystals allowed to remain in the cold in contact with the mother-liquor, they are reconverted into the original acid. The difference in the solubility of the dextro- and lævo-rotatory camphoric acids can be still further increased by the addition of acetic acid.
W. R. D.

Synthesis of Tartaric Glucoside. By A. GUYARD (*Bull. Soc. Chim.*, **41**, 291).—When tartaric anhydride is added to glucose which has been heated to incipient fusion, water is given off, and a white substance remains which is entirely soluble in water. The aqueous solution is unaltered by prolonged ebullition, and neither tartaric acid nor glucose can be detected by the ordinary reactions. When the solution is boiled with a dilute mineral acid, tartaric acid and glucose are regenerated. W. R. D.

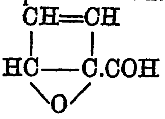
Occurrence of Citric Acid in the Seeds of Leguminosæ. By H. RITTHAUSEN (*J. pr. Chem.* [2]. **29**, 357—359).—Malic, oxalic, and citric acids have been proved to exist in the seed of the yellow lupin (*Lup. luteus*) (Beyer, Abstr., 1872, 519; *J. pr. Chem.* [2], **2**, 339), by the author and others. He has since found citric acid in the seeds of *Vicia sativa*, *V. faba*, *Pisum sativum*, and *phaseolus*. The powdered seeds were extracted with water, acidified with hydrochloric acid, the solution neutralised with potash or soda and concentrated; the residue, after filtration, was treated with basic lead acetate; the precipitate was decomposed with sulphuretted hydrogen in the usual way, and the clear liquid rendered strongly alkaline with lime-water. The precipitate, consisting chiefly of calcium phosphate, was filtered off and the solution boiled to precipitate the calcium citrate, from which the citric acid was prepared by decomposition with sulphuric acid. P. F. F.

Furfuraldehyde. By A. GUYARD (*Bull. Soc. Chim.*, **41**, 289—291).—When paper steeped in aniline acetate is immersed in a liquid containing furfuraldehyde, a magnificent rose-red colour is produced. Furfuraldehyde is contained in pyroligneous acid, and it is to this substance that acetic acid, prepared from pyroligneous acid, owes the peculiar odour which renders it unfit for the preparation of vinegar. The furfuraldehyde can be removed from pyroligneous acid, from which the tar has been separated, by agitating it with benzene. The compound remains when the benzene is evaporated. The acid can be purified by distillation. W. R. D.

Constitution of Furfuraldehyde. By A. PAWLINOFF and G. WAGNER (*Ber.*, **17**, 1967—1969).—One of the authors has recently shown that aldehydes combine directly with zinc alkyls forming the alkylates of secondary alcohols (*Jour. Russ. Chem. Soc.*, 1884, [i], 283). Two formulæ have been proposed for furfuraldehyde:



by Kanonnikoff, and



by Baeyer.

The action of zinc ethyl gives a means of investigating the question, as if a hydroxyl-group be present it will attack that as well as the aldehyde-group. The authors' results show that the second oxygen atom is not present as hydroxyl, the product of the reaction yielding, on treatment with water, *ethyl furfuryl carbinol*, $C_4H_3O.CHEt.OH$.

Its formation is represented by the equations—

$$C_4H_3O.CHO + ZnEt_2 = C_4H_3O.CHEt.OZnEt \text{ and}$$
$$C_4H_3O.CHEt.OZnEt + 2H_2O = C_4H_3O.CHEt.OH + C_2H_6 + Zn(OH)_2.$$

It is a colourless viscid liquid of agreeable aromatic odour, and is moderately soluble in water. It boils without decomposition at 180° under 749 mm. pressure, has a sp. gr. of 1·066 at 0°, and of 1·053 at 15·5° (water at 0° = 1). Acetic anhydride exerts a dehydrating influence on it, converting it into a mixture of hydrocarbons.

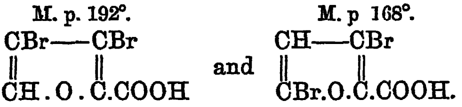
A. J. G.

Substitution-derivatives of Pyromucic Acid. By H. B. Hill and C. R. Sanger (*Ber.*, **17**, 1759—1764).—Tönnies described (Abstr., 1878, 785) a dibromopyromucic acid (m. p. 184—186°), obtained by the action of potash on pyromucic acid tetrabromide, but did not give the details of its preparation.

If an alcoholic solution of the tetrabromide is poured slowly into excess of strong alcoholic soda, care being taken to prevent any great rise in temperature, the sodium salts of two dibromopyromucic acids are obtained. These salts are sparingly soluble in alcohol, and the acids can be easily separated by means of the difference in the solubilities of their calcium salts. The more soluble salt yields an acid melting at 192°; the less soluble one melting at 168°. The former acid crystallises in flat needles, easily soluble in boiling water, in alcohol, ether, boiling benzene or chloroform, very sparingly in carbon bisulphide and light petroleum. When heated with dilute nitric acid (1 : 5) it dissolves with evolution of carbonic anhydride, and the solution contains a mixture of mucobromic and dibromomaleic acids. This acid is undoubtedly the same as that obtained by Tönnies. By the action of bromine-water on his acid, Tönnies obtained an easily soluble substance melting at 88°, which he believed to be the aldehyde of dibromofumaric acid. The authors have obtained a compound having the same properties, but only in very small quantity. When the acid is suspended in water, and bromine vapour is passed into the liquid by means of a current of air, tetrabromotetraphenol (tetrabromofurfuran), C_4Br_4O, melting at 64—65°, is formed, according to the equation $C_6H_2Br_2O_3 + 2Br_2 = C_4Br_4O + CO_2 + 2HBr$.

The second dibromopyromucic acid, melting at 168°, can be more easily prepared by the action of bromine (2 mols.) on dry pyromucic acid. The resulting mixture of the acid and its dibromide is treated with water to decompose the bromide, and the acid purified by means of its calcium salt: some dibromomaleïc acid is always formed in the reaction. This dibromopyromucic acid is easily soluble in boiling water, in alcohol, and ether, in boiling benzene or chloroform, sparingly in carbon bisulphide. When heated with dilute nitric acid, it is oxidised and yields monobromofumaric acid, $C_4H_3BrO_4$. When bromine is allowed to act on the acid suspended in water, monobromomaleic bromide, $C_4HBr_3O_2$, is formed. This last reaction seems to proceed most regularly when the bromine is added quickly. Monobromomaleïc bromide crystallises in long white needles melting at 55°. It is slowly acted on by boiling water, and yields, apparently, a mixture of monobromofumaric, monobromomaleïc, and dibromosuccinic acids. The other usual solvents dissolve it readily. When decomposed with potash, it yields monobromomaleïc acid.

Judging from their oxidation-products, the authors believe that the two acids may best be represented by the formulæ



$$\begin{array}{l}\text{M. p. 192°.}\\ \text{CBr——CBr}\\ \|\qquad\quad \|\\ \text{CH.O.C.COOH}\end{array} \quad \text{and} \quad \begin{array}{l}\text{M. p 168°.}\\ \text{CH——CBr}\\ \|\qquad\quad \|\\ \text{CBr.O.C.COOH.}\end{array}$$

and therefore names them respectively *βγ-* and *βδ-dibromopyromucic acid.*

When treated in ammoniacal solution with zinc-dust, both acids yield *β-monobromopyromucic acid* melting at 128—129°. This acid crystallises in needles, and is easily soluble in the usual solvents. When boiled with dilute sulphuric acid, it yields monobromofumaric acid melting at 176—177°.

δ-Monobromopyromucic acid melting at 183—184° combines easily with bromine to form an additive product, which melts at 170° with decomposition; this, when treated with alcoholic potash, readily yields *tribromopyromucic acid,* crystallising in small tufts of needles melting at 218—219°. It is sparingly soluble in boiling water, easily in ether or alcohol, and almost insoluble in light petroleum and carbon bisulphide. When oxidised by moderately strong nitric acid (1 : 2), it yields dibromomaleïc acid: bromine-water converts it into tetrabromotetraphenol, together with a small quantity of dibromomaleïc acid.

L. T. T.

Optical Behaviour of certain Amido-acids. By E. Schulze and E. Bosshard (*Ber.*, **17**, 1610).—The amido-acids obtained on heating conglutin with hydrochloric acid are optically active; leucine dissolved in hydrochloric is dextrorotatory, and tyrosine lævorotatory; glutaminic acid, under the same conditions, is also dextrorotatory. The tyrosine, leucine, and glutamic acid, which are obtained by the action of baryta-water on conglutin, are however optically inactive; this applies to both acid and alkaline solutions, and in the case of the two latter substances has also been proved for aqueous solutions. Differences of solubility of the active and inactive amido-acids have also been observed.

A. K. M.

Aceturic Acid (Acetylglycocoll). By T. Curtius (*Ber.*, **17**, 1663—1674).—The author prepares aceturic acid by boiling glycocine (40 grams), dried, and finely powdered, with acetic anhydride (60 grams) and benzene (250 grams) for four hours, the flask being frequently shaken to prevent the glycocine from caking. The benzene is distilled off, the residue dissolved in hot alcohol, and the solution decolorised by animal charcoal. The reaction is nearly quantitative, and may be expressed thus:

$$2NH_2.CH_2.COOH + \overline{Ac}_2O = 2NH\overline{Ac}.CH_2.COOH + H_2O.$$

The yield is not so good when finely powdered dry glycocine-silver (30 grams) is boiled with acetic chloride (16 grams) and benzene (200 grams), as in Kraut and Hartmann's method (*Zeitschr. f.*

Chem., 1868, 79). In this reaction, however, other compounds are formed, as in the reaction between benzoic chloride and glycocine-silver (Abstr., 1883, 337); the analogue of the acid, $C_{10}H_{11}N_3O_4$, has, for instance, been obtained, and forms a microcrystalline powder melting above 260° after first blackening; it is decomposed by boiling with mineral acids, with formation of acetic acid, glycocine, and a substance which yields ammonia when heated with aqueous alkalis. Aceturic acid separates from a hot saturated aqueous solution in colourless lanceolate crystals radiating from a common centre, and from a dilute solution, by evaporation in a vacuum, in small lustrous diaxial crystals; it melts at 206°. A litre of water at 15° dissolves 27 grams of the acid; it is moderately soluble in cold, readily in hot alcohol, and very readily in boiling water, but is insoluble in boiling ether, benzene, and toluene; it is only sparingly soluble in hot glacial acetic acid or acetone. Aceturic acid gives a red colour with ferric chloride and a deep blue colour with phenol and hypochlorites, and is decomposed by acids and alkalis much more readily than hippuric acid. It combines with hydrochloric and sulphuric acids, but the salts obtained are readily decomposed by water; with bases, however, it forms stable salts, most of which are very soluble in water. The *silver salt*, $NH\overline{Ac}.CH_2.COOAg$, is moderately soluble in cold, very readily in hot water, and insoluble in absolute alcohol; the *ammonium salt*, $NH\overline{Ac}.CH_2.COONH_4,H_2O$, crystallises in glistening needles or large plates which effloresce over sulphuric acid; when boiled with water or alcohol, it splits up into free acid and ammonia; it is moderately soluble in cold, very readily in hot water, less so in hot alcohol. The *barium salt*, $(NH\overline{Ac}.CH_2.COO)_2Ba,5H_2O$, crystallises in clusters of needles which deliquesce on exposure to the air, and lose only a part of their water when heated at 205°; it melts at about 200° and decomposes at 250—260°: water and spirit dissolve it very readily in the cold, whilst hot absolute alcohol dissolves it but sparingly. The *copper salt*, $(NH\overline{Ac}.CH_2.COO)_2Cu,4\frac{1}{2}H_2O$, crystallises in azure-blue needles, loses $3\frac{1}{2}H_2O$ at 105°, and decomposes a little above 120°; it is very readily soluble in cold water and in hot absolute alcohol. The *thallium salt*, $NH\overline{Ac}.CH_2.COOTl,2(?)H_2O$, forms small lustrous crystals resembling anatase, easily soluble in cold water. The *nickel, magnesium, lead, and mercurous salts* are also crystalline. The *methyl salt*, $NH\overline{Ac}.CH_2.COOMe$, forms long colourless rhomboidal plates, melts at 58·5°, and boils at 254° (712 mm.); it is sparingly soluble in boiling ether, very readily in alcohol, chloroform, benzene, and water. The *ethyl-derivative*, $NH\overline{Ac}.CH_2.COOEt$, crystallises in large rhombic plates, is hygroscopic, and very readily taken up by all solvents; it melts at 48° and boils at 260° (712 mm.). The conversion of ethyl aceturate into ethyl acetylglycollate, $CH_2(O\overline{Ac}).COOEt$, by the action of chlorine on its alkaline solution (*Annalen*, **99**, 181) is very imperfect, the chlorine attacking the acetyl-group, and the ethyl acetylglycollate being much more readily decomposed by alkalis than the corresponding benzoyl-compound. A quantitative method of preparing it consists in boiling ethyl diazoacetate with glacial acetic acid, $N_2CH_2.COOEt + \overline{Ac}OH = CH_2(O\overline{Ac}).COOEt + N_2$. When ethyl aceturate is gently heated with aqueous ammonia, ammonium aceturate is formed together with *aceturamide*, $NH\overline{Ac}.CH_2.CONH_2$. This crystallises in large colourless plates melting at 137°; it is insoluble in ether, readily soluble in alcohol and water, and, when boiled with these, is rapidly decomposed with evolution of ammonia.

A. K. M.

Glutamic Acid. By C. SCHEIBLER (*Ber.*, 17, 1725—1729). The author has prepared a quantity of this acid from beetroot molasses obtained in working the strontium process. Oebbeke has examined and measured crystals of this acid, and of its hydrochloride, side by side with crystals of Ritthausen's glutamic acid, and declares them to be identical. The author has made determinations of the rotary power of glutamic (amidoglutaric) acid and its salts as likely to prove of value in determining the sugar remaining in molasses. A Soleil-Scheibler polariscope was used with a column of solution 220 mm. long. A 2 per cent. solution of the free acid at 21° had a sp. gr. 1·0070, and a rotation 1·3°, giving $[\alpha]_j = +11{\cdot}6^\circ$ or $[\alpha]_D = +10{\cdot}2^\circ$. A 4 per cent. solution, rapidly cooled to prevent crystallisation, gave a rotation 2·7° at 23°, or $[\alpha]_j = +12{\cdot}0^\circ$, or $[\alpha]_D = +10{\cdot}6^\circ$. A solution containing calcium salt equivalent to 2 per cent. had a sp. gr. 1·0240 at 20° and a rotation $-1{\cdot}2^\circ$ at 22°. This gives for the salt $[\alpha]_j = -4{\cdot}2^\circ$ or $[\alpha]_D = -3{\cdot}7^\circ$; and for the acid in the salt $[\alpha]_j = -5{\cdot}3^\circ$ or $[\alpha]_D = -4{\cdot}7^\circ$. A 4 per cent. solution of the hydrochloride (= 3·205 per cent. acid) had a sp. gr. 1·0158 at 19° and a rotation +5·2, giving for $C_6H_9NO_4,HCl$ $[\alpha]_j = +23{\cdot}1^\circ$ or $[\alpha]_D = +20{\cdot}4^\circ$, or for the acid therein $[\alpha]_j = +28{\cdot}9^\circ$ or $[\alpha]_D = 25{\cdot}5^\circ$. A nitric acid solution shows strong dextro-rotation, varying in amount according to the quantity of nitric acid employed in the solution. L. T. T.

Uric Acid. By E. FISCHER (*Ber.*, 17, 1776—1788).—In continuation of his previous communication (this vol., 996), the author describes several more derivatives of uric acid which he has obtained, and then enters into a theoretical discussion as to the constitution of uric acid.

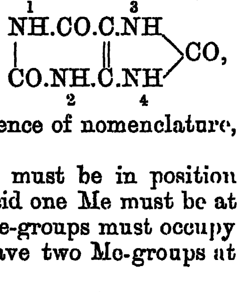
Monomethyluric Acids.—The α-acid described by Hill (this Journal, 1876, ii, 75) yields monomethylalloxan and carbamide on oxidation: when heated with concentrated hydrochloric acid, it splits up into carbonic anhydride, ammonia, methylamine, and glycocine. The β-acid, briefly described by the author (this vol., 996) under the name of trihydroxymethylpurin, is best prepared by heating dichlorhydroxymethylpurin with concentrated hydrochloric acid at 135—140°. The ammonium salt is not decomposed when the excess of ammonia used in its preparation is boiled off, but on cooling separates from the solution as a gelatinous mass. When treated with an ammoniacal solution of silver nitrate, silver is deposited. When heated with phosphoric chloride and oxychloride at 130°, it is partly reconverted into dichlorhydroxypurin. When oxidised with nitric acid or chlorine-water it is easily decomposed into alloxan and methylcarbamide. When heated for five or six hours at 170° with about five times its weight of strong hydrochloric acid, it is decomposed, yielding the same products as the α-acid.

Dimethyluric Acids.—The α-acid of Hill is decomposed on oxidation into monomethylalloxan and monomethylcarbamide: when heated with hydrochloric acid at 170°, it yields ammonia, methylamine, and glycocine. Its ammonium salt, unlike that of the α-mono-acid, is decomposed by boiling—the free acid being re-formed. When heated for some time at 125° with phosphoric chloride and oxychloride, an unstable chlorinated compound is produced which, however, differs altogether from the chlorinated body obtained from the β-acid. The β-acid (already described under the name of trihydroxydimethylpurin) is decomposed when heated with hydrochloric acid at 170°, yielding carbonic anhydride, ammonia, methylamine, and sarcosine. Its ammonium salt is not decomposed by boiling. When heated with phosphoric chloride and oxychloride at 135°, it is almost entirely reconverted into dichloroxydimethylpurin. When oxidised with nitric acid or chlorine-water, traces only of alloxan are produced, the principal product being a body of the composition $C_7H_{10}N_4O_5$. It is formed according to the equation $C_7H_8N_4O_4 + H_2O + O = C_7H_{10}N_4O_5$, and is a derivative of mesoxalic acid. It has no analogue in the oxidation-products of any of the uric acid derivatives, and the author proposes to name it *oxy-β-dimethyluric acid*. It crystallises in large, colourless, and well-formed plates, melts at 173—174°, and is completely decomposed at a slightly higher temperature. When its aqueous solution is boiled, decomposition sets in, gas is evolved freely, and easily soluble products are formed. Ammonia produces no red coloration, hydrogen sulphide has no action, but hydriodic acid reduces it, forming an easily soluble crystalline compound still under investigation. Barium hydroxide gives no precipitate with a cold aqueous solution of the compound, but on heating barium mesoxalate is at once precipitated, whilst carbamide, and probably dimethylcarbamide, remain in solution. When oxidised with chromic mixture, it yields cholestrophane, $C_5H_6N_2O_3$: this formation of cholestrophane proves that both methyl-groups in this compound, and consequently in β-dimethyluric acid, are combined with the two nitrogen-atoms which are split off from β-monomethyluric acid in the form of monomethylcarbamide. *Consequently it is clear that in uric acid there is a carbamido-group containing two imido-groups distinct from the nucleus which is removed as alloxan on oxidation in acid solution.*

Trimethyluric Acid.—The author has not been successful in his attempts to methylate α-dimethyluric acid. When the lead salt of β-dimethyluric acid, however, is heated for eight hours at 125—130° with an equal weight of methyl iodide and double its weight of ether, the product boiled with water, the hot extract treated with sulphuretted hydrogen, and the filtrate supersaturated with ammonia and concentrated to a small bulk, trimethyluric acid separates out as a white crystalline mass melting at 345°. It is slightly soluble in alcohol and chloroform, readily in strong hydrochloric acid. It is more easily soluble in ammonia than in water, but the ammonium salt is decomposed again by boiling. Its alkaline salts crystallise in needles. With ammoniacal silver, it yields a crystalline compound containing silver and ammonia;* this is easily soluble in hot water, and with excess of silver nitrate yields a pale yellow gelatinous precipitate. If, however, the acid is dissolved in a large quantity of hot ammonia, the calculated quantity of silver nitrate added, and the ammonia then boiled off, the normal silver salt, $C_8H_9AgN_4O_3$, crystallises out in thin needles. Trimethyluric acid shows the murexide reaction much more strongly than does β-dimethyluric acid, and is more unstable towards acids. It is decomposed by fuming hydrochloric at 130°, and yields a crystalline compound easily soluble in boiling water, and melting at 330°. Trimethyluric acid is isomeric with hydroxycaffeïne, and their melting points are identical, but they are without doubt totally distinct bodies.

Tetramethyluric acid was prepared from trimethyluric acid by treating its silver salt with methyl iodide. It crystallises in thin white needles, melts at 218°, and distils undecomposed. It is easily soluble in boiling water or chloroform, more sparingly in alcohol and ether. It has no acid properties, but is very unstable towards alkalis, giving off methylamine. It shows the murexide reaction, but more feebly than the trimethyl acid. It is isomeric, but not identical with methoxycaffeïne. When heated with hydrochloric acid at 170°, this acid yields methylamine, but *no trace of ammonia. It is thus clear that in tetramethyluric acid all four nitrogen-atoms are united to methyl.*

Taking all these results into consideration, the author looks upon the correctness of Medicus' uric acid formula,



$$\begin{array}{l}\overset{1}{\mathrm{N}}\mathrm{H.CO.C.}\overset{3}{\mathrm{N}}\mathrm{H} \\ |\qquad\quad\ \|\qquad\ \ >\mathrm{CO}, \\ \mathrm{CO.}\underset{2}{\mathrm{N}}\mathrm{H.C.}\underset{4}{\mathrm{N}}\mathrm{H}\end{array}$$

as fully established, and he proposes for convenience of nomenclature, &c., to number the four imide-groups as above.

In α-monomethyluric acid the methyl-group must be in position 1 or 2, in the β-acid in 4. In α-dimethyluric acid one Me must be at 1 or 2, the other at 4; in the β-acid the two Me-groups must occupy 3 and 4. The only trimethyluric acid must have two Me-groups at 3 and 4, and one at 1 or 2.

The author considers the formation of dichloroxymethylpurin by the action of phosphoric chloride on β-monomethyluric acid to be analogous to the conversion of acid amides into imido-chlorides investigated by Wallach.

L. T. T.

Nitration of Benzene-derivatives. By P. SPINDLER (*Annalen*, **224**, 283—313).—In addition to that portion of the research which refers to the nitration of benzene (Abstr., 1883, 975), the results of the author's experiments on the nitration of chloro- and bromo-benzene, toluene, ortho-, meta-, and para-benzoic nitranilide are given in the following table.

10 c.c. of nitric acid (sp. gr. 1·5) mixed with varying quantities of water were used, and the results are expressed in molecules of NO_2 per 100 mols. of toluene, &c., taken.

10c.c HNO_3 + x c.c. H_2O.	Toluene. Days.		Chlorobenzene. Days.		Bromobenzene. Days.		Benzylnitranilide Ortho. Hours.		Meta.		Para.

The author's theoretical conclusions on this subject have been already published (*loc. cit.*). W. C. W.

Replacement of Amido-groups in Aromatic Derivatives by Chlorine. By T. SANDMEYER (*Ber.*, **17**, 1633—1635).—In an attempt to prepare phenylacetylene by the action of cuprous acetylide on diazobenzene chloride, *chlorobenzene* was obtained. This result is due to the formation of cuprous chloride, and is best carried out as follows: 150 grams of a 10 per cent. solution of cuprous chloride in hydrochloric acid are heated almost to boiling in a flask provided with a reflux condenser, and a solution of diazobenzene chloride is then gradually added, the whole being kept well shaken; each drop of the diazobenzene solution produces a yellow precipitate which, however, at once decomposes with evolution of nitrogen. The product is distilled in a current of steam, dried and fractioned, when chlorobenzene is obtained of constant boiling point (130°). In explanation of this reaction, the author suggests the two equations: $PhN : NCl + Cu_2Cl_2 = PhN(CuCl).N(CuCl)Cl$ and $PhN(CuCl).N(CuCl)Cl = N_2 + Cu_2Cl_2 + PhCl$, the intermediate compound $PhN(CuCl).N(CuCl)Cl$ being, perhaps, the yellow precipitate mentioned. Cupric and ferrous chlorides do not act in this way. Metamidobenzoic acid has in the same way been converted into metachlorobenzoic acid, and the reaction simplified by treating a mixture of the amido-compound and cuprous chloride with potassium nitrite. The author is trying the reaction with other substances, and already finds that it holds with metanitraniline and paraphenylenediamine. A. K. M.

Reaction of Iodine with Carbon Compounds at High Temperatures. By B. RAÝMAN and K. PREIS (*Annalen*, **223**, 315—323).—In earlier communications (Abstr., 1879, 623; 1880, 463), the authors have shown that by the action of iodine at 250° on aromatic compounds containing long side-chains, the side-chains are separated and split into methyl-groups which then enter the aromatic nucleus, forming methyl, dimethyl, &c., derivatives, the most probable course of the reaction being that methyl iodide substitution-derivatives of the aromatic nucleus are first formed, and by their further action yield free iodine and aromatic methyl substitution-derivatives. In accordance with this view, the present experiments were made by heating at 250° aromatic hydrocarbons with alkyl iodides and a small quantity of iodine. To remove the hydriodic acid formed in some cases the corresponding alkyl bromide, in others isobuty alcohol was added.

Benzene with methyl iodide and iodine yielded methane, toluene, and higher hydrocarbons not investigated.

Toluene with ethyl iodide and iodine gave xylenes (principally metaxylene), a hydrocarbon, C_9H_{12} (ethyltoluene ?) and hydrocarbons of higher boiling point, probably hydrides and ethylphenyls.

Metaxylene with iodine and methyl iodide yielded pseudocumene, mesitylene, a hydrocarbon, $C_{10}H_{14}$, most probably identical with that prepared by Holtmeyer (*Zeit. f. Chem.*, 1867, 689) from mesitylene, and a hydrocarbon, $C_{11}H_{16}$, distilling between 205° and 223°.

Commercially pure pseudocumene (pseudocumene and mesitylene) with ethyl iodide and iodine gave symmetrical (?) ethyldimethylbenzene.

Hexyl iodide, when heated with iodine for five hours at 256°, yields a combustible gas and hydriodic acid in large quantities, methyl iodide in small quantity, the main product being hexane. A. J. G.

Action of Methylene Chloride on Toluene and Benzene. By C. Friedel and J. M. Crafts (*Bull. Soc. Chim.*, **41**, 322—327).—Ditolylmethane, dimethylanthracene, together with para-, meta-, and probably ortho-xylene, are obtained by acting on toluene boiling at 110—111°, with methylene chloride boiling at 40—45°, in presence of aluminium chloride. The reactions are represented in the following way: $2C_6H_5Me + CH_2Cl_2 = CH_2(C_6H_4Me)_2 + 2HCl$, and $2C_6H_5Me + 2CH_2Cl_2 =$  $C_6H_4Me\left\langle\begin{matrix}CH\\|\\CH\end{matrix}\right\rangle C_6H_4Me + 4HCl + H_2$. The hydrogen liberated in this reaction reduces the methylene chloride to methyl chloride, and this reacting with toluene in presence of aluminium chloride yields xylene; para- and meta-xylene were recognised by their oxidation-products, but the ortho variety was also probably produced. When benzene is treated with methylene chloride in presence of aluminium chloride, diphenylmethane and anthracene are obtained, and also, by a secondary reaction, toluene. The decompositions are $C_6H_6 + CH_2Cl_2 = CH_2(Ph)_2 + 2HCl$; $2C_6H_6 + 4CH_2Cl_2 = C_{14}H_{10} + 4HCl + 2MeCl$; and $C_6H_6 + MeCl = C_6H_5Me + HCl$. The results obtained by Schwarz are attributable to the use of methylene chloride containing chloroform. W. R. D.

Action of Isobutyl Chloride on Benzene. By E. Gossin (*Bull. Soc. Chim.*, **41**, 446—447).—By the action in the cold of 50 grams of isobutyl chloride (boiling at 68—69°) on 150 grams of benzene and about 50 grams of aluminium chloride, two liquids of the formula $C_{10}H_{14}$ are obtained. The one boils at 166—167°, and is identical with the compound obtained by Fittig from bromobenzene and isobutyl bromide; the other boils at 152—155°, and is formed only in very small quantity, it appears to be tertiary butylbenzene.

W R. D

Derivatives of Metaxylene. By A. COLSON (*Compt. rend.*, 99, 40—42.)—Crude xylene is not entirely freed from paraxylene even by two successive treatments with dilute nitric acid, and the dibromoderivative described by Radziszewski and Wispek as dibromometaxylene (melting at 140—141°), is really dibromo-*para*-xylene in a more or less pure condition.

Dibromometaxylene, $C_6H_4(CH_2Br)_2$, is obtained from the pure metaxylene of commerce by the same method as the ortho-derivative, and may be purified by recrystallisation from light petroleum, or, if ebullition and too long contact are avoided, from alcohol of 90°. It forms white crystals which melt at 77·1°, and dissolve in ether and chloroform, in three times their weight of boiling light petroleum, and in a smaller quantity of boiling alcohol. Sp. gr. of the crystals at 0° = 1·734; of the liquid at 90° = 1·61.

Metaxylene glycol, $C_6H_4(CH_2.OH)_2$, is obtained by saponifying the dibromo-derivative with an aqueous solution of potassium carbonate, evaporating to dryness on the water-bath, and extracting with ether. On slow evaporation, the ether leaves an oily liquid which quickly solidifies in microscopic crystals melting at 45·5—46·2°. The crystals are inodorous and have a bitter taste. They dissolve in about seven times their weight of ether at 12°, but are much more soluble in water and very readily form supersaturated solutions. They also have a tendency to remain in superfusion; the sp. gr. of the liquid at 18° is 1·16. On oxidation, metaxylene glycol yields isophthalic acid, and when treated with concentrated aqueous hydrobromic or hydrochloric acid, yields the corresponding bromide or chloride. Dichlorometaxylene is a crystalline compound which melts at 34·2°.

The following table gives the melting point of several derivatives of the xylenes:—

	Para.	Ortho.	Meta.
Dichloroxylene ...	100·5°	54·5°	34·2°
Dibromoxylene ...	143·0	94·9	77·1
Xyleneglycol.....	112·5	64·6	46·2
Xylene..........	16·0	?	?

C. H. B.

Orthoxylene-derivatives. By G. LESER (*Ber.*, 17, 1824—1826). —*Orthoxylylene sulphide*, $C_6H_4\left<\begin{matrix}CH_2\\CH_2\end{matrix}\right>S$, was prepared by treating an alcoholic solution of orthoxylylene bromide with a saturated aqueous solution of potassium sulphide, and then distilling in a current of steam. It is a colourless oil, with a strong odour of mercaptan. It distils undecomposed, and solidifies to large crystals a little above 0°. *Orthoxylylenediethyl ether*, $C_6H_4(CH_2.OEt)_2$, is obtained by boiling orthoxylylene bromide with a large excess of alcoholic potash. It is a light colourless oil of pleasant odour, and boils at 247—249° under 720 mm. pressure. *Orthoxylylenedianilide* (or diphenylorthoxylylenediamine), $C_6H_4(CH.NHPh)_2$, is obtained by boiling an alcoholic solution of orthoxylylene bromide with an excess of aniline. It crystallises from alcohol in small colourless needles melting at 172°. It is a feeble base, and is soluble in concentrated hydrochloric acid, but is reprecipitated from this solution on the addition of water. *Orthoxylylene iodide* is obtained by digesting the bromide with excess of potassium iodide, or better by treatment of phthalic alcohol (xylylene hydroxide) with fuming hydriodic acid and amorphous phosphorus. It crystallises from ether in well-formed yellow prisms, melting at 109—110°. L. T. T.

Preparation of Nitriles. By G. KRÜSS (*Ber.*, **17**, 1766—1768).—Letts showed (this Journal, **25**, 1020) that most of the aromatic nitriles may be prepared by heating potassium thiocyanate with the respective aromatic acids, the reaction taking place according to the equation—

$$2R.COOH + CNSK = R.CN + R.COOK + H_2S + CO_2.$$

By this reaction only half the acid employed is converted into the nitrile. By substituting lead thiocyanate in place of the potassium salt, the author is enabled to convert the whole of the acid into its nitrile,

$$2Ph.COOH + Pb(CNS)_2 = 2Ph.CN + PbS + H_2S + 2CO_2.$$

The acid and thiocyanate are heated together in the dry state at 190—195°. In preparing benzonitrile by this process, the author obtained 50—60 grams nitrile from 100 grams benzoic acid, as compared with 33 grams obtained by Letts. Letts was unable to obtain cinnamonitrile by his method, the decomposing point of potassium thiocyanate lying below the temperature necessary for the reaction. Lead thiocyanate being more active than the potassium salt, the author succeeded in preparing cinnamonitrile by the new process, obtaining 5 grams nitrile from 15 grams acid. L. T. T.

Nitration of Thiophene-derivatives. By H. KREIS (*Ber.*, **17**, 2073—2075).—Although thiophene and its homologues are completely oxidised by treatment with nitric acid, thiophene-derivatives containing negative groups can be nitrated.

Iodonitrothiophene, $C_4SH_2I.NO_2$.—On mixing iodothiophene with excess of nitric acid at the ordinary temperature, a violent reaction takes place, and the compound is completely oxidised. If the nitric acid is added drop by drop, however, with continued shaking, and cooling between each addition of acid, the required nitro-compound is formed. It crystallises in lemon-yellow prisms, has an intense bitter-almond-like odour, melts at 74°, and is soluble in alcohol; insoluble in water.

Dibromodinitrothiophene, $C_4SBr_2(NO_2)_2$, is prepared by suspending dibromothiophene in five times its volume of sulphuric acid, and adding nitric acid drop by drop. It is unnecessary to cool the mixture. It forms hard, pale-yellow crystals, which melt at 134°; it is readily soluble in hot, but only sparingly in cold alcohol.

A. J. G.

Conversion of Aromatic Amines into the Ethers of the corresponding Phenols. By A. W. HOFMANN (*Ber.*, **17**, 1917—1920).—In order to obtain tetramethylbenzene (see p. 1320) more easily than by the action of hydrochloric acid on the nitrile, the author converted tetramethylamidobenzene into the diazo-compound, and boiled that with alcohol. Instead of the expected hydrocarbon, he obtained the *ethyl ether*, $C_6HMe_4.OEt$, an aromatic oil boiling at 236—237°.

In order to determine whether this was a special reaction of the body in question, or of more general application, he has prepared several more diazo-compounds, and decomposed them by means of alcohol.

Cumidine thus treated yielded the ether $C_6H_2Me_3.OEt$, boiling at 223—224°, together with a sparingly soluble crystalline substance which melts at 173°, and is now undergoing investigation. When methyl and amyl alcohols were substituted for ethyl alcohol, the methyl and amyl ethers were obtained respectively. The *methyl ether* boils at 213—214°, the *amyl ether* at 265—266°.

The reaction was also tried with aniline, toluidine, &c., and in all cases the corresponding ethers were formed, sometimes together with a small quantity of the hydrocarbon. It is therefore clear that when a diazo-compound is boiled with alcohol the diazo-group displaced is not always replaced by hydrogen, but often by an oxy-radicle (ethoxyl, methoxyl, &c.) (see also Haller, this vol., p. 1322). L. T. T.

Action of Nitro-hydrobromic Acid on Organic Compounds.

By H. BRUNNER and C. KRAEMER (*Ber.*, **17**, 1872—1874).—The authors are now engaged in investigating the action of a mixture of hydrobromic and nitric acids on inorganic and organic substances, to determine whether it acts in a manner analogous to aqua-regia. The present communication treats of some compounds of interest in relation to the authors' work on the phenol-colouring matters (see this vol., pp. 1333 and 1340).

Aniline, dimethylaniline, diphenylamine, phenol, quinol, catechol, and α-naphthol yield no colouring matters when treated with nitro-hydrobromic acid. Resorcinol yields a lustrous green mass which dissolves in alcohol to a red solution; this, on the addition of an alkali, turns blue, and shows a brown fluorescence. This colouring matter has the formula $C_{36}H_{25}BrN_2O_{10}$; it probably must be considered as a brominated derivative of the compound $C_{36}H_{26}N_2O_{10}$.

With nitro-hydrobromic acid, orcinol yields a reddish-brown amorphous body containing bromine; this is being investigated.

L. T. T.

Condensation-products of Aromatic Bases with Aldehydes.

By O. FISCHER and C. SCHMIDT (*Ber.*, **17**, 1889—1896).—I. *Orthonitrobenzaldehyde and Dimethylaniline.*—The leuco-base orthonitrotetramethyldiamidotriphenylmethane thus produced has been already described (Abstr., 1882, 834). Its crystals are monoclinic, and measurements thereof gave $a : b : c = 1\cdot1795 : 1 : 0\cdot5262$ and $\beta = 85° \; 0'$. Its melting point is 159—160°. By oxidation of the sulphate of this leuco-base with lead dioxide, the colour-base *orthonitro-malachite-green*, $C_{23}H_{25}N_3O_3$, is obtained. It forms small, orange, lustrous crystals which melt at 163°. It is easily soluble in benzene, ether, and alcohol. Its neutral salts are green, with a blue shade. The reduction-product already described (*loc. cit.*) forms with benzene colourless crystals melting at 134—135°. The leuco-base, when boiled with acetic anhydride, yields a monacetyl-derivative, melting at 186°. This body, when oxidised with a peroxide, yields *acetamidobenzaldehyde green*, a beautiful green colouring matter. When the acetyl-compound is converted into its sulphate before oxidation, the acetyl is eliminated during the reaction, $C_{23}H_{27}N_3O$ being formed. The neutral salts of this base are green, with a blue shade. The introduction of a nitro- or amido-group into the benzene nucleus, in the para-position to the methane-group, thus causes a tendency of the colour towards blue, whilst, as is known, these groups in the meta-position scarcely alter the colour-shade.

II. *Orthonitrobenzaldehyde and Diethylaniline.*—Analogous compounds are produced with diethylaniline. *Orthonitrotetrethyldiamidotriphenylmethane* melts at 109—110°. Its crystals are of a reddish-orange, belong to the triclinic system, and give $a:b:c = 0\cdot7720:1:0\cdot8037$, and $\alpha = 100°\ 55'$, $\beta = 95°\ 52'$, $\gamma = 94°\ 38'$. The *amido-base* crystallises in needles melting at 136°. The *colour-base* is a deep bluish-green.

III. *Vanilline and Dimethylaniline.*—The *leuco-base*, $C_{24}H_{28}N_2O_2$, melts at 135—136°, and forms colourless crystals. The *colour-base* is violet.

L. T. T.

Nitrotoluidine (m. p. 91·5°) prepared from Liquid Dinitrotoluene. By C. Ullmann (*Ber.*, **17**, 1957—1964).—Bernthsen has shown (Abstr., 1883, 579) that two nitrotoluidines are obtained on reducing liquid dinitrotoluene, the one [$Me : NO_2 : NH_2 = 1 : 2 : 4$] already known, and a second melting at 91·5°, and yielding a benzoyl-derivative melting at 167—167·5°. This latter had been previously obtained in an impure form by Cunerth (this Journal, 1875, 82), who had shown the methyl- and nitro-groups to be relatively in the ortho-position. The author confirms this result, and further shows that by conversion of the nitrotoluidine into a nitrocresol, of this into the amidocresol, and by then eliminating the amido-group by Griess's reaction, orthocresol is obtained. The nitrotoluidine, therefore, must have the constitution [$Me : NO_2 : NH_2 = 1 : 2 : 6$].

1 : 2 : 6 *Nitrotoluidine* crystallises in long silky needles, and is readily soluble in alcohol, ether, and benzene. The *hydrochloride*, $C_6H_3Me(NO_2).NH_2,HCl$, crystallises in long flat needles, readily soluble in water, and also readily decomposed by it. When heated, it begins to lose hydrochloric acid at 80°. The *sulphate* forms small crystals, relatively sparingly soluble in water. The *acetyl-compound*, $C_6H_3Me(NO_2).NH\overline{Ac}$, obtained by the action of acetic chloride on an alcoholic solution of the base, crystallises in long, brilliant, colourless needles, melts at 157·5—158°, is readily soluble in alcohol and ether, sparingly soluble in cold water.

Toluylenediamine, $C_6H_3Me(NH_2)_2[1 : 2 : 6]$.—The hydrochloride is obtained by heating nitrotoluidine on the water-bath with tin, hydrochloric acid, and stannous chloride; it crystallises in thick colourless needles. The free base, prepared by the dry distillation of the hydrochloride with lime, crystallises in yellowish-white prisms, and melts at 103·5°. It appears to be more stable than its isomerides. The aqueous solution turns brown slowly on exposure to air. Its solution in sulphuric acid gives a yellowish-brown coloration with potassium nitrite. With paranitrosodimethylaniline it gives, first a green, and then a blue coloration, turning violet on long standing; ordinary 1 : 2 : 4 toluylenediamine gives the same reaction. With ferric chloride, or with chromic acid, it gives a deep brown coloration.

Nitrocresol, $C_6H_3Me(NO_2)$ OH [1 : 2 : 6], prepared by means of the diazo-reaction from the 1 : 2 : 6 nitrotoluidine, crystallises in woolly yellow needles, melts at 142—143°, is very sparingly soluble in cold water, readily soluble in alcohol and ether, soluble in aqueous baryta or soda, with intense yellowish-red colour. The alkali compounds could not be isolated. Silver nitrate gives a white precipitate, sparingly soluble in ammonia, and crystallising from dilute nitric acid in interlaced needles.

Amidocresol, $C_6H_3Me(NH_2)$.OH [1 : 2 : 6], is obtained as hydrochloride by the reduction of the nitrocresol with tin and hydrochloric acid; by treating this with sodium carbonate, the free base may be obtained, crystallising in concentrically grouped needles. It melts at 124—128°; is sparingly soluble in cold water and ether. It dissolves in soda and ammonia, without characteristic coloration. By heating it with sulphuric acid, and then pouring into water, a solution is obtained green by reflected, flesh-coloured by transmitted light. The *hydrochloride* crystallises in white needles, can be sublimed, is readily soluble in water and alcohol. It is stable in the pure and dry condition, but very unstable if impure.

Dihydroxytoluene, $C_6H_3Me(OH)_2$ [1 : 2 : 6], was prepared from the 1 : 2 : 6 amidocresol by Neville and Winther's method (Trans., 1882, 415). The yield was very small. It crystallises in nearly colourless needles, melts at 63—66°, has a biting taste and phenol-like odour, and is readily soluble in water or alcohol. It dissolves readily and without coloration in soda and in ammonia, the solution in the latter slowly turning a pale dirty blue. It gives a white precipitate with bromine-water, a magenta coloration rapidly changing to yellowish-brown with bleaching-powder, a rose-red with chloroform and soda. It reduces ammoniacal silver solution in the cold. By heating it with phthalic anhydride, and dissolving the product in soda, a rose-red liquid, with strong green fluorescence, is obtained. It is probably identical with γ-isorcinol, but it is impossible, from the small yield, to speak as yet with certainty. A. J. G.

Action of Dimethylparatoluidine and Dimethylaniline on Ethylene Bromide. By H. HÜBNER, A. TÖLLE, and W. ATHENSTÄDT (*Annalen*, **224**, 331—353).—*Ethylene ditolyldimethylammonium bromide*, $(C_7H_7Me_2NBr)_2C_2H_4$, and a small quantity of ethylene ditolylmethylamine, $(C_7H_7MeN)_2C_2H_4$, are formed when a mixture of ethylene bromide and dimethylparatoluidine is heated at 100—110° in sealed tubes for four days. The product is dissolved in water and boiled, in order to remove unaltered dimethyltoluidine and ethylene bromide. On cooling, a portion of the amine crystallises out, and the remainder is precipitated by ammonia. The solution of ethylene ditolyldimethylammonium bromide is converted into the carbonate by the action of silver carbonate. The single salts of this base are very soluble in alcohol and water; the double salts crystallise readily. The platinochloride, $(C_7H_7Me_2NCl)_2C_2H_4,PtCl_4$. forms orange-coloured needles; the mercuriochloride, $(C_7H_7Me_2NCl)_2C_2H_4,2HgCl_2$, and stannichloride, $(C_7H_7Me_2NCl)_2C_2H_4,SnCl_4$, crystallise in colourless needles. The picrate forms pale-yellow needles or plates which melt at 196°. The aqueous solution of the carbonate is decomposed by heat, yielding ethylenedimethyltolylamine. This amine crystallises in colourless plates or prisms melting at 80°; and dissolves freely in benzene or ether. The hydriodide forms rhombic plates, the oxalate colourless needles, the platinochloride, $(C_7H_7MeN)_2C_2H_4,H_2PtCl_6$, an orange powder, and the mercuriochloride thick needles. Almost all the salts are unstable, and are very soluble in water. Two mols. of ethylenedimethyltolylamine unite with 1 mol. of methyl iodide, forming *ethylenemethyltolylamine-dimethyltolylammonium iodide*, $C_7H_7Me.NC_2H_4.NI(C_7H_7Me_2)$, a colourless crystalline compound, soluble in hot water. The corresponding carbonate is insoluble in water. The double salt with mercuric chloride is crystalline. Ethylenedimethyltolylamine is decomposed by heat, yielding triethylenetritolylamine, $(C_6H_4Me.N:C_2H_4)_3$, and dimethyltolylamine. Ethylene bromide acts on dimethylaniline at 100°, forming *ethylenediphenyldimethylammonium bromide*, $(PhMe_2NBr)_2C_2H_4$, a deliquescent salt, deposited from an alcoholic solution in colourless prisms. The corresponding hydroxide dissolves in water, yielding a solution which absorbs carbonic anhydride, forming a crystalline carbonate. The aqueous solution of the carbonate is not decomposed by boiling, but the carbonate is decomposed by dry distillation, forming dimethylaniline.

The *chloride*, $(PhMe_2NCl)_2C_2H_4$, crystallises in deliquescent prisms, freely soluble in alcohol, and the picrate forms yellow needles melting at 124°; it dissolves sparingly in cold alcohol or water.

The following table shows the chief points of difference between the salts of trimethylphenylammonium and those of ethylenediphenyldimethylammonium:—

	Trimethylphenylammonium.	Ethylenediphenyldimethylammonium.
Mercuriochloride ...	Deposited from water in colourless needles.	The same.
Solubility in H_2O ..	M. p. 187°. 1 in 275·5 at 6·2	M. p. 175°. 1 in 317·9 at 6·2.
Platinochloride	Deposited from water in yellowish-red needles.	The same.
Soluble in H_2O	1 in 304·9 at 7·4	1 in 404·8 at 7·4.
Iodide	Deposited from alcohol in colourless plates.	The same.
Soluble in alcohol ..	1 in 45·5 at 8·2	1 in 46·4 at 8·2.
Dichromate	1 in 200 of cold water.	1 in less than 75 parts of cold water.

W. C. W.

Derivatives of Pseudocumidine. By E. FRÖHLICH (*Ber.*, 17, 1801—1809).—*Phthalopseudocumide*, $C_6H_2Me_3N:C_8H_4O_2$, was prepared by heating cumidine with phthalic anhydride. It crystallises in rhombic prisms, melts at 148°, and distils without decomposition at a temperature above the boiling point of mercury. It is easily soluble in carbon bisulphide, chloroform, and benzene, sparingly so in alcohol and ether, and insoluble in water. It sometimes crystallises in needles which, however, change back to the prisms on shaking, or often spontaneously.

Benzoylphthalopseudocumide, $C_6H\overline{Bz}Me\,N : C_8H_4O_2$ is formed when a mixture of phthalopseudocumide and benzoic chloride is heated with a little zinc chloride at 175—180° for 8 hours. It crystallises in small glittering rhombohedra which melt at 181°, and are readily soluble in boiling acetic acid, sparingly so in alcohol, ether, and carbon bisulphide, insoluble in water. When quickly distilled in small quantities, it passes over unchanged, but is totally decomposed if distilled in large quantity or slowly.

Benzoylpseudocumidine, $C_6H\overline{Bz}Me_3.NH_2$, is prepared by the saponification of the compound just described, with concentrated sulphuric or hydrochloric acid at 140—150°. If saponified with alcoholic potash an intermediate compound, $C_6H\overline{Bz}Me_3.NH.CO.C_6H_4.COOH$, is first formed; and heating in closed tubes at 100° for 24 hours must be resorted to to complete the saponification. Benzoylpseudocumidine crystallises in lemon-yellow needles or scales which melt at 130°. It is easily soluble in alcohol, ether, benzene, and chloroform, almost insoluble in water, and is not volatile with steam. It forms crystallisable salts with one equivalent of acid. The platinochloride $(C_{16}H_{17}NO)_2,H_2PtCl_6$, crystallises in orange needles. With benzoic chloride it yields benzoylbenzopseudocumide, $C_6H\overline{Bz}Me_3.NH\overline{Bz}$, which forms colourless glittering needles; it melts at 227°, and is sparingly soluble in ether and alcohol, easily in boiling glacial acetic acid, insoluble in water.

Benzoylpseudocuminol, $C_6H\overline{Bz}Me_3\,OH$, is obtained from the cumidine by means of the diazo-reaction. It yields colourless micaceous scales melting at 187°. It is easily soluble in alcohol and ether, insoluble in water, but dissolves in sodium hydroxide. It is not volatile with steam.

Phthalopseudocumidamide, $C_6H_4(CONH_2).CONH.C_6H_2Me_3$, is obtained when a hot saturated solution of phthalopseudocumide is treated with a slight excess of ammonia. It crystallises in colourless needles, melts at 218°, and is decomposed at that temperature into ammonia and phthalocumide. It is sparingly soluble in alcohol. It is of interest as being the first phthalamide which has been obtained, all attempts to prepare such an amide having previously led to the formation of the corresponding imide. Sulphuric acid decomposes this body into phthalic acid and cumidine without the formation of a trace of sulphonic acid. If methylamine be substituted for ammonia in the above reaction, *methylphthalopseudocumidamide*, $C_6H_2Me_3.NH.CO.C_6H_4.CONHMe$, is formed. This crystallises in needles melting at 215° with decomposition. It is sparingly soluble in alcohol and ether, insoluble in water. *Allylphthalopseudocumidamide*, prepared in like manner, forms silky needles melting at 179° with decomposition. It is easily soluble in alcohol. Di- and tri-methylamine and their homologues, as also aromatic amines, are without action on phthalopseudocumide.

Phthalopseudocumide acid, $C_6H_2Me_3\,NH.CO,C_6H_4.COOH$, is obtained by heating phthalopseudocumide with alcoholic potash on the water bath for half an hour. It crystallises in colourless needles and melts at 179° with decomposition. It is easily soluble in alcohol, chloroform, and glacial acetic acid, sparingly so in ether and carbon bisulphide, insoluble in water. It forms metallic salts, of which the *lead, silver, mercury, and copper* salts are sparingly soluble. The ammonia salt when heated on the water-bath gives up ammonia and water, and reforms phthalopseudocumide. By continued treatment with alcoholic potash or with sulphuric acid it is decomposed into phthalic acid and pseudocumidine. L. T. T.

Tetramethylated Amidobenzene. By A. W. HOFMANN (*Ber.*, 1912—1916).—The author has examined an oil which was formed as a bye-product in the preparation of solid cumidine on a large scale. The crude product boiled between 240—300°. As the cumidine was prepared by the action of methyl alcohol on xylidine hydrochloride, it seemed probable that this bye-product would contain methylated homologues of cumidine.

Amongst several substances to be described at a future time, the author succeeded in isolating a pale-yellow oil boiling at 252—253°, which proved to be tetramethylamidobenzene, $C_6HMe_4.NH_2$. It solidifies at 11° to a crystalline mass which melts at 14°; and at 24° has sp. gr. 0.978. It is a primary amine, and yields a crystalline hydrochloride and platinochloride. Its salts crystallise well, and are mostly soluble in boiling water. The *dimethylated base*, $C_6HMe_4.NMe_2$, was obtained by treating the free base with methyl iodide. It is a colourless liquid, and boils at 236—238°. Its platinochloride is crystalline. The *isonitrile*, $C_{10}H_{13}.NC$, of the original base, is easily obtained by heating the latter with chloroform and potassium hydroxide. It is a white crystalline substance melting at 51°. It has the odour characteristic of isonitriles, but in a very subdued degree. When heated to 240° violent reaction sets in, the temperature of the whole rises, and at 260° the normal nitrile distils over. This body solidifies on cooling and then melts at 68—69°. This nitrile is exceedingly stable, and the author has not yet succeeded in converting it into the corresponding acid. Heated to 250° with hydrochloric acid, it is decomposed into a *tetramethylbenzene*, $C_6H_2Me_4$, and carbonic anhydride. The author is unable to say yet whether this hydrocarbon is identical or not with that described by Jannasch (*Ber.*, 8, 356). If the original base is digested with carbon bisulphide, sulphuretted hydrogen is evolved, and a thiocarbimide and a thiocarbamide are formed. The thiocarbimide, $C_6HMe_4.NCS$, crystallises at 65°. When distilled with powdered potash, it yields the base in a very pure state. The *thiocarbamide*, $CS(NH.C_6HMe_4)_2$, crystallises in plates which melt at 278°. By means of the diazo-reaction, the base was converted into the *phenol* $C_6HMe_4.OH$: this forms white crystals melting at 80—81°, and has the usual properties of phenols.

L. T. T.

Secondary Amines. By W. GEBHARDT (*Ber.*, 17, 2088—2095). This paper deals with the products of the action of isothiocyanates, of isocyanates, of thiocyanates, and of cyanates on secondary amines.

Methyldiphenylthiocarbamide, NHPh.CS.NMePh, prepared by the action of methylaniline on phenyl isothiocyanate, crystallises in thick rhombic prisms, is readily soluble in benzene, ether, glacial acetic acid, chloroform, and hot alcohol, sparingly soluble in cold alcohol and light petroleum, insoluble in water. It melts at 87°, distils at 204—206°. It is resolved into its components by distilling it with steam (when they recombine in the distillate), or by heating it with phosphoric acid. Boiled with aniline it yields thiocarbanilide. In sealed tubes at 250°, the reaction between methylaniline and phenyl isothiocyanate takes a different course, dimethylaniline and thiocarbanilide being formed.

Ethyldiphenylthiocarbamide, NHPh.CS.NEtPh, prepared in like manner from ethylaniline, closely resembles the methyl compound, and melts at 89°.

Phenylmethylparatolylthiocarbamide, $NH(C_7H_7).CS.NMePh$, prepared from paratolyl isothiocyanate and methylaniline, crystallises in small rhombic tables, melts at 124°, is readily soluble in benzene, sparingly in light petroleum.

Phenylethylparatolylthiocarbamide, $NH(C_7H_7).CS.NEtPh$, resembles the preceding compound, and melts at 90°.

Phenylmethyl-β-naphthylthiocarbamide, $NH(C_{10}H_7).CS.NMePh$, prepared from methylaniline and β-naphthyl isothiocyanate, forms long yellow needles and melts at 127°.

Triphenylthiocarbamide, $NHPh.CS.NPh_2$:—Diphenylamine, and phenyl isothiocyanate do not react at ordinary temperatures, but on heating the mixture at 280° for several days triphenylthiocarbamide is formed. It crystallises in long white needles, melts at 152°, is soluble in hot alcohol and alkalis, sparingly in cold alcohol.

Methyldiphenylcarbamide, NHPh CO.NMePh, prepared by mixing methylaniline and phenyl isocyanate, crystallises in small needles, melts at 104°, distils at 203—205°, is readily soluble in benzene, ether, chloroform, glacial acetic acid, and hot alcohol, but only sparingly in cold alcohol or hot water, and is almost insoluble in light petroleum and alkalis.

Ethyldiphenylcarbamide, NHPh.CO.NEtPh, forms large transparent prisms and melts at 91°.

Unsymmetrical methylphenylthiocarbamide, NH_2 CS.NMePh, is prepared by evaporating to dryness mixed aqueous solutions of methylaniline hydrochloride and excess of potassium thiocyanate. It crystallises in thick, colourless rhombic tables, melts at 107°, and is soluble in alcohol, benzene, and hot water.

Unsymmetrical ethylphenylthiocarbamide, NH_2 CS.NEtPh, crystallises in long, hard, nacreous prisms and melts at 113°.

Unsymmetrical methylphenylcarbamide, NH_2.CO.NMePh, prepared from methylaniline hydrochloride and potassium cyanate, crystallises in very thin striated rhombs of fatty lustre, melts at 82°, and is readily soluble in all the ordinary solvents with the exception of light petroleum.

Unsymmetrical ethylphenylcarbamide, NH_2.CO.NEtPh, forms silvery plates and melts at 62°.

The unsymmetrical diphenylcarbamide is not obtained by the action of diphenylamine hydrochloride on potassium cyanate.

A. J. G.

Action of Ferric Chloride on Orthophenylenediamine. By F. Wiesinger (*Annalen*, **224**, 353—356).—On the addition of ferric chloride to a solution of orthophenylenediamine hydrochloride, red needle-shaped crystals are deposited, of the composition

$$C_{24}H_{18}N_6O,2HCl.$$

The formation of this salt by the action of ferric chloride on orthodiamidobenzene hydrochloride was observed by Griess (*J. pr. Chem.*, **3**, 143; **5**, 202), but its properties were not investigated. The hydrochloride crystallises from water in ruby-coloured plates, containing 5 mols. H_2O. On decomposition with soda, it yields the free base $C_{24}H_{18}N_6O$ as a yellow crystalline precipitate, which dissolves sparingly in alcohol and water, with partial decomposition. The *sulphate*, $C_{24}H_{18}N_6O,H_2SO_4 + 3H_2O$, crystallises in needles, which resemble chromic anhydride in appearance. The *nitrate* is very unstable.

W. C. W.

New Aniline Colours. By Petrieff (*Bull. Soc. Chim.*, **41**, 310).—Aniline hydrochloride, when treated with an aqueous solution of potassium nitrite, yields a crystalline compound having the formula $C_{18}H_{18}N_4$, which melts at 95°, and is soluble in most liquids. Its salts are decomposed by water. It dyes a golden-yellow. When the compound is fused with aniline hydrochloride, a blue dye of the formula $C_{30}H_{26}N_4$ is obtained, together with a violet product, which probably has the formula $C_{24}H_{22}N_4$. The same compound, when fused with α-naphthol, gives an orange-coloured substance, of the formula $C_8H_{27}N_4$, and with β-naphthol an orange-red colouring matter.

W. R. D.

Action of Alcohol on Diazo-compounds. By S. Haller (*Ber.*, **17**, 1887—1889).—It is generally stated that when a diazo-salt is boiled with absolute alcohol, the diazo-group is replaced by hydrogen. But in this reaction there are always many bye-products formed. Diazocumene sulphate, when boiled with alcohol, yields only a very small quantity of hydrocarbon, the principal product being its ethyl ether. Diazobenzene sulphate, β-diazonaphthalene, &c., give similar results. It would seem, therefore, that with the decomposition of diazo-compounds by alcohol, the reaction sometimes brings about the replacement of the diazo-group by hydrogen, sometimes by ethoxyl, or some similar oxy-radicle. (See also Hofmann, this vol., p. 1314).

L. T. T.

Behaviour of Aldehyde, Glucose, Peptone, Albuminous Bodies, and Acetone towards Diazobenzenesulphonic Acid. By Petri (*Zeit. Phys. Chem.*, **8**, 291—298).—An alkaline solution of diazobenzenesulphonic acid added to the aldehydes of the fatty series or to glucose dissolved in weak alkali, produces a beautiful magenta-red reaction on standing 10 or 20 minutes; warming the solution hastens its appearance; it is only the fixed alkalis that can be used. The intensity of the colour depends very much on the proportion of the reagents; too much aldehyde or diazo-acid causes the colour to disappear. Concentrated solutions absorb all the light, except the red end of the spectrum as far as C. On dilution, the absorption becomes less, only extending to D, while at the same time a clearing takes place in the blue between F and G. If cautiously neutralised either with mineral or organic acids, the colour disappears, but reappears again quite unchanged in properties on adding alkali; addition of an excess of mineral acid likewise produces a red colour, although differing in spectroscopic properties from the original. All attempts to separate the colouring matter with the usual solvents have failed. Bromine, chlorine, iodine, sulphurous and nitrous acids, together with sodium amalgam and zinc-dust (the last two when air is excluded), decolorise the red solution. If the sodium amalgam or zinc is filtered off and the filtrate exposed to the air, the colour reappears.

Aqueous solutions of peptone or albuminous bodies produce an orange-yellow to an orange-red colour with the alkaline diazo-acid, but it differs from the colour above described in both spectroscopic properties and its behaviour towards acids. When neutralised carefully, the orange-red is changed to yellow, but the colour does not reappear when an excess of mineral acid is employed. *Ammonia*, as well as fixed alkalis, reproduce it. When subjected to reduction with sodium amalgam or zinc-dust with access of air, a magenta-red colour is produced, which does not differ in any of its properties from the colour in the aldehyde reaction. Acetone, too, behaves like the aldehydes.

J. P. L.

Action of Phenylhydrazine on the Imido-ethers. II. By A. PINNER (*Ber*, **17**, 2002—2004).—In the first part of this paper (this vol., p. 743), the author described the formation of benzenyldiphenylazidine from phenylhydrazine and benzimido-ether hydrochloride. *Methenyldiphenylazidine*, $NHPh.N:CH.N_2H_2Ph$, is prepared by adding phenylhydrazine to a solution of formimido-ether hydrochloride in absolute alcohol, and allowing the mixture to stand for some weeks. It crystallises in yellow plates, melts at 185°, is soluble in hot benzene, sparingly soluble in cold, readily soluble in hot alcohol, and gives a deep-red coloration with hydrochloric or sulphuric acid. The yield is not good, resinous products being largely formed.

With acetimido-ether, the reaction takes a different course, the product being *ethenylphenylazidine hydrochloride*, $NH:CMe.N_2H_2Ph,HCl$. It crystallises in long colourless prisms, containing $\frac{1}{2}$ mol. or $1\frac{1}{2}$ mol. H_2O, accordingly as it is crystallised from hot or cold alcohol. It is readily soluble in alcohol, insoluble in ether and benzene. It commences to decompose at 150°. A. J. G.

Derivatives of Benzylidinephenylhydrazine. By V. SCHROEDER (*Ber.*, **17**, 2096—2098).—*Acetobenzylidinephenylhydrazine*,

$$NPh\overline{Ac}.N:CHPh,$$

is obtained by dissolving benzylidenephenylhydrazine in acetic chloride and pouring the solution into water, or better by boiling the hydrazine with $1\frac{1}{2}$—2 parts of acetic anhydride and excess of sodium acetate for about three hours, the product being poured into water, and the crystalline mass that separates carefully washed with water, and recrystallised from dilute alcohol. It forms long colourless needles which melt at 115°. It is insoluble in cold water, soda, ammonia, and hydrochloric acid. It dissolves in sulphuric acid, the solution acquiring an odour of bitter almonds; addition of water reprecipitates the substance apparently unchanged.

Metanitrobenzylidinephenylhydrazine, obtained by heating phenylhydrazine with metanitrobenzaldehyde, forms red needles and melts at 121°. Its *acetyl compound*, $C_{15}H_{13}N_3O_3$, closely resembles the acetyl compound described above, and is prepared in a similar manner; it crystallises in yellow needles which melt at 170°.

Benzylidine-aniline does not yield an acetyl compound when treated with acetic chloride or anhydride. A. J. G.

Action of Benzoic Chloride on Amidines. By A. PINNER (*Ber.*, 17, 2004—2006).—By the action of benzoic chloride on benzamidine hydrochloride at 120—140° there were obtained cyaphenine and dibenzamide in small quantity, the main product of the reaction being a substance of the empirical formula C_7H_7NO, isomeric or polymeric with benzamide. It melts with decomposition at 230°, benzonitrile being one of the products. It is being examined further.

The substance of the formula $C_{14}H_{14}NO_2$, obtained by Pinner and Klein by the action of fuming sulphuric acid on benzonitrile diluted with benzene, and termed by them benzimido-benzoate, is in reality dibenzamide. A. J. G.

Structure of Hydroxylamine-derivatives. By W. LOSSEN (*Ber.*, 17, 1587—1589).—The author refers to a previous paper (*Ber.*, 16, 873), in which it is assumed that the action of hydroxylamine on acid chlorides is different from that of ammonia; and that benzhydroxamic acid, obtained from benzoic chloride and hydroxylamine, no longer contains the benzoic radical, but that its formula is OH.CPh : NOH. In like manner, ethylbenzhydroxamic acid may be represented by the formula OEt.CPh : NOH. This last formula is assigned by Pinner (this vol., p. 739) to his benzoximido-ether, obtained by the action of hydroxylamine hydrochloride on benzimido-ether. The author has compared the two substances, and finds that they are identical. The product of the action of benzimido-ether on hydroxylamine hydrochloride contains α- and β-ethylbenzhydroxamic acids, which may be separated by partially neutralising with potash, and agitating with ether; this extracts the β-modification, whilst the α-acid remains behind as potassium salt. Another substance, $C_7H_8N_2O$, is also produced, the formation of which may be expressed thus:

$$OEt.CPh:NH + NH_3O,HCl = OH.NH.CPh:NH,HCl + EtHO;$$

it resembles, and is perhaps identical with, the compound obtained by Tiemann (this vol., p. 734) from hydroxylamine and benzonitrile, and also with that obtained by Pinner (this vol., p. 739) by the action of hydroxylamine on benzamidine. It melts at about 76—77°.

A. K. M.

Remarks on the Previous Communication. By A. PINNER (*Ber.*, 17, 1589—1590).—In reply to Lossen (see preceding Abstract), the author points out that the method of acting on hydroxylamine with benzimido-ether as modified by that chemist, is not favourable to the formation of benzoximido-ether, and he is of opinion that this is not identical with ethylbenzhydroxamic acid, but that it may possibly be readily converted into the latter. A. K. M.

Amidoximes and Azoximes. By F. TIEMANN and P. KRÜGER (*Ber.*, 17, 1685—1698).—The following experiments were undertaken to decide whether the compounds obtained by the action of hydroxylamine on the acid nitriles are oxamidines, NH : CR.NH.OH, or amidoximes, NH_2.CR : N.OH (see this vol., p. 734). The preparation of the compound $C_7H_8N_2O$, from benzonitrile and hydroxylamine, has already been described; it melts at 79—80°, and not at 70° as previously stated. It yields well-crystallised salts both with acids and alkalis, and like hydroxamic acid has a tendency to form acid salts of the alkali-metals; the hydrochloride has the formula $C_7H_8N_2O,HCl$. When a solution of the compound $C_7H_8N_2O$ in alcoholic potash is warmed with a few drops of chloroform, the isonitrile odour is momentarily produced, and is succeeded by that of benzonitrile, the decomposition then proceeding further. The above compound combines with carbanil to form a carbamide, and with phenyl isothiocyanate to form a thiocarbamide. When sodium nitrite solution is added to a solution of the hydrochloride, nearly pure nitrous oxide is evolved, benzamide being simultaneously produced:

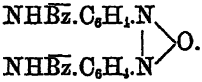
$$NH_2.CPh : NOH,HCl + NaNO_2 = PhCONH_2 + N_2O + NaCl + H_2O.$$

All these reactions indicate the presence of the group NH_2 and the constitution NH_2.CPh : NOH (*benzenylamidoxime*). If, however, the conditions of the last experiment be modified, an excess of nitrite and a higher temperature being employed, and the solution slightly acidified, the decomposition goes further, some nitrogen is given off, and a small quantity of benzoic acid is also produced. The methyl-ether of benzenylamidoxime, NH_2.CPh : NOMe, is readily obtained by heating a solution of benzenylamidoxime, sodium methylate, and methyl iodide in methyl alcohol for some hours at 100°; the greater part of the alcohol is then evaporated, and the methyl-derivative precipitated by water. It dissolves sparingly in cold, more readily in hot water, and is readily soluble in alcohol and ether; it melts at 57°, boils above 230°, and has basic but no acid properties. By the action of sodium nitrite on the hydrochloride, nitrogen is evolved, and a compound, $C_8H_9NO_2$, produced: $NH_2.CPh : NOMe,HCl + NaNO_2 = OH.CPh : NOMe + NaCl + N_2 + H_2O$; the product, OH.CPh : NOMe, is named the methyl ether of *benzhydroximic acid*, this being isomeric with Lossen's benzhydroxamic acid, COPh.NH.OH. It is an oil boiling at 225°, is insoluble in water, but readily soluble in alcohol, ether, and chloroform; it has neither basic nor any pronounced acid properties. When benzenylamidoxime is treated with water and sodium-amalgam, ammonia and benzaldehyde are readily detected by their odour. On warming the liquid, an oil separates, the quantity of which is increased on neutralising with hydrochloric acid; it is readily soluble in hydrochloric acid, the solution yielding benzaldehyde when heated. This product is no doubt the benzaldoxime prepared by Petraczek (Abstr., 1883, 569), its formation being expressed thus: $NH_2.CPh\!:\!NOH + H_2 = CHPh\!:\!NOH + NH_3$. Secondary products are also formed. Benzenylamidoxime is identical with the compound obtained by Pinner from hydroxylamine and benzenylamidine hydrochloride (this vol., p. 739), and with the secondary product, $C_7H_8N_2O$, obtained by Lossen by the action of hydroxylamine hydrochloride on benzimido-ether (this vol., p. 1324). The above facts show that the addition-product from hydroxylamine and benzonitrile is an amidoxime, and therefore that the compounds obtained by the action of hydroxylamine on nitriles in general are to be regarded as belonging to this class of compounds. By the action of benzenylamidoxime on benzoic chloride, *benzoylbenzenylamidoxime*, $NH_2.CPh\!:\!NOBz$, is obtained crystallising in slender white needles; it melts at 140°, is insoluble in water, readily soluble in alcohol, ether, and benzene; it shows basic but no acid properties. When heated above its melting point, water is given off, and *dibenzenylazoxime*,  $N{<}\begin{matrix}\text{-CPh-}\\ \text{O.CPh}\end{matrix}{>}N$, is produced. This is an indifferent and very stable compound, insoluble in dilute acids and in alkalis; its solutions in concentrated nitric and sulphuric acids may be heated without decomposition; by continued boiling with tin and hydrochloric acid, it is reduced to benzonitrile. Dibenzenylazoxime is almost insoluble in water, readily soluble in alcohol, ether, and benzene, melts at 108°, and boils at 290°; it is readily volatile in steam, and forms long white needles on sublimation. It is also formed on heating benzenylamidoxime with benzoic chloride, benzotrichloride, or benzoic acid, and in all reactions in which benzoic acid is formed by the partial decomposition of benzenylamidoxime at a moderately high temperature, as, for example, by the action of nitrous acid. *Benzenylazoximethenyl*,  $N{<}\begin{matrix}\text{-CPh-}\\ \text{O.CMe}\end{matrix}{>}N$, obtained by boiling benzenylamidoxime with acetic anhydride, crystallises in flat prisms, sublimes at ordinary temperatures, and is readily volatile in steam; it melts at 41°, dissolves sparingly in water, but readily in alcohol, ether, and benzene. An isomeric *ethenylazoximebenzenyl*,  $N{<}\begin{matrix}\text{-CMe-}\\ \text{O.CPh}\end{matrix}{>}N$, melting at 57°, has been prepared by Nordmann from ethenylamidoxime (from acetonitrile). In naming the azoximes which contain two different hydrocarbon radicles, that which is united to the oxygen-atom is placed at the end of the name as in the above examples. Benzenylazoximethenyl, which appears to be produced by the action of chloroform on an alkaline solution of benzenylamidoxime, is likewise to be distinguished from methenylazoximebenzenyl, which should result from the action of benzoic chloride on methenylamidoxime, $NH_2.CH\!:\!NOH$.

A. K. M.

Reduction of Benzoylorthonitranilide. By W. G. MIXTER (*Amer. Chem. J.*, 6, 26—28).—Hubner (*Ann. Chem.*, 208, 302), by the action of tin and hydrochloric acid on benzoyl-*o*-nitranilide, obtained benzenylphenylenamidine, $C_{13}H_{10}N_2$; other reduction-products have not been prepared. The para- and meta-nitranilides, when treated with zinc and ammonia, yield azo- and amido-derivatives this vol., p. 665); it is now shown that analogous ortho-compounds are formed in a similar manner.

Orthazoxybenzanilide,



$$\left.\begin{array}{l} NH\overline{Bz}.C_6H_4.N \\ \quad\;\, | \\ NH\overline{Bz}.C_6H_4.N \end{array}\right> O.$$

— Benzoylorthonitranilide is dissolved in alcohol, and zinc, ammonia, and platinic chloride added. The new compound slowly separates from the solution. It is yellow, sparingly soluble in alcohol, and melts at 195°. If the mother-liquor is evaporated to dryness, and the residue extracted with boiling water, it gives, on cooling, crystals of *benzoylorthophenylenediamine*,

$$NH_2.C_6H_4.NH\overline{Bz},$$

melting at 140°. It is more easily obtained by reducing benzoylorthonitranilide with alcoholic ammonium sulphide. The platinochloride is a slimy precipitate. During the reduction with zinc and ammonia, some benzenylphenylenamidine is formed. H. B.

Nitrosophenols. By H. GOLDSCHMIDT and H. SCHMID (*Ber.*, 17, 2060—2065).—To test the general applicability of the method of formation of nitrosophenols by the action of hydroxylamine on quinones (Goldschmidt, this vol., p. 735), the authors now apply the reaction to thymoquinone, toluquinone, and α-naphthaquinone.

Thymoquinone is reduced by free hydroxylamine to hydrothymoquinone; hydroxylamine hydrochloride, on the other hand, converts it into nitrosothymol. Unsuccessful attempts were made to convert thymoquinone into a di-isonitroso-compound.

Toluquinone, dissolved in 200 times its weight of water mixed with hydroxylamine hydrochloride, and allowed to remain for 24 hours, yields white needles of *nitroso-orthocresol*,

$$C_6H_3OMe : NOH\ [O : Me : NOH = 1 : 2 : 4].$$

It decomposes between 130—140°, gives Liebermann's nitroso-reaction, dissolves in alkalis with reddish-brown colour, and is converted into dinitro-orthocresol by treatment with nitric acid.

α-Naphthoquinone, when treated with hydroxylamine hydrochloride, is converted into α-nitroso-α-naphthol. This substance, when pure, decomposes *without fusion* at 190°; it is generally stated to melt at 175°. The authors did not succeed in replacing the second oxygen-atom in α-naphthaquinone by an isonitroso-group. These and the earlier results obtained show that in all quinones 1 oxygen-atom can be replaced by the oximido-group, but that both oxygen-atoms can only be so replaced in those quinones in which both CO-groups are in the ortho-position. A. J. G.

Para- and Ortho-nitrophenyl Ethers of Dinitrophenol and of Picric Acid. By C. WILLGERODT and E. HUETLIN (*Ber.*, 17, 1764—1766).—These four ethers were prepared by the action of alcoholic solutions of α-dinitrochlorobenzene and of picryl chloride (trinitrochlorobenzene) on potassium para- and ortho-nitrophenate. In the case of the two ethers from α-dinitrochlorobenzene, heating in closed tubes for 5—6 hours at 150—160° was necessary: the derivatives of picric acid were easily prepared by digestion on the water-bath. In the preparation of the potassium phenates, care must be taken not to add excess of potash, or the ethyl ethers will also be formed.

α-Dinitrophenyl paranitrophenyl oxide,

$$C_6H_3(NO_2)_2.O.C_6H_4.NO_2\ [O : NO_2 : NO_2 = 1 : 2 : 4;\ O : NO_2 = 1 : 4],$$

crystallises from water in hexagonal plates melting at 114°, and soluble in ether, benzene, glacial acetic acid, and acetone. *α-Dinitrophenyl orthonitrophenyl oxide* crystallises in minute needles melting at 119°. It resembles the para-derivative in solubility, &c.

Trinitrophenylparanitrophenyl oxide,

$$C_6H_2(NO_2)_3.O.C_6H_4.NO_2\ [O : NO_2 : NO_2 : NO_2 = 1 : 2 : 4 : 6;\ O : NO_2 = 1 : 4],$$

crystallises in small, thin, transparent, colourless scales which melt at 153°, and are easily soluble in alcohol, chloroform, benzene, glacial acetic acid, and acetone; more sparingly in ether and light petroleum. *Trinitrophenyl orthonitrophenyl oxide* crystallises from alcohol in small and almost colourless needles which melt at 172—173°, and resemble the para-compound in solubility, &c. L. T. T.

Mercaptans. By O. STADLER (*Ber.*, 17, 2075—2081).—From the analogy in behaviour between mercaptans and phenols, it seemed probable that the mercaptans of the fatty group might, like the phenols, yield azo-compounds by reaction with diazo-compounds. The author's results show that not azo- but diazo-compounds are formed.

By the action of diazobenzenesulphonic acid on ethyl mercaptan suspended in ice-water and mixed with soda, a substance of the formula $C_8H_9N_2S_2O_3Na$ (probably $SO_3Na.C_6H_4.N{=}N.SEt$), is obtained, crystallising in clear yellow needles. It explodes when heated on platinum-foil; by boiling in alcoholic solution, nitrogen is evolved and the sulphonic acid of ethyl phenyl sulphide is formed. The sodium salt, $SO_3Na.C_6H_4\ SEt$, crystallises in white plates. Distilled with ammonium chloride, it yields ethyl phenyl sulphide.

Diazobenzene chloride and ethyl mercaptan reacted, giving an oily product, which, after extraction with ether, &c., proved to be a mixture of ethyl bisulphide and ethyl phenyl sulphide. On repeating this experiment, however, the ethereal solution exploded with considerable violence, showing that an unstable nitrogen-compound had been formed, but its isolation could not be effected.

Phenyl mercaptan is conveniently prepared by distilling a mixture of sodium benzenesulphonate and potassium hydrosulphide in a vacuum. A. J. G.

Bromoparaxylenol. By P. ADAM (*Bull. Soc. Chim.*, **41**, 288—289).—When this compound is prepared by the ordinary method, condensation-products are formed which render the purification of the brominated derivative extremely difficult. It may be readily prepared by the action of bromine on xylenol heated to 160°; the source of heat is removed and the bromine is introduced rapidly (30 grams per minute). The solid product is purified by distilling with steam. or better, by exposing it in a vacuum, then washing with a little light petroleum and pressing between paper. It crystallises in white needles insoluble in water, but soluble in half their weight of boiling alcohol; they melt at 74°. When boiled with a large excess of water, bromoparaxylenol is decomposed, hydrobromic acid is evolved, and a substance remains in solution which is deposited when the liquid is evaporated in a vacuum. The author is continuing the study of the derivatives of this compound. W. R. D

Derivatives of Dimethylquinol. By A. BAESSLER (*Ber.*, **17**, 2118—2129).—*Amidodimethylquinol*, $C_6H_3(OMe)_2,NH_2$ (comp. Muhlhauser, Abstr., 1882, 302). Sodium-amalgam is gradually added to an alcoholic solution of nitrodimethylquinol, acidulated with acetic acid, until red needles are deposited on the sides of the vessel. The alcohol is then evaporated, water added, and the liquid extracted with ether. On evaporation, the ethereal solution leaves a mixture of red and yellow crystals which are boiled with very dilute alcohol; this leaves a residue consisting of azodimethylquinol mixed with small quantities of hydrazodimethylquinol. The solution contains amidomethylquinol, which is purified by crystallisation, conversion into the hydrochloride, &c. Amidodimethylquinol crystallises in nacreous plates, melts at 81—82°, is sparingly soluble in cold, soluble in hot water, alcohol, benzene, light petroleum, and carbon bisulphide. It is very unstable, being readily decomposed when heated above the melting point, and partially also by evaporating its aqueous solution. The hydrochloride crystallises in white efflorescent needles. The platinochloride is obtained as a brown precipitate.

Acetamidodimethylquinol, $C_6H_3(OMe)_2 NH\overline{Ac}$, obtained by the action of acetic anhydride on the base, crystallises in silvery white plates and melts at 91°. *Nitroacetamidodimethylquinol*,

$$C_6H_2(NO_2)(OMe)_2.NH\overline{Ac},$$

obtained by adding fuming nitric acid, drop by drop, to a saturated aqueous solution of the acetyl-compound, crystallises in nodular groups of needles and melts at 164°.

Dimethylquinoltrimethylammonium iodide, $C_6H_3(OMe)_2.NMe_3I$, is prepared by heating amidodimethylquinol with methyl iodide and a little methyl alcohol in sealed tubes at 150° for five hours. It crystallises in white needles, melts at 202°, is readily soluble in water and dilute alcohol, nearly insoluble in benzene, chloroform, and light petroleum, sparingly soluble in absolute alcohol. By the action of moist silver oxide, it is converted into the corresponding *hydroxide*, which crystallises in colourless needles. The *chloride*,

$$C_6H_3(OMe_2).NMe_3Cl,$$

crystallises in needles, melts at 172°, and is readily soluble in water. The *platinochloride*, $[C_6H_3(OMe)_2NMe_3Cl]_2,PtCl_4$, is a yellow crystalline substance.

By the action of phenyl isothiocyanate on amidodimethylquinol, a compound of the formula $NHPh.CS.NH.C_6H_3(OMe)_2$ is obtained, crystallising in white, microscopic needles, and melting at 137°; it is readily soluble in hot benzene and alcohol, insoluble in water.

Dimethylquinol-thiocarbamide, $CS[NH.C_6H_3(OMe)_2]_2$, is prepared by digesting amidodimethylquinol, alcoholic potash, and carbon bisulphide for some hours on the water-bath; it crystallises in white microscopic needles, melts at 109°, is readily soluble in hot alcohol, benzene, and chloroform, sparingly in light petroleum, and insoluble in water.

Azodimethylquinol, $N_2[C_6H_3(OMe)_2]_2$, is prepared from an alcoholic solution of nitrodimethylquinol by the action of sodium-amalgam in presence of a small amount of ammonia, or by the action of zinc and potash. It is separated from the hydrazodimethylquinol simultaneously formed, by heating it with dilute hydrochloric acid, in which the hydrazo-compound dissolves completely. The azoquinol crystallises in red needles, melts at 140°, is readily soluble in absolute alcohol, benzene, chloroform, carbon bisulphide, and aniline, more sparingly in light petroleum and dilute alcohol, and is nearly insoluble in water. It dissolves without decomposition in strong hydrochloric acid with deep blue colour, and in concentrated sulphuric acid with violet colour; the latter solution suffers partial decomposition on standing, turning first blue and then green. By the action of bromine on an alcoholic solution of the azo-compound, *dibromazodimethylquinol*, $C_{16}H_{16}Br_2N_2O_4$, is obtained. It forms a red crystalline mass, melts at 220°, is soluble in benzene, chloroform, and carbon bisulphide, very sparingly in alcohol, and is insoluble in water. It dissolves in sulphuric acid without decomposition to form a deep-violet solution.

The hydrazo-compound could not be isolated; in solution it oxidises with great readiness to form the azo-compound.

Tetramethoxydiamidodiphenyl, $NH_2.C_6H_2(OMe)_2.C_6H_2(OMe)_2.NH_2$, is obtained as hydrochloride by the action of hydrochloric acid on solutions of the hydrazo-compound, and by the action of stannous chloride and hydrochloric acid on the azo-compound. The free base crystallises in snow-white needles, melts at 210°, is easily soluble in chloroform, carbon bisulphide, hot benzene, and boiling alcohol, but only sparingly in light petroleum or water. The hydrochloride,

$$C_{16}H_{20}N_2O_4,2HCl,$$

crystallises in stellate groups of small white needles, and is readily soluble in water. The platinochloride, $C_{16}H_{20}N_2O_4,H_2PtCl_6$, is obtained as a yellow precipitate. The phenylthiocarbamide-derivative,

$$C_{12}H_4(OMe)_4(NH.CS.NHPh)_2,$$

forms white flocks, melts at 184°, is soluble in alcohol and benzene, insoluble in light petroleum and water. The diacetyl-derivative, $C_{12}H_4(OMe)_4(NHAc)_2$, crystallises in white needles, melts at 251°, is readily soluble in alcohol, benzene, chloroform, and carbon bisulphide, but only very sparingly in light petroleum or water. A. J. G.

Compounds of Phenols with Ethyl Acetoacetate. β-Methylumbelliferone II. By H. v. Pechmann and J. B. Cohen (*Ber.*, **17**, 2129—2138).—In the first communication on this subject (v. Pechmann and Duisberg, this vol., p. 66), a series of compounds were described, obtained by the action of phenols on ethyl acetoacetate in presence of sulphuric acid. These compounds were regarded as coumarins, or hydroxycoumarins, in which substitution had occurred in the side-chains. In particular, the compound derived from resorcinol showed such strongly-marked analogy with the hydroxycoumarin, umbelliferone, that it was termed β-methylumbelliferone, and had assigned to it the constitution  $\underset{(4)}{OH.C_6H_3}\left\langle\begin{array}{l}CMe:CH\\ \qquad\quad\;|^{(1)}\\ O\text{——}\underset{(2)}{CO}\end{array}\right.$. This view, although opposed to that of Willenberg (Abstr., 1882, 1289) and of Michael (this vol., p. 736), is confirmed by the results now brought forward.

Allyl resorcinol methyl ether,

$$C_6H_3(OH)(OMe).CMe:CH_2\ [OH:OMe:C_2MeH_2 = 2:4:1],$$

isomeric with eugenol, is obtained by heating umbellic acid. It forms a nearly colourless thick oil of agreeable odour, distils at 245—250°, is insoluble in water, but miscible with most other solvents. Concentrated sulphuric acid dissolves it with red coloration. It is soluble in aqueous soda, but not in sodium carbonate.

Methylic dimethyl-β-methylumbellate is obtained by heating the monomethyl acid with methyl iodide and sodium methylate in sealed tubes for five hours at 90°. The *free acid,*

$$C_6H_3(OMe)_2.CMe:CH.COOH\ [4:2:1],$$

crystallises in small colourless needles, melts at 145°, is insoluble in water, readily soluble in ether, benzene, alcohol, and chloroform. A solution of the ammonium salt gives a white curdy precipitate with lead acetate, a clear green precipitate with copper sulphate, and a yellow amorphous precipitate with ferric chloride. The silver salt forms a white granular powder. The *methyl salt,*

$$C_6H_3(OMe)_2.CMe:CH.COOMe,$$

is an oil boiling at 310—320°, and soluble in the ordinary solvents. By oxidation with an alkaline solution of potassium permanganate, it is converted into dimethyl-β-resorcylic acid. This acid was shown by Tiemann and Will (*Ber.*, **15**, 2080) to be formed by the oxidation of umbelliferone, thus proving the side-chains in these compounds to occupy the same positions as in umbelliferone.

The authors regard Michael's tribromo-derivative, obtained by the action of bromine on β-methylumbelliferone, as *β-methylbromumbelli-*

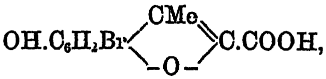
ferone dibromide. They have only to add to Michael's description that it gives a violet coloration with dilute soda.

β-Methylumbelliferone dibromide methyl ether,

$$\mathrm{OMe.C_6H_3}{<}\begin{matrix}\mathrm{CMeBr}\\ \mathrm{O.CO}\end{matrix}{>}\mathrm{CHBr}.$$

The action of bromine on the methyl ether differs slightly from that on β-methylumbelliferone, an additive product being obtained. It crystallises in colourless needles, melts at 233—235°, is insoluble in water, somewhat soluble in alcohol, ether, chloroform, and glacial acetic acid. Both bromine-atoms are removed by boiling it with alcoholic potash.

Bromhydroxy-β-methylcoumarilic acid,



$$\mathrm{OH.C_6H_2Br}{<}\begin{matrix}\mathrm{CMe}\\ \mathrm{O}\end{matrix}{>}\mathrm{C.COOH},$$

is obtained by boiling the tribromo-compound with alcoholic potash. It forms slender colourless needles, melts with decomposition at 221°, is readily soluble in alcohol, ether, and chloroform, sparingly in benzene, insoluble in water. It dissolves in sulphuric acid to a colourless solution, which turns purplish-violet on heating. Ferric chloride gives a yellow coloration. When the silver salt is distilled, it yields a crystalline substance, probably *bromhydroxy-β-methylcoumarone;* this yields a deep blue-coloured body by the action of gentle oxidising agents.

Methoxy-β-methylhydrocoumaric anhydride, $C_{22}H_{22}O_6$, is obtained by the action of sodium-amalgam on a solution of β-methylumbelliferone methyl ether in dilute alcohol. It crystallises in nearly colourless prisms, melts at 243—244°, is soluble in hot glacial acetic acid, insoluble in alcohol and ether. Sulphuric acid dissolves it, with feeble blue fluorescence. Soda only dissolves it on boiling.

Nitro-β-methylumbelliferone, $C_{10}H_7(NO_2)O_3$, is prepared by adding the calculated quantity of nitric acid, drop by drop, to the finely divided β-methylumbelliferone suspended in glacial acetic acid, and well cooled. It crystallises in straw-yellow needles, is insoluble in water, sparingly soluble in alcohol, benzene, and glacial acetic acid.

Dinitro-β-methylumbelliferone, $C_{10}H_6(NO_2)_2O_3$, is prepared by the action of excess of nitric acid on β-methylumbelliferone suspended in acetic acid, the mixture being finally heated on the water-bath. It crystallises in lustrous golden-yellow needles, melts at 220°, is readily soluble in alcohol and glacial acetic acid, sparingly in chloroform, benzene, and carbon bisulphide.

Amido-β-methylumbelliferone, $C_{10}H_7O_3.NH_2$, is prepared by the action of tin and hydrochloric acid on the mononitro-compound. It forms yellowish needles, melts at 247°, is sparingly soluble in the ordinary solvents, and gives an intense green coloration with ferric chloride. The sulphate, $(C_{10}H_9NO_3)_2,H_2SO_4 + 2H_2O$, is very sparingly soluble in cold water.

Nitrosoamido-β-methylumbelliferone, $C_{10}H_6(NO)O_3.NH_2$, is obtained by the action of nitrous acid on the sulphate of the amido-derivative. It crystallises in yellowish-red needles, melts at 140°, is readily soluble in alcohol, sparingly in water, ether, benzene, and chloroform. It has no basic properties, is soluble in alkalis, with deep red colour, is not decomposed by boiling with acids, and gives Liebermann's reaction. A. J. G.

Azoresorcinol and Azoresorufin. By H. BRUNNER and C. KRÄMER (*Ber.*, 17, 1847—1866).—In a preliminary notice (Abstr., 1882, 784), H. Brunner stated that by acting with sulphuric acid on a mixture of nitrobenzene and resorcinol, he had obtained a colouring matter which he believed to be identical with the diazoresorufin described by Weselsky (*Ber.*, 4, 614). In conjunction with C. Krämer, he has now carefully compared these two substances, and proved the correctness of his surmise. This body was prepared by Weselsky by heating his diazoresorcinol with sulphuric acid at 210°; by Liebermann (this Jour., 1874, 693) by heating resorcinol with sulphuric acid containing nitrous acid; by Bindschedler and Busch, and also by Fèvre, from nitrosoresorcinol (from amyl nitrite and sodium resorcinol) and sulphuric acid. When prepared by Brunner's method, the substance in question is always accompanied by paramidophenolsulphonic acid (see p. 1354) in the form of white silky needles. The mixed compounds are dissolved in hot ammonia, and hydrochloric acid is added to the still hot solution. Diazoresorufin is at once precipitated, and if the solution be not too concentrated, all the sulphonic acid remains in solution and crystallises out on cooling. The diazoresorcinol employed by Weselsky was obtained by acting on resorcinol with nitric acid saturated with nitrous anhydride. It forms deep green crystals, which dissolve in alkalis to a bluish-violet solution with brown fluorescence. Weselsky gave $C_{18}H_{12}N_2O_6$ as the formula of this compound, but a careful re-examination by the author has proved that its true composition is $C_{12}H_9NO_4$, so that, taking into account its formation from nitrosoresorcinol, it may be looked upon as formed according to the reaction—

$$C_6H_4(OH)_2 + NO.C_6H_3(OH)_2 = C_6H_4{<}\substack{O\\O}{>}N.C_6H_3(OH)_2.$$

As it is not a diazo-compound, the author proposes to substitute the name *azoresorcinol* for diazoresorcinol, and in like manner diazoresorufin becomes *azoresorufin*.

Azoresorufin prepared by any of the above-mentioned methods has the formula $C_{24}H_{16}N_2O_7$ ($C_{36}H_{14}N_4O_2$, Weselsky). It is a reddish-brown powder sparingly soluble in alcohol, insoluble in water and in ether. It dissolves in sulphuric acid to a blue solution containing a sulphonic acid, which is, however, decomposed by water. Alkalis convert it into a very intense brilliant carmine solution, having a vermilion fluorescence. This is an intensely strong colouring matter, and forms a valuable test for the presence of traces of alkali.

By the action of acetic chloride on azoresorcinol, Weselsky obtained a compound (crystallising in yellow scales) to which he ascribed the formula $C_{48}H_{30}N_4Cl_8O_{15}$, and which he regarded as hexacetyl-azoresorcinol, in which each of the four nitrogen-atoms is further combined with two chlorine-atoms. The authors have carefully examined this reaction, and have obtained two compounds. The one crystallises in small golden-yellow scales of the formula $C_{14}H_8ClNO_3,HCl$, and is not an acetyl-compound. The other compound forms a green amorphous mass easily soluble in ether. It gave results leading to the formula $C_{26}H_{21}N_2Cl_3O_6$ (or $C_{21}H_{11}EtClN_2O_6,2HCl$). It is probable that here we have first the formation of a dihydrochloride of chlorazoresorufin monacetate, which in the process of purification with alcohol exchanges its acetyl-group for ethyl.

Azoresorufin diacetate, $[C_6H_4O_2N.C_6H_3(O\overline{Ac})]_2$, was obtained by digesting azoresorcinol with sodium acetate and acetic anhydride at 135°. It forms a yellowish-brown amorphous substance, easily soluble in acetone, chloroform, and acetic acid, sparingly in alcohol or ether. When evaporated with hydrochloric acid on the water-bath, it yields a yellow hydrochloride.

Azoresorufyl hydrochloride, $C_{24}H_{14}Cl_2N_2O_5,2HCl$, was obtained by digesting azoresorcinol with fuming hydrochloric acid under pressure at 100°. It forms bluish-violet crystals.

Both azoresorcinol and azoresorufin yield identical products on reduction, either in acid or in alkaline solution. When azoresorcinol is reduced with tin and hydrochloric acid, a compound is formed which is soluble in dilute hydrochloric acid, and crystallises in iridescent scales. Its formula is $C_{48}H_{16}N_4O_{13},4HCl + 4H_2O$. When quickly dried at 100°, it forms a blue powder which dissolves in boiling acetone or alcohol (if slightly acidulated with hydrochloric acid) with an indigo colour, and these solutions both yield large well-formed crystals very much resembling potassium permanganate in appearance. When once formed, these crystals redissolve with difficulty. Although exactly alike in appearance, analysis showed these two substances differed in the quantity of hydrochloric acid they contain. That crystallised from alcohol has the formula $C_{48}H_{16}N_4O_{13},3HCl$, that from acetone, $C_{48}H_{46}N_4O_{13},HCl$. Hydrating agents (such as dilute alkalis) gradually convert these compounds, first into azoresorutin, then into azoresorcinol.

Tetrahydrazoresorufin, $C_{24}H_{16}N_2O_7,H_4$, is formed if azoresorcinol is subjected to reduction with zinc and hydrochloric acid. It crystallises in dark blue crystals with a strong coppery iridescence. At 100° it loses water, and is reconverted into azoresorufin. It forms a dihydrochloride yielding colourless crystals. The tetrahydro-compound is also formed when sulphuretted hydrogen is passed into an ammoniacal solution of resorufin. Sodium-amalgam seems to form a colourless leuco-compound, but this is so unstable that the authors have not succeeded in isolating it.

Dibromazoresorcinol hydrobromide, $C_{12}H_7Br_2NO_4,HBr$, is obtained by adding bromine to a solution of azoresorcinol in sodium hydroxide. It forms a glistening green mass soluble in alcohol to a blue liquid having a brownish-red fluorescence.

Hexabromazoresorufin hydrobromide, $C_{24}H_{10}Br_6N_2O_7,HBr$, is probably identical with the bromodiazoresorufin of Bindschedler and Busch, and of the Bavarian Aniline and Soda Works. It is obtained from resorufin in a manner similar to that by which the last-named compound is prepared from azoresorcinol. It is an amorphous red substance, soluble in alcohol to a violet liquid with a bluish-red fluorescence.

Trinitrazoresorcinol, $C_{12}H_6(NO_2)_3NO_4$, was obtained by nitration with nitric acid of sp. gr. 1·37. Care must be taken in the nitration, or the substance will be completely oxidised. It forms green glistening crystals. This compound is probably what Weselsky described as tetrazoresorcinol nitrate, and to which he ascribed the formula $C_{36}H_{12}N_8O_{12},6NO_3$. It is soluble in water, ether, and alcohol, forming indigo-coloured solutions.

Hexanitrazoresorufin, $C_{24}H_{10}(NO_2)_6N_2O_7$, prepared in a similar manner, crystallises in small green needles, which dissolve in water, alcohol, and ether to purple solutions. L. T. T.

Derivatives of Pyrogallol and Phloroglucinol, and their Relation to Daphnetin and Æsculetin. By W. Will and K. Albrecht (*Ber.*, **17**, 2098—2109).—Whilst daphnetin was known to be a derivative of pyrogallol, it was still uncertain which of the two other trihydroxybenzenes æsculetin was derived from. The results given in the present paper show that it is not derived from phloroglucinol, and must therefore be derived from hydroxyquinol.

Ethylic triethylgallate, $C_6H_2(OEt)_3.COOEt$, is prepared by boiling ethyl gallate and ethyl iodide with potash. It crystallises in lustrous needles, melts at 51°, and is readily soluble in alcohol, ether, and benzene.

Triethylgallic acid, $C_6H_2(OEt)_3.COOH$, is obtained by saponification of the ethyl salt with alcoholic potash, and decomposition of the potassium salt formed with hydrochloric acid. It is crystalline, melts at 112°, is sparingly soluble in cold, more readily in boiling alcohol. It does not give a coloration with ferric salts. The neutral solution of the ammonium salt gives a clear greenish-blue precipitate with copper salts, white precipitates with lead and zinc salts. The silver salt, $C_{13}H_{17}O_5Ag$, is obtained by precipitation with silver nitrate as a voluminous white precipitate sparingly soluble in hot water, and can be crystallised from it. It melts at 200°, and decomposes into carbonic anhydride and pyrogallol triethyl ether.

Ethyl pyrogallocarboxylate, $C_6H_2(OH)_3.COOEt$, obtained by saturating a solution of pyrogallocarboxylic acid in alcohol with hydrochloric acid, forms a crystalline mass; when crystallised from hot water it unites with 1 mol. of H_2O, and then melts at 86°; the anhydrous salt melts at 102°. It commences to sublime at 100°. It is soluble in alcohol and ether, insoluble in hot water. With ferric chloride, it gives a greenish-brown coloration like that produced by the free acid. By the action of ethyl iodide and potash, it is converted into *ethylic triethylpyrogallocarboxylate*, a colourless, odourless, volatile oil, insoluble in water and alkalis, readily soluble in alcohol and ether.

Triethylpyrogallocarboxylic acid, $C_6H_2(OEt)_3.COOH$ [COOH : OEt : OEt : OEt = 1 : 2 : 3 : 4], prepared from the ethyl salt, is crystalline, melts at 100·5°, and is identical with the triethoxybenzoic acid obtained from daphnetin. The silver salt, $C_{13}H_{17}O_5Ag$, is moderately soluble in water, and decomposes at 130° into carbonic anhydride and pyrogallol triethyl ether.

Phloroglucinocarboxylic acid, $C_6H_2(OH)_3.COOH$, is prepared by heating pure phloroglucinol (1 part), hydrogen potassium carbonate (4 parts), and water (4 parts) in sealed tubes for 13 hours at 130°.

The product of the reaction is treated with dilute hydrochloric acid and extracted with ether. The ethereal solution is next shaken with aqueous hydrogen sodium carbonate, whereby the acid passes into the aqueous solution, whilst unaltered phloroglucinol remains dissolved in the ether. The sodium carbonate solution is then acidified, the acid extracted with ether, and the ethereal solution allowed to crystallise. The free acid resembles gallic and pyrogallolcarboxylic acids in appearance and behaviour. It crystallises with 1 mol. H_2O, decomposes slowly when heated (even below 100°), and finally melts at 206° (the melting point of phloroglucinol). The aqueous solution on boiling is completely decomposed into carbonic anhydride and phloroglucinol. An alkaline solution turns brown if exposed to the air. Ferric chloride gives an intense blue coloration, which soon turns to a dirty brown. An aqueous solution of the acid gives white precipitates with lead and silver salts.

In preparing this acid with phloroglucinol prepared from resorcinol there is obtained in addition another acid quite insoluble in water, and therefore readily separated from phloroglucinolcarboxylic acid. *Diresorcinoldicarboxylic acid*, $COOH.C_6H_2(OH)_2.C_6H_2(OH)_2.COOH$, obtained thus, is sparingly soluble in alcohol, more readily in ether. It decomposes above 300° without previous fusion. Diresorcinol when heated with hydrogen potassium carbonate, as described above, yields this acid exclusively. The potassium salt, $C_{14}H_8O_8K_2$, crystallises in slender white needles; the barium salt, $C_{14}H_8O_8Ba + 6H_2O$, forms lustrous needles; the silver salt, $C_{14}H_8O_8Ag_2$, is precipitated in white flocks.

Phloroglucinol diethyl ether, $C_6H_3(OEt)_2.OH$.—By the action of hydrochloric acid gas on an alcoholic solution of phloroglucinolcarboxylic acid, there was obtained, not as was expected, the ethyl salt of the acid, but phloroglucinol diethyl ether, a substance crystallising in long colourless lustrous needles, and melting at 75°. It distils unaltered, is soluble in water or dilute alcohol, and is also readily soluble in alkalis, from which solution addition of acids reprecipitates it unchanged. It may also be prepared by the action of hydrochloric acid gas on an alcoholic solution of phloroglucinol. Attempts to prepare an ethylated phloroglucinol-carboxylic acid were unsuccessful.

Phloroglucinol triethyl ether, $C_6H_3(OEt)_3$, is obtained by the action of ethyl iodide and alcoholic potash on phloroglucinol diethyl ether. It is crystalline, melts at 43°, can be distilled with steam, is readily soluble in alcohol and ether, insoluble in water and alkalis. It is not identical with the triethyl ether obtained by dry distillation of the calcium salt of the triethoxybenzoic acid derived from æsculetin. As the three triethoxybenzenes theoretically possible are now known, and as two of them are characterised as the triethyl ethers of pyrogallol and phloroglucinol respectively, it follows that the third must be the triethyl ether of hydroxyquinol.

This conclusion that æsculetin is not a phloroglucinol-derivative, is in agreement with the results lately obtained by v. Pechmann and Welsh (this vol., p. 1346).

A. J. G.

Nitro-derivatives of Paracresyl Benzyl Ether. By P. FRISCHE (*Annalen*, **224**, 137—155).—*Nitrocresyl benzyl ether*,

$$CH_2Ph.O.C_6H_3Me.NO_2\ [NO_2 : CH_3 = 2 : 4],$$

prepared by the action of potassium nitrocresol on benzyl chloride, crystallises in broad needles which dissolve in benzene, ether, light petroleum, and alcohol. The crystals melt at 54° and decompose when strongly heated.

Dinitrocresyl benzyl ether, $CH_2Ph.\underset{1}{O}.C_6H_2\underset{2}{(NO_2)}\underset{4}{Me}.\underset{6}{NO_2}$, can only be prepared by acting on silver dinitrocresol with benzyl iodide. It is deposited from hot alcohol in crystalline plates melting at 109°, which decompose on exposure to the light.

Cresyl nitrobenzyl ether, $C_6H_4\underset{4}{Me}.\underset{1}{O}.\underset{1}{CH_2}.C_6H_4.\underset{4}{NO_2}$, also crystallises in plates which melt at 91°.

Nitrocresyl nitrobenzyl ether, $\underset{2}{NO_2}.C_6H_3\underset{4}{Me}.\underset{1}{O}.CH_2.C_6H_4.\underset{4}{NO_2}$, forms silky needles which are soluble in benzene and hot acetic acid and melt at 163°.

Dinitrocresyl nitrobenzyl ether, $\underset{2}{NO_2}.\underset{4}{Me}\underset{6}{(NO_2)}C_6H_2.O.CH_2.\underset{1}{C_6H_4}.\underset{4}{NO_2}$, melts at 186·5° and dissolves in hot glacial acetic acid. It is not only formed by the actions of nitrobenzyl iodide on silver dinitrocresol, but also by the nitration of many of the above ethers.

Nitrocresyl benzyl ether, on nitration, yields nitrocresol and benzyl alcohol, which are further changed into dinitrocresol and nitrobenzyl nitrate, a small quantity of dinitrocresyl nitrobenzyl ether is also formed. Under similar treatment, the isomeric cresyl nitrobenzyl ether gives a much larger yield of dinitrocresyl nitrobenzyl ether. Dinitrocresol paranitrobenzyl nitrate and a large quantity of dinitrocresyl nitrobenzyl ether are obtained by the action of strong nitric acid on nitrocresyl nitrobenzyl ether.

Alcoholic ammonia acts slightly on nitrocresyl benzyl ether, and has no action on cresyl nitrobenzyl ether. It converts dinitrocresyl benzyl ether into dinitroparatoluidine and benzyl alcohol, and saponifies dinitrocresyl nitrobenzyl ether, forming nitrobenzyl alcohol and dinitrotoluidine.

Attempts to reduce these nitro-ethers to amido-compounds were unsuccessful. W. C. W.

Nitration of the Phenyl and Cresyl Ethers of Phosphoric Acid. By M. RAPP (*Annalen*, **224**, 156—178).—When a solution of monophenylphosphoric acid in strong nitric acid is poured into water, the nitro-product is not precipitated, but on evaporating the mixture (after the addition of alcohol) to remove the excess of nitric acid, *mononitromonophenyl phosphate* is obtained in crystalline plates melting at 112°. The crystals are soluble in ether, benzene, chloroform, and in hot water. They are decomposed by potash, yielding paranitrophenol and potassium phosphate, and they are also decomposed by the prolonged action of nitric acid.

Dinitrodiphenyl-phosphoric acid, $PO(O.C_6H_4.NO_2)_2.OH$, prepared from diphenyl phosphate, crystallises in white needles melting at

133·5°, which are soluble in ether, benzene, and hot alcohol. If the crystals are mixed with the mononitro-derivative, they dissolve freely in cold chloroform.

Trinitrotriphenyl phosphate, $PO(O.C_6H_4.NO_2)_3$, is deposited from hot acetic acid in oblique prisms which melt at 155° and are insoluble in the ordinary solvents. On decomposition with potash, the theoretical yield of paranitrophenol is obtained. This substance may with advantage be prepared by means of this reaction. Trinitrotriphenyl phosphate is converted into dinitrodiphenyl ethyl phosphate by prolonged boiling with alcohol. Trinitrotriphenyl phosphate has also been obtained by Engelhardt and Latschinoff (*Zeit. f. Chem.*, 1870, 230), by the action of phosphorus pentachloride on paranitrophenol.

Monoparacresyl phosphate, $PO(O.C_6H_4Me)(OH)_2$, forms white plates which melt at 116°, and dissolve freely in alcohol, ether, and water. Triparacresyl phosphate has been previously described by A. Wolkow (*ibid.*, 1870, 322), who found the melting point 8° too low, viz., 68° instead of 76°. No nitro-derivatives of these ortho- or para-cresyl phosphates could be obtained. W. C. W.

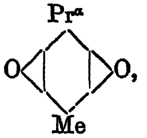
Hydroxydihydrocarbostyril. By A. Einhorn (*Ber.*, 17, 2011—2014).—*Hydroxydihydrocarbostyril*,  $C_6H_4\left\langle\begin{array}{l}CH(OH).CH_2\\ \qquad\qquad\quad|\\ N{=\!=\!=\!=}C.OH\end{array}\right.$, the lactime of orthamidophenyllactic acid is prepared by the reduction of orthonitrophenyl-β-lactic acid or orthonitrophenyllactamide with ferrous hydroxide and ammonia. It crystallises with $2H_2O$ in well-formed lustrous white needles, and is readily soluble in water, ether, and chloroform. The hydrated compound melts at 95—97°; after drying over sulphuric acid, it loses its water of crystallisation and then melts at 149°. It is converted into carbostyril by heating it several times to the fusing point, or by adding a small quantity of acid or alkali to its aqueous solution, or even by boiling the solution for five minutes. It is isomeric with the hydroxyhydrocarbostyril (m. p. 197—198°), obtained by Erlenmeyer and Lipp (Abstr., 1883, 992) by the reduction of the nitration-products of phenyl-α-lactic acid.

A. J. G.

Safrole. By J. Schiff (*Ber.*, 17, 1935—1940).—*Safrole* is the main constituent of the essential oil of sassafras (from *Laurus sassafras*). It crystallises at low temperatures (Arzruni, this Journal, 1877, ii, 202), melts at 8°, forms, at ordinary temperatures, a clear colourless oil of sharp taste; its sp. gr. 1·0956 at 18°. Is of neutral reaction, optically inactive, and boils at 232°. The author's analysis confirm the formula $C_{10}H_{10}O_2$, assigned to safrole by St. Evre (*Ann. Chim. Phys.* [3], 12, 107), and by Grimaux and Ruotte (*Compt. rend.*, 68, 928). The oxygen-atoms in safrole would appear not to be present as hydroxyl, as neither hydrochloric acid nor phosphoric chloride converts it into a chlorine-derivative. Safrole is not affected by aqueous or alcoholic potash, and is only very slightly attacked by fusion with caustic potash, does not reduce ammoniacal silver solutions, does not unite with bisulphites, and is not acted on by ammonia or nascent hydrogen. It is therefore neither an ethereal salt, an aldehyde, nor a ketone. A large number of reducing agents were tried but had no action on it. Heated for 24 hours with metallic sodium, it suffers no change beyond apparently partial polymerisation. Oxidation with nitric acid and with a saturated solution of potassium permanganate completely convert safrole into carbonic anhydride and oxalic acid. Dilute permanganate oxidises it to carbonic anhydride, oxalic acid, formic acid, propionic acid, and a small quantity of a neutral substance of the formula $C_{10}H_{12}O_4$, crystallising in microscopic rhombic prisms; this melts at 59°, decomposes on heating to 120°, is soluble in hot water, alcohol, ether, and in aqueous ammonia and potash; iodine completely decomposes safrole; chlorine converts it into a mixture of liquid chlorine-derivatives which decompose below 100° and could not be separated.

A. J. G.

Constitution of Safrole. By T. Poleck (*Ber.*, 17, 1940—1944). —From a consideration of the results detailed in the preceding paper, of the negative result of his own experiments with reducing agents, and of its indifference to hydroxylamine, the author considers that the constitution of safrole is best expressed by the formula



i.e., as cymene in which four hydrogen-atoms have been replaced by oxygen. Measurements of the refractive index give results showing that probably either three or four carbon-atoms are in double union. At present there is no direct proof of the presence of the benzene-ring.

A. J. G.

Salts and Ethers of Aurin and Rosolic Acid. By E. Ackermann (*Ber.*, 17, 1624—1627).—Graebe and Caro showed that, by treating aurin and rosolic acid with acetic anhydride, it cannot be proved that these substances contain two hydroxyl-groups; the author, however, proves this by means of salts and ethers. The *silver salt* of aurin, obtained by precipitating the ammonium salt, forms an insoluble brownish-red crystalline powder, apparently of no very definite composition; the *potassium salt* obtained by neutralising aurin with potash dissolves very readily in water, readily also in alcohol; it was found to contain 17·1 per cent. potassium, whilst the formula $C_{19}H_{12}K_2O_3$ requires 21·3 per cent. On adding lead acetate to an ammoniacal solution of aurin, a reddish-brown basic salt, $2C_{19}H_{12}O_3Pb + PbO$, is precipitated. Better results are obtained with the nitro- and bromo-derivatives, these more negative compounds yielding salts of constant composition. *Tetranitro-aurin*,

$$C_{19}H_{10}(NO_2)_4O_3,$$

forms brownish-yellow microscopic needles which explode on heating; it melts at about 140°, is almost insoluble in water, benzene, chloroform, and ether, readily soluble in alcohol; alkalis and alkaline carbonates dissolve it with dark-red coloration; the *barium salt* dried at 150° has the composition $C_{19}H_8(NO_2)_4O_3Ba$, and forms a black powder with greenish lustre; the *silver salt*, $C_{19}H_8(NO_2)_4O_3Ag_2$, forms a black-brown precipitate which detonates when heated; the *ethyl-derivative*, $C_{19}H_8(NO_2)_4O_3Et_2$, obtained by heating the silver salt with ethyl iodide, melts at 105°, dissolves readily in benzene and alcohol, but is insoluble in water and alkaline carbonates. The *silver salt of tetrabromaurin*, $C_{19}H_8Br_4O_3Ag_2$, forms a dark-violet precipitate which when dry has a strongly metallic lustre; it is insoluble in water, ether, and benzene. The *ethyl-derivative*, $C_{19}H_8Br_4O_3Et_2$, is readily soluble in alcohol, ether, and benzene, insoluble in alkaline carbonates; it forms reddish microscopic crystals melting at 110—115°. The *silver salt of tetrabromorosolic acid*, $C_{20}H_{10}Br_4O_3Ag_2$, is obtained as a dark-violet precipitate; the *ethyl-derivative*, $C_{20}H_{10}Br_4O_3Et_2$, melts at 110—115°, is soluble in alcohol, benzene, and ether, but insoluble in water and alkaline carbonates. A. K. M.

Fluoresceïns from Maleic Acid. By G. LUNGE and R. BURCKHARDT (*Ber.*, **17**, 1598—1600).—Maleic anhydride (1 mol.) and resorcinol (2 mols.) are heated together for two hours at 150°, the product poured into cold water, and then extracted with boiling water. The solution on cooling deposits a yellowish-red substance, which decomposes above 240° without melting. Its formation may be expressed thus:—

$$C_2H_2{<}^{CO}_{CO}{>}O + 2C_6H_4(OH)_2 = C_{16}H_{12}O_6 + H_2O.$$

This fluoresceïn of maleic acid is sparingly soluble in water, more readily in alcohol and in other indifferent solvents. Its alcoholic solution is yellowish-red with greenish fluorescence; the addition of soda or ammonia produces a splendid magenta coloration, with strong green fluorescence. Lead acetate produces a reddish-brown precipitate, $C_{16}H_8O_5Pb$, 1 mol. H_2O being eliminated; barium acetate also yields a precipitate, but neither of these salts has been obtained in the crystalline state; silver nitrate produces decomposition; aluminium salts yield pink, and iron salts brownish-red compounds.

When maleic anhydride and α-naphthol are heated together, no fluoresceïn appears to be formed, whilst in the presence of zinc chloride or sulphuric acid a substance is obtained soluble in water. Its alcoholic solution is bright yellow, with a deep yellow fluorescence; its ammoniacal solution is of a magenta colour, with yellowish-red fluorescence. β-Naphthol also yields a fluoresceïn, which gives a brown solution with alkalis, showing greenish-blue fluorescence, whilst from orcinol, a brown solution with moss-green fluorescence is obtained. Further experiments are being made. A. K. M.

Phenol Colouring Matters. By C. KRAEMER (*Ber.*, **17**, 1875—1884).—After calling attention to the fact that the three compounds, nitrobenzene, Weselsky's reagent (nitrous nitric acid), and Liebermann's reagent (nitrosylsulphuric acid), give in reaction with phenols sometimes identical, sometimes different results, the author describes some new compounds related to the classes of bodies formed.

Azoresorufin dimethyl ether, $[C_6H_4O_2N.C_6H_3(OMe)]_2O$, obtained by heating paranitrotoluene with resorcinol and sulphuric acid, forms dark-red needles, soluble in alcohol to a purple liquid, having a vermilion fluorescence. Ortho- and meta-nitrotoluene appear to give no such reaction.

Phenol-dyes.—Exactly following Liebermann's direction for the preparation of his phenol-dye to which he ascribed the formula $C_{18}H_{15}NO_3$ (this Journal, 1875, 167), the author finds that the product so obtained is a mixture of two substances, the one, A, soluble, the other, B, insoluble in ether. A, *soluble in ether*, has the formula $C_{18}H_{15}NO_3$ ascribed to his compound by Liebermann. It forms a red amorphous mass, easily soluble in alcohol and ether, and is undoubtedly Liebermann's compound. Its constitution is probably $OH.C_6H_4.N(OPh)_2$. B, *insoluble in ether*, is a black amorphous mass, soluble in strong sulphuric acid to a green, and in alkalis to a brown liquid. When exposed to the atmosphere, it gradually becomes violet in colour, and this takes place immediately when it is treated with hypochlorites. In properties, it resembles the substance obtained by Lex (*Ber.*, 3, 457) by the action of potassium nitrite on an aqueous solution of phenol. It has the formula $C_{18}H_{15}NO_4,H_2O$, and is an oxidation-product of the soluble compound. Its constitution, therefore, is probably $OH.C_6H_4.NO(OPh)_2 + H_2O$.

Orcinol-dyes.—1. By the action of nitrosylsulphuric acid on orcinol, Liebermann obtained a green substance, to which he gave the formula $C_{21}H_{18}N_2O_5$, together with a second less nitrogenised compound. On repeating this experiment, the author has obtained two colouring matters, which are both soluble in alcohol, but can be separated by means of their sodium salts. The *sodium salt soluble in alcohol* yields a brown amorphous dye, having a green iridescence. In alkalis, it forms a red fluorescent solution. It has the formula $C_{21}H_{21}NO_6$, and the probable constitution $C_6H_2Me(OH)_2.N(O.C_6H_3Me.OH)_2$. The *sodium salt insoluble in alcohol* yields a very similar amorphous green mass, which dissolves in alkalis to a non-fluorescent violet solution. Its formula is $C_{21}H_{21}NO_7$, and therefore stands in the same relation to the substance just described, as the phenol-dye A does to B. Its constitution is probably $C_6H_2Me(OH)_2.NO(O.C_6H_3Me.OH)_2$.

2. With Weselsky's reagent, orcinol yielded a scarlet powder, having the formula $C_{11}H_{11}NO_3$, already ascribed to it by Weselsky. It is probably

$C_6H_2MeO.N{<}{}^{O}_{O}{>}C_6H_4Me$.

Mononitroso-orcinol was prepared by the action of amyl nitrite on the sodium compound of orcinol. It forms small dark red prisms which blacken at 110°. It is easily soluble in alcohol, ether, and acetone, sparingly so in water, and almost insoluble in chloroform. Its neutral alkali salts give with lead salts orange, with copper salts brown, and with mercuric salts yellow precipitates. When heated with orcinol and sulphuric acid, it yields Weselsky's dye, $C_{11}H_{11}NO_3$.

When nitrobenzene, orcinol, and sulphuric acid are heated together the same compound, $C_{14}H_{11}NO_3$, is produced, but only in exceedingly small quantity. L. T. T.

Action of Potassium Cyanide on Nitrated Benzaldehyde. By B. Homolka (*Ber.*, 17, 1902—1904).—The introduction of a nitrogroup into benzaldehyde does not generally prevent it from forming condensation-products with acetone, aldehyde, acetic anhydride, &c.; but in some cases, as in the formation of benzoïn-derivatives, it does prevent such reaction. The action of potassium cyanide on *paranitrobenzaldehyde* yields paranitrobenzoic acid, together with a red resinous body not further investigated, whilst with *orthonitrobenzaldehyde*, orthazoxybenzoic acid, described by Griess (this Jour., 1875, 460), is formed. This acid was converted into orthohydrazobenzoic acid, which crystallises in scales (m. p. 205°). L. T. T.

Benzeneazoketone. By V. v. Richter and H. Münzer (*Ber.*, 17, 1926—1930).—When ethylic benzeneazoacetoacetate, prepared according to V. Meyer's directions (Abstr., 1878, 396), is heated with an alcoholic or aqueous solution of caustic soda, *benzeneazoacetone*, $Ph.N_2.CH_2.COMe$, is formed. It crystallises in pale yellow needles or prisms which melt at 148—149°, and are easily soluble in alcohol, sparingly so in boiling water. The decomposition takes place entirely in the ketone direction, no benzeneazoacetic acid being formed. Benzeneazoacetone has a characteristic odour. Another method of preparation is to heat free benzeneazoacetoacetic acid to 170—180°, when carbonic anhydride is eliminated. Attempts to oxidise the ketone to benzeneazoacetic acid were unsuccessful.

Ethylic paratolueneacetoacetate, prepared in a similar manner, crystallises in yellow needles, which melt at 69—70°. When saponified with caustic soda, *paratolueneazoacetone*, $C_6H_4Me.N_2.CH_2.COMe$, is formed. This crystallises in yellow needles melting at 114—115°. It is also formed from the free acid by heat. L. T. T.

Action of Chromyl Chloride on Cymene. By V. v. Richter and G. Schüchner (*Ber.*, 17, 1931—1935).—By the action of chromyl chloride on cymene, Étard obtained two aldehydes of the formula $C_6H_4Pr^{\alpha}.COH$; isocumaldehyde melting at 81° and boiling at 220°, and terecumaldehyde, a liquid boiling at 219—220° (*Ann. Chim. Phys.* [5], 22, 259). As Paternò and Scichilone (Abstr., 1881, 423) could not obtain an aldehyde from cymene it appeared advisable to repeat the reaction.

The authors employed the pure paracymene obtained by heating camphor with phosphoric anhydride (cf. Armstrong and Miller, this vol., p. 44). The oxidation was effected according to Étard's directions. Although the preparation was repeated many times, only a single aldehyde was obtained, and was found to be not a cumaldehyde, but the isomeric *paratolylpropaldehyde*, $C_6H_4Me.CH_2.CH_2.COH$ [1 : 4]. It is a colourless strongly refractive oil, boils at 222—223°, has a peculiar peppermint-like odour, does not solidify at −15°, and at 13° has a sp. gr. 0·9941. It unites with hydrogen sodium sulphite to form a compound of the formula $C_{10}H_{12}O,HNaSO_3$, crystallising in white nacreous needles. It reduces ammoniacal silver solution and gives a violet coloration with a solution of magenta decolorised by sulphurous acid. By oxidation with potassium permanganate, it yields terephthalic acid, and with nitric acid, it gives paratoluic acid together with small quantities of terephthalic acid and of a nitro-acid. The aldehyde unites with phenylhydrazine to form an oily compound. With acetone, in presence of potash, it yields an oil giving numbers on analysis approximating to the formula

$$C_6H_4Me.CH_2.CH_2.CH : CH.COMe.$$

Experiments are in progress to endeavour to oxidise the aldehyde to paratolylpropionic acid. Étard's results are probably due to his employment of the impure cymene obtained by the action of bromine on turpentine. A. J. G.

Amidoacetophenone and Allied Substances. By P. Klingel (*Ber.*, **17**, 1613—1614).—When a mixture of aniline, zinc chloride, and an excess of acetic anhydride, is boiled for several hours, the acetyl-derivative of paramidoacetophenone is produced, from which paramidoacetophenone, $COMe.C_6H_4NH_2$, may be obtained, having all the properties assigned to it by Drewsen (*Annalen*, **212**, 163). Acetorthamidotoluene, $COMe.C_6H_3Me.NH_2$, may be obtained in the same way; it forms needles when crystallised quickly, and prisms when slowly crystallised; it melts at 102°. The platinochloride, $(C_9H_{11}NO)_2,H_2PtCl_6$, forms slender, yellow, sparingly soluble needles. Acetoparamidotoluene is more difficult to prepare. The author is continuing the experiments. A. K. M.

Preparation of Vanillin. By Haarmann and Reimer (*Dingl. polyt. J.*, **253**, 391).—When coniferin is oxidised with aqueous chromic acid, it is converted into glucovanillin. For this purpose a solution of 10 parts coniferin in 200 parts water, is treated at the ordinary temperature with a solution of 8 parts chromic acid dissolved in a small quantity of water, and the mixture allowed to stand for several days. Barium carbonate is then added to precipitate the chromium. The solution is evaporated to a small bulk, treated with alcohol and filtered. The filtrate, on evaporation, yields crystals of glucovanillin, melting at 170°. Concentrated sulphuric acid dissolves coniferin, forming a deep violet solution, whilst with glucovanillin it gives a pale yellow solution. On treating glucovanillin with emulsin in aqueous solution, or on boiling it with dilute mineral acids, it is resolved into glucose and vanillin. The latter may be extracted from the solution by ether. D. B.

Cinnamaldehyde. By T. Zincke and D. v. Hagen (*Ber.*, **17**, 1814—1817).—When an alkaline aqueous solution of cinnamaldehyde is treated with potassium cyanide, a yellow amorphous product is formed, which is soluble in alcohol, acetic acid, &c., and gives numbers on analysis very close to those required by cinnamaldehyde. The authors have not further investigated this substance.

Cinnamaldehyde dibromide, CHPhBr.CHBr.COH, is obtained by the direct addition of bromine to the aldehyde dissolved in ether, chloroform, or carbon bisulphide. It crystallises in small needles, which melt at 100°, with evolution of hydrobromic acid, and have a very pungent odour. It is very unstable, deliquesces on keeping, and gives off hydrobromic acid. When boiled with alcohol or acetic acid it gives off hydrobromic acid, and forms *monobromocinnamaldehyde*, $CPhBr : CH.COH$; this is, however, best prepared by the action of potassic acetate on the dibromide. Monobromocinnamaldehyde crystallises in plates or monoclinic prisms, soluble in alcohol and ether. It melts at 72—73°, and is very stable. Alcoholic potash, ammonia, and aniline, react with it at high temperatures, but no satisfactory results were obtained. It does not combine with bromine, but with phenylhydrazine it yields the compound,

$$CPhBr : C_2H_2 : N_2HPh,$$

which forms glistening yellow scales melting at 129—130°. When boiled with an acetic solution of chromic acid, the monobrominated derivative is oxidised to α-bromocinnamic acid, thus proving the correctness of the above formula. Monobromocinnamaldehyde when treated at 10° with nitric acid of 1·5 sp. gr., yields two *mononitro-derivatives*. The *α-compound* (which is the less soluble in alcohol) forms yellowish needles melting at 136°, and yields a ruby-coloured compound with phenylhydrazine; this melts at 154°, and by the action of reducing agents is converted into an easily soluble base, which is now under investigation. The *β-compound* forms yellow needles melting at 96—97°, and yields a hydrazine-compound crystallising in large golden-yellow scales, melting with decomposition at 134°. This β-compound also yields a base on reduction. L. T. T.

Derivatives of Cinnamaldehyde. By G. Peine (*Ber.*, **17**, 2109—2118).—*Hydrocinnamide* ($C_{27}H_{24}N_2 = N_2(CH.CH : CHPh)_3$.—Laurent obtained a compound to which he assigned this name and formula by the action of ammonia on oil of cinnamon. The author finds the first product of the reaction to have a more complex constitution; but by treatment in alcoholic solution with concentrated hydrochloric acid, hydrocinnamene hydrochloride is obtained, although the yield is very small owing to the formation of resinous bye-products. By shaking together for some weeks aqueous ammonia and an ethereal solution of cinnamaldehyde, a good yield of hydrocinnamide is obtained. It crystallises in white needles, melts at 106°, and is not decomposed by heating with concentrated hydrochloric acid for some hours at 250°. The hydrochloride, $C_{27}H_{24}N_2,HCl + 3H_2O$, crystallises in colourless tables, melts at 220—221°, is soluble in alcohol and chloroform, insoluble in water, ether, benzene, and light petroleum. The platinochloride has the formula $(C_{27}H_{24}N_2)_2,H_2PtCl_6$. Experiments to convert hydrocinnamide into bodies resembling amarine and lophine were not successful.

Phenyl-α-hydroxycrotononitrile, $CHPh : CH.CH(OH).CN$, is obtained by mixing an ethereal solution of cinnamaldehyde with a slight excess of potassium cyanide, and adding concentrated hydrochloric acid, drop by drop, until no more hydrocyanic acid is evolved. It forms a crystalline mass, melts at 75°, is readily soluble in alcohol, ether, benzene, and chloroform, insoluble in light petroleum.

Phenyl-α-hydroxycrotonic acid, $CHPh : CH.CH(OH).COOH$, is pro-pared by boiling the nitrile for several hours with dilute hydrochloric acid. It crystallises in long, flat needles, and melts at 115—116°. It has been previously obtained by Matsmoto (this Journal, 1876, i, 80). The methyl salt, $C_9H_8(OH).COOMe$, forms a clear yellow liquid of ethereal odour, and boils at 290°. The ethyl salt, $C_9H_8(OH).COOEt$, boils at 295°.

Phenyl-α-anilidocrotononitrile, CHPh : CH(CHPh).CN, obtained by boiling alcoholic solutions of aniline and phenyl-α-hydroxycrotononitrile, is crystalline, melts at 130°, is insoluble in water and light petroleum, readily soluble in alcohol, ether, benzene, and chloroform. By dissolving it in concentrated sulphuric acid, and pouring the solution into water, it is converted into *phenyl-α-anilidocrotonamide*, $CHPh : CH.CH(NHPh).CONH_2$. This crystallises in thin plates, melts at 171°, is readily soluble in alcohol and chloroform, sparingly soluble in hot water.

Phenyl-α-anilidocrotonic acid, CHPh : CH.CH(NHPh).COOH, prepared by the action of hydrochloric acid on the amide, crystallises in microscopic needles, melts at 154°, is readily soluble in alcohol, ether, and chloroform, somewhat soluble in benzene, insoluble in water and light petroleum. Possessing both acid and basic properties, it dissolves in solutions of acids and bases. With a solution of the ammonium salt, barium, zinc, lead, and silver salts give white crystalline precipitates; copper salts give a green precipitate which can be obtained crystallised in needles of the formula $(C_6H_{14}NO_2)_2Cu$.

Cinnamaldehyde can be synthesised by heating a mixture of benzaldehyde (10 parts), acetaldehyde (15 parts), water (900 parts), and aqueous soda of 10 per cent. (10 parts), with frequent shaking for 8—10 days at a temperature of about 30°.

Salts of Cinnamaldehyde-anilide.—The hydrochloride forms yellow needles and melts at 149°. The sulphate, $(C_{15}H_{13}N),H_2SO_4$, crystallises in yellow needles and melts at 157°; the nitrate also crystallises in yellow needles. The platinochloride, $(C_{15}H_{13}N)_2,H_2PtCl_6$, crystallises well.
A. J. G.

Condensations with Orthonitrocinnamaldehyde. By A. Einhorn (*Ber.*, 17, 2026—2028).—Baeyer and Drewson have shown (this vol., p. 58) that orthonitrobenzaldehyde and acetaldehyde react to form a loose compound of orthonitrophenyllactic aldehyde with 1 mol. acetaldehyde; and this, when boiled with acetic anhydride is converted into orthonitrocinnamaldehyde. The author now shows that orthonitrocinnamaldehyde can further react with acetaldehyde to form a condensation-product. Nitrocinnamaldehyde is mixed with 7—8 times the amount of acetaldehyde, and dilute soda added from time to time until a permanent alkaline reaction is obtained. At first the reaction is moderated by cooling the containing vessel with ice-water, later on the temperature is allowed to rise. The product is separated by precipitation with water and purified by treatment with animal charcoal and recrystallisation from alcohol. It then forms sulphur-yellow crystals and melts at 153°. It combines readily with bromine and shows all the properties of an aldehyde. Its analysis agrees with the formula $C_{11}H_9NO_3$, and it is probably

orthonitrocinnamylacraldehyde. Its further investigation is in progress.
A. J. G.

Some New Coumarins. II. By H. v. Pechmann and W. Welsh (*Ber.*, **17**, 1646—1652).—This is a continuation of Pechmann's work on the production of coumarins, by the action of sulphuric acid and a phenol on malic acid (this vol., p. 1173). It is found that the different phenols behave very differently, although phloroglucol is the only one experimented with which did not yield a coumarin-like compound; thus, whilst resorcinol, orcinol, and pyrogallol give an abundant yield of the respective coumarins, only small quantities are obtained from phenol, cresol, thymol, quinol, and naphthol.

Orthomethylparapropylcoumarin,  $C_6H_3MePr<\genfrac{}{}{0pt}{}{CH:CH}{O}>CO$, obtained from malic acid and thymol, crystallises from water or very dilute alcohol in slender white needles; it has an odour resembling that of thymol and coumarin. It melts at 53°, distils between 220° and 230°, is very sparingly soluble in water, readily in alcohol, ether, glacial acetic acid, benzene, and chloroform. In its behaviour to alkalis it resembles ordinary coumarin.

Metahydroxycoumarin,  $OH.C_6H_3<\genfrac{}{}{0pt}{}{CH:CH}{O}>CO$, prepared from malic acid and quinol, is isomeric with umbelliferone. It melts at 248—250°, dissolves sparingly in water, readily in alcohol and glacial acetic acid; it yields colourless solutions with concentrated sulphuric acid and with alkalis, and gives no reaction with ferric chloride. When boiled with acetic anhydride, it forms an *acetyl-derivative* which crystallises in splendid needles melting at 147°, is insoluble in water, but readily soluble in alcohol, ether, benzene, and chloroform.

Homo-umbelliferone,  $OH.C_6H_2Me<\genfrac{}{}{0pt}{}{CH:CH}{O}>CO$, from malic acid and orcinol, melts at 248°, dissolves in alcohol, glacial acetic acid, and acetone, and is insoluble in water, benzene, and chloroform. In its physical and chemical properties it bears a strong resemblance to umbelliferone. It forms blue fluorescent solutions with alkalis which become colourless on heating; its solution in concentrated sulphuric acid also exhibits blue fluorescence. Ferric chloride shows no reaction. By fusion with potash, it is converted into acetic acid, and orcylaldehyde, $C_8H_8O_3$ (*Ber.*, **12**, 1001); this melts at 179°, is soluble in alcohol, ether, and chloroform, gives a reddish-brown reaction with ferric chloride, and yields a crystalline compound with phenylhydrazine. The *acetyl-derivative* of homo-umbelliferone melts at 126—127°, and is identical with Tiemann and Helkenberg's homacetoxycoumarin (*Ber.*, **12**,, 1002). The compound,

$$C_{10}H_6<\genfrac{}{}{0pt}{}{CH:CH}{O}>CO,$$

obtained from β-naphthol and malic acid, is different from Kauffmann's β-naphthacoumarin (Abstr., 1882, 1068). It crystallises from dilute alcohol in yellowish needles, melts at 141°, is insoluble in water, sparingly soluble in ether, readily in alcohol, acetic acid, benzene, and chloroform. α-Naphthol yields mere traces of a crystalline condensation-product. Attempts to prepare æsculetin from malic acid and phloroglucol yielded no coumarin. The dihydroxycoumarin obtained by the condensation of phloroglucol with ethyl acetoacetate, does not bear the slightest resemblance to æsculetin. From these results, it seems probable that æsculetin bears no relation to phloroglucol, and the authors intend to try to produce it from Barth and Schreder's hydroxyquinol (Abstr., 1883, 987).

A. K. M.

Bromoxylic Acid and Hydroxy-xylic Acid. By E. Gunter (*Ber.*, **17**, 1608—1609).—Süssenguth's monobromopseudocumic acid is a bromoxylic acid, identical with that obtained on brominating xylic acid dissolved in glacial acetic acid. When treated with sodium-amalgam, it yields xylic acid (m. p. 126°), and on heating this with hydrochloric acid at 220°, metaxylene is obtained. By fusing the brominated acid with potash, three hydroxy-acids are obtained. The acid formed in largest quantity melts at 170.5°, yields no blue coloration with ferric chloride, is scarcely volatile in steam, and is not decomposed by hydrochloric acid at 200—210°. Assuming that no molecular change occurs during its formation, its constitution must be $C_6H_2Me_2(OH).COOH$ [OH : Me : Me : COOH = 1 : 2 : 4 : 5]. The second acid melts at 144°, gives a blue colour reaction with ferric chloride, is readily volatile in steam, and is completely decomposed on heating it with hydrochloric acid at 200—210°, yielding carbonic anhydride and *paraxylenol;* this shows that it has the constitution $C_6H_2Me_2(OH).COOH$ [Me : OH : COOH : Me = 1 : 2 : 3 : 4]. The third hydroxy-acid melts at 153°, is not coloured blue by ferric chloride, and yields *paraxylenol* when heated with hydrochloric acid at 200—210°; its constitution is therefore

$$C_6H_2Me_2(OH).COOH\ [OH : Me : COOH : Me = 1 : 2 : 4 : 5].$$

From these results, it would appear that either a molecular change takes place by the action of potash on the bromoxylic acid, or that the latter is mixed with isomeric acids, which, however, is not probable. On brominating paraxylic acid, a monobromo-derivative is obtained, crystallising in slender white needles melting at 189°; it dissolves readily in alcohol, sparingly in water. The *barium salt* is moderately soluble, and crystallises in dense aggregates of needles; the *calcium salt* forms groups of colourless prisms easily soluble in hot water; the *cadmium salt* forms readily soluble flat white prisms; the *potassium salt* crystallises in small needles readily soluble in water, and the *copper salt* in small blue rhombic plates. A. K. M.

Synthesis of Hippuric Acid and Hippuric Ethers. By T. Curtius (*Ber.*, **17**, 1662—1663).—A good yield of hippuric acid is obtained by the action of benzoic anhydride on glycocoll:

$$2(NH_2.CH_2.COOH) + \overline{Bz}_2O = 2(NH\overline{Bz}.CH_2.COOH) + H_2O.$$

Finely-powdered dry glycocine is gradually added to an excess of hot benzoic anhydride, and the whole heated in an oil-bath until a red mass is obtained; this is dissolved in water, neutralised with alkali, acidulated, and allowed to remain for some days. The precipitate is boiled with water, using animal charcoal, and the filtrate is concentrated and allowed to crystallise. The product contains some benzoic acid, which may be removed by treatment with light petroleum. In order to prepare ethyl hippurate, a mixture of benzoic anhydride and glycocoll ether in calculated quantities is digested at about 100° and the product crystallised from boiling water; it forms white needles which melt at 60°. A. K. M.

Derivatives of Phenylcinnamic Acid. By A. G. CABELLA (*Gazzetta*, **14**, 114—116).—Phenylcinnamic acid was prepared by Oglialoro (Abstr., 1879, 640), and its silver, lead, barium, and ethyl salts examined and described. The author has prepared *methylic phenylcinnamate*, CHPh : CPh.COOMe, by passing dry hydrochloric acid gas into a solution of the acid in methyl alcohol. It crystallises from dilute alcohol in long needles which melt at 77—78°. Bromine does not combine with it when the two are dissolved in chloroform and allowed to remain at the ordinary temperature, but if the mixture is heated in a water-bath, in a flask furnished with a reflux condenser, an action takes place, and the dibrominated compound, CHBrPh.CBrPh.COOMe, is obtained. This crystallises in transparent plates which melt at 105—108°. The bromine in it could not be determined by Carius' method, as it was not completely oxidised by the nitric acid. C. E. G.

Derivatives of Benzoylimidocinnamic Acid. By J. PLÖCHL (*Ber.*, **17**, 1616—1624).—The author refers to a previous paper (this vol., p. 604) in which he described the formation of benzoylimidocinnamic acid by the condensation of hippuric acid with benzaldehyde, and also its decomposition by acids or alkalis into benzoic acid, ammonia, and phenylglycidic acid. When benzoylimidocinnamic acid is heated in a sealed tube with concentrated aqueous ammonia. the *lactimide of benzoyldiamidohydrocinnamic acid*, $CHPh\left\langle\begin{array}{c}CH(NH\overline{Bz})\\NH\end{array}\right\rangle CO$, is obtained, crystallising in lustrous needles or prisms. It melts at 187°, is insoluble in water, dilute acids, or alkalis, sparingly soluble in ether, but more readily in hot alcohol or acetic acid; it is very stable, but may be decomposed by hot mineral acids or caustic alkalis. The ammoniacal mother-liquors from the lactimide contain benzamide and an acid, $C_{16}H_{13}O_3N$, isomeric with benzoylimidocinnamic acid. The acid $C_{16}H_{13}O_3N$ is separated from its ammonium salt by adding a mineral acid, and is purified by crystallisation from dilute acetic acid; it melts at 131°, dissolves very readily in ether and alcohol, is also soluble in hot water and crystallises in needles or prisms. It is identical with *α-benzoylamidocinnamic acid*, obtained as given below, and its formation from benzoylimido-cinnamic acid is explained by a simple molecular change similar to that of hydrobenzamide into amarine (Abstr., 1882, 329). *α-Benzoylamidocinnamic acid*, CHPh : C(NH$\overline{\text{Bz}}$).COOH, is prepared by heating the lactimide of benzoyldiamidohydrocinnamic acid in acetic acid solution with a quantity of dilute hydrochloric acid rather more than sufficient to remove 1 mol. NH_3; as the solution cools, the acid crystallises out in nodular groups of prisms. *α-Amidocinnamic acid*, $CHPh:C(NH_2).COOH$, is prepared by heating benzoylamidocinnamic acid, or the lactimide of the benzoyldiamido-acid, with 20 per cent. hydrochloric acid at 120°. The acid liquid is separated from the benzoic acid produced, evaporated to dryness, the residue dissolved in a little water and the amido-acid separated by the addition of sodium carbonate or acetate. It forms white scales of silvery lustre, and in its physical properties is scarcely to be distinguished from phenylalanine. When heated in a capillary tube, it is gradually decomposed between 240—250°, whilst phenylalanine melts above 260° with vigorous evolution of carbonic anhydride. Its copper salt, $(C_9H_8NO_2)_2Cu,2H_2O$, also agrees in its properties with that of phenylalanine, and in the amount of water of crystallisation. The hydrochloride of amidocinnamic acid has the composition $(C_9H_9NO_2)_2,HCl$, and crystallises in flat needles, sparingly soluble in cold water and alcohol, whilst phenylalanine yields a normal hydrochloride, readily soluble in water but very sparingly in concentrated hydrochloric acid. When rapidly heated, α-amidocinnamic acid yields styrolamine and the lactide of the acid, phenylalanine yielding phenylethylamine and a lactimide. With nitrous acid, a sparingly soluble oily hydroxy-acid, probably α-hydroxycinnamic acid, is obtained. The formation of the amidocinnamic acid is expressed thus:

$$CHPh:C(NH\overline{Bz}).COOH + H_2O = CHPh:C(NH_2).COOH + \overline{Bz}OH.$$

But besides this reaction, another takes place resulting in the formation of phenylacetic acid. Reducing agents convert amidocinnamic acid into phenylalanine, identical with that obtained by Erlenmeyer and Lipp (*Annalen*, **219**, 200). A. K. M.

Hydroparacoumaric Acid. By G. C. STÖHR (*Annalen*, **225**, 57—94).—Considerable interest is attached to hydroparacoumaric acid, chemically, from its connection with the cinnamic acid group, and physiologically, as a product of the decomposition of tyrosine from the albumin in the intestines; as such, it has been found in patients suffering from peritonitis, and in normal human urine. The ethyl salt of this acid is also probably present in the rhubarb.

The acid is best prepared by converting ethyl paranitrocinnamate by hydrogenation into paramidohydrocinnamic acid, which by means of the diazo-compound is then transformed into the corresponding hydroxyl-compound, or *hydroparacoumaric acid*,

$$OH.C_6H_4.CH_2.CH_2.COOH.$$

It crystallises from its solutions in ether in pale-golden prisms of the monoclinic system; it melts at 128°. It gives a characteristic blue coloration with ferric chloride, the phenol reaction with nitrous acid, and a white precipitate with mercuric nitrate. It does not reduce Fehling's solution. The salts of this acid have been described by Hlasiwetz and Baumann.

With bromine, the acid yields a *dibromo-derivative*,

$$OH.C_6H_2Br_2.C_2H_4.COOH,$$

which crystallises in needles melting at 107°; its *ammonium* salt forms colourless needles; its silver, copper, and lead salts are amorphous precipitates.

Dinitrohydroparacoumaric acid, $OH.C_6H_2(NO_2)_2.CH_2 COOH$, obtained by the action of concentrated nitric acid on hydroparacoumaric acid, forms flat prismatic crystals of the rhombic system, melting at 137·5°, soluble in alcohol and acetic acid. This acid forms two series of salts, the one strongly acid, decomposing carbonates, the other neutral. Of the former, the *ammonium* salt crystallises in reddish-golden needles, the *silver* salt in grouped needles, the *calcium* salt in golden prisms; the *iron* and *copper* salts are amorphous precipitates; of the latter the *ammonium* salt crystallises in golden needles, and the *silver* salt in dark-red needles. The hydrogen ethereal salts are best obtained by saturating alcoholic solutions of the acid with hydrochloric acid, and the neutral ethereal salts by the action of the alcoholic iodides on the silver ethereal salts. Of the former, the *methyl* salt crystallises in long, colourless needles melting at 87°, the *ethyl* salt in citron, six-sided tables; both decompose carbonates readily. Of the latter, the *dimethyl* salt forms colourless prismatic needles, melting at 53°; the *methyl ethyl* salt, $MeO.C_6H_2(NO_2)_2.C_2H_4.COOEt$, colourless glistening needles melting at 71°; the *ethyl methyl*, $EtO.C_6H_2(NO_2)_2.C_2H_4.COOMe$, colourless needles melting at 36°, and the *diethyl* salt, glistening needles melting at 49°.

Dinitromethylhydroparacoumaric acid, $MeO.C_6H_2(NO_2)_2.C_2H_4.COOH$, obtained by the decomposition of either the methyl ethyl or dimethyl salt by heating it with sulphuric acid, crystallises in aggregated flat prisms melting at 124°, readily soluble in alcohol; the corresponding *ethyl* compound in long colourless needles melting at 126°. In order to determine the relative position of the two nitro-groups in dinitrohydroparacoumaric acid, its methyl salt was subjected to oxidation by chromic mixture; dinitroanisic acid was obtained, convertible into chrysanisic and dinitroparoxybenzoic acids and β-dinitrophenol. These results show that the two nitro-groups are in the ortho-position to the hydroxyl, and in the meta-position to the side-chain: thus to dinitrohydroparacinnamic acid must be ascribed the formula

$$OH.C_6H_2(NO_2)_2.C_2H_4.COOH\ [OH : NO_2 : C_2H_4 : COOH : NO_2 = 1 : 2 : 4 : 6.]$$

Dinitroparamidohydrocinnamic acid, $NH_2.C_6H_2(NO_2)_2.C_2H_4.COOH$, obtained from the above-mentioned methyl salt by heating it with ammonia, crystallises in dark-golden needles with a green reflection; it melts at 190°, is sparingly soluble in cold, but moderately in hot water and in alcohol. Its metallic salts crystallise in golden needles, its *methyl* salt in brilliant reddish leaflets melting at 102°, its *ethyl* salt in golden-yellow leaflets melting at 95°. The acid and its ethereal salts are readily converted by heating with alkalis into dinitrohydroparacoumaric acid.

Mononitrohydroparacoumaric acid, $HO.C_6H_3(NO_2).C_2H_4.COOH$, obtained from hydroparacoumaric acid by treatment with nitric acid, crystallises in tufts of needles melting at 90·5°; its *methyl* salt crystallises in golden needles melting at 64°, and its *ethyl* salt in concentrically-grouped golden needles melting at 30°. As the acid does not yield hydroxyhydrocarbostyril on reduction, the nitro-group is in the ortho-position to the hydroxyl-group, and in the meta to the side-chain. The formula

$$OH.C_6H_3(NO_2).C_2H_4.COOH\ [OH : NO_2 : C_2H_4.COOH = 1 : 2 : 4],$$

therefore represents its constitution. V. H. V.

Etherification of the Three Isomeric Nitrophenyl-β-lactic Acids. By A. Einhorn and G. Prausnitz (*Ber.*, **17**, 1659—1662).—According to Basler (*Ber.*, **16**, 3007), paranitrophenyl-β-lactic acid may be converted into the corresponding β-lactone by heating it with an alcoholic solution of zinc chloride. The authors have repeated the experiment, but cannot confirm Basler's results; not a trace of lactone could be detected in the product, which consisted of the ethyl-derivative of the acid, or, when methyl alcohol was employed, of the methyl-derivative. Ortho- and meta-nitrophenyl-β-lactic acids yield the same results. Orthonitrophenyl-β-lactic acid was heated with methyl alcohol and zinc chloride for 2—3 hours at 100°, and also 120°, and the product when cold poured into water. The methyl orthonitrophenyl-β-lactate, $C_{10}H_{11}NO_5$, obtained melts, after purification, at 50—51°, and is identical with the product of the action of hydrochloric acid on orthonitrophenyl-β-lactic acid and methyl alcohol. When either of the three nitrophenyl-β-lactic acids is heated on a water-bath with aqueous zinc chloride, no action takes place, the original substance being recovered unchanged. Metanitrophenyl-β-lactic acid was treated as above, ethyl alcohol being employed; no carbonic anhydride was evolved on heating at 120°, which should have been the case had a lactone been present: the product, $C_{11}H_{13}NO_5$, melts at 56°, and is identical with the ethyl-derivative obtained by boiling silver metanitrophenyl-β-lactate with ethyl iodide. The same experiment was made with paranitrophenyl-β-lactic acid, using methyl and ethyl alcohols, and here again no carbonic anhydride could be detected. The methyl ether melts at 73—74° (72—74° Basler), and the ethyl ether, $C_{11}H_{13}NO_5$, at 45—46°, as given by Basler. A. K. M.

β-Lactone of Isopropylnitrophenyllactic Acid. By A. Einhorn and W. Hess (*Ber.*, **17**, 2015—2026).—By the nitration of cumenylacrylic acid in the cold, there is obtained orthonitrocumenylacrylic acid, and a small quantity (10—12 per cent.) of paranitrocinnamic acid. The formation of the latter is interesting, there being no analogous case of so moderately energetic a reagent as cold nitric acid splitting off an alkyl-group from a substituted benzene, and replacing it by a negative group. The acids are separated by repeated crystallisation from hot alcohol, in which paranitrocinnamic acid is but sparingly soluble.

Orthonitrocuminylacrylic acid, $C_6H_3Pr^\beta(NO_2).CH : CH.COOH = [4 : 2 : 1]$, when perfectly pure, crystallises in long, pale wine-yellow needles, and melts at 156—157° (as ordinarily obtained in a nearly pure state, it forms hard prismatic crystals, and melts at 152—153°). It is readily soluble in alcohol, ether, benzene, chloroform, and glacial acetic acid; sparingly soluble in hot water, and insoluble in light petroleum. It gives a brown coloration when heated with concentrated hydrochloric acid. The barium salt crystallises in needles; the silver, lead, zinc, and copper salts are sparingly soluble precipitates; the methyl salt forms tufts of thin needles. As the nitrocumaldehyde obtained on oxidation is not the known metaldehyde (metacuminol, melting at 54°), the nitro-group must be in the orthoposition.

Orthonitrocumaldehyde, $C_6H_3Pr^{\beta}(NO_2).COH$ [4 : 2 : 1], is prepared by oxidising the nitrocumenylacrylic acid with potassium permanganate, the well-cooled liquid being shaken with benzene throughout the oxidation. On evaporating the benzene, the aldehyde is left as an oil, and is purified by distillation with steam, conversion into the bisulphite-compound, &c. It then forms an oil, showing but little tendency to crystallise, even after standing for some days over sulphuric acid at the summer temperature. It reduces ammoniacal silver solution, and yields a compound with hydrogen sodium sulphite, crystallising in needles. When treated with acetone and soda, it yields a blue colouring matter, which, from its properties, is undoubtedly di-isopropyl indigo. This reaction confirms the presence of a nitrogroup in the ortho-position.

Paraisopropylorthonitrophenyl-β-bromopropionic acid,

$$C_6H_3Pr^{\beta}(NO_2).CHBr.CH_2.COOH,$$

is prepared by adding excess of glacial acetic acid, saturated at 0° with hydrobromic acid, to finely-powdered nitrocumenylacrylic acid. It crystallises in nearly colourless silky prisms, melts with decomposition at 127°, is readily soluble in alcohol, ether, benzene, chloroform, and glacial acetic acid, soluble in hot water, sparingly soluble in carbon bisulphide. On long boiling with water, it suffers decomposition, the liquid acquiring a green colour, and having an odour of nitroisopropylvinyl, and containing small quantities of nitrocumenylacrylic acid. Alkalis in the cold, and sulphuric acid on heating, remove the elements of hydrobromic acid, and regenerate nitrocumenylacrylic acid. From its chemical behaviour, and from analogy with the formation of the β-brominated acids by the action of hydrobromic acid on cinnamic and orthonitrocinnamic acids, there can be little doubt that the bromine-atom occupies the β-position.

β-Lactone of isopropylnitrophenyllactic acid,

$$C_6H_3Pr^{\beta}(NO_2).CH{<}\genfrac{}{}{0pt}{}{CH_2}{-O-}{>}CO \; [4 : 2 : 1],$$

is best prepared by adding soda in very slight excess to the β-brominated acid, and allowing the solution to stand for 12 hours. In addition to the lactone, small quantities of nitrocumenylacrylic acid and isopropylnitrophenyllactic acid are formed. It crystallises in hard colourless crystals, melts at 73°, and on further heating is decomposed, leaving a blue residue that exhibits the indigo spectrum. It is readily soluble in alcohol, ether, benzene, glacial acetic acid, chloroform, and carbon bisulphide, sparingly in light petroleum. On boiling it with water, the chief products are carbonic anhydride and isopropylnitrostyrene. Concentrated sulphuric acid dissolves it to a yellow solution, becoming green on heating; the addition of water precipitates a green colouring matter in flocks; this is soluble in chloroform. Hydrobromic acid reconverts the lactone into the brominated acid. By the action of alkalis, or their carbonates, or chalk, it is converted into the corresponding propylnitrophenyllactate.

Isopropylnitrophenyllactamide, $C_6H_3Pr^\beta(NO_2).CH(OH).CH_2.CONH_2$ [4 : 2 : 1], prepared by the action of ammonia on the lactone or on the brominated acid, crystallises in stellate groups of pale yellowish-green prisms, melts at 150°, is readily soluble in hot water, benzene, chloroform, and glacial acetic acid, insoluble in ether and carbon bisulphide.

Paraisopropylorthonitrophenyllactic acid,

$$C_6H_3Pr^\beta(NO_2).CH(OH).CH_2.COOH,$$

is best prepared by boiling the brominated acid with soda, separating the isopropylnitrostyrene formed simultaneously, by distillation with steam, and finally decomposing the sodium salt with an acid. (There appears to be no formation of nitrocumenylacrylic acid or di-isopropylindigo in this reaction, which thus differs from that with the lower homologues of the orthonitrocinnamic series.) It crystallises in silvery pale-yellow laminæ, melts at 119—120°, is readily soluble in alcohol, ether, benzene, chloroform, glacial acetic acid, acetone, and hot water, sparingly soluble in carbon bisulphide, nearly insoluble in light petroleum. The sodium salt is crystalline; the calcium salt forms transparent prisms; the barium salt nodular groups of very slender needles; the cadmium salt forms roundish tables; the silver salt is obtained as a white precipitate, blackening on exposure to light; the copper, lead, and zinc salts are sparingly soluble precipitates. Hydrobromic acid reconverts the lactic acid into the brominated acid. Sulphuric acid removes the elements of water, nitrocumenylacrylic acid being formed.

Isopropylnitrostyrene, $C_6H_3Pr^\beta(NO_2).CH:CH_2$ [4 : 2 : 1], prepared as mentioned above, is an oil of agreeable aromatic odour; it could not be solidified in a freezing mixture. It is very unstable, soon suffering spontaneous decomposition on standing. A. J. G.

Caffeic Acid in Hemlock. By A. W. HOFMANN (*Ber.*, **17**, 1922—1925).—From the great similarity between conhydrine and tropine, the author believed that the former compound, like the latter, exists in plants in combination with an acid. He has now isolated caffeic acid from the alkaline residues left after driving over conine and conhydrine in the process of their extraction from hemlock. The alkaline residue was acidified and extracted with ether, and the residue then further purified. L. T. T.

Preparation of Phenolsulphuric Acid from Urine. By L. BRIEGER (*Zeit. Physiol. Chem.*, 8 [4], 311—312).—The author's method may in some cases be advantageous, although Baumann's is the most accurate for quantitative determinations.

Fresh urine is treated with neutral acetate of lead as long as anything is precipitated, the precipitate filtered off, and the filtrate treated in the same way with basic lead acetate. From this filtrate the excess of lead is removed by sulphuretted hydrogen, the filtrate is evaporated to a thick syrup, and kept for some time in a vacuum. The potassium phenolsulphate which crystallises out in plates is purified by recrystallisation from hot absolute alcohol. A small quantity is retained by the basic lead acetate precipitate. J. P. L.

Amidophenolsulphonic Acids and their Relationship to Liebermann's Colouring Matters. By H. Brunner and C. Kraemer (*Ber.*, **17**, 1867—1872).—When prepared by Brunner's reaction from resorcinol and nitrobenzene, azoresorufin, as already mentioned (p. 1333), is always accompanied by paramidophenolsulphonic acid. The latter is not formed when nitrobenzene alone is heated with sulphuric acid, so that its origin is evidently closely connected with the formation of azoresorufin. Taking into account the formation of azoresorufin from nitrosoresorcinol, the authors believe that during the progress of the above reaction an intramolecular rearrangement takes place in the nitrobenzene, somewhat according to the following equation:—

$$2C_6H_5.NO_2 = C_6H_4(OH).NO + C_6H_3(OH)_2N\colon$$

This dyad radicle $C_6H_3(OH)_2N\colon$ would at the moment of its formation react with a molecule of resorcinol and one of nitrosoresorcinol to form azoresorufin and paramidophenol—

$$C_6H_3(OH)_2N\colon + C_6H_4(HO)_2 + C_6H_4(OH).NO + H_2 =$$
$$C_6H_3(OH)_2.N{<}{}^{O}_{O}{>}C_6H_4 + C_6H_4(OH).NH_2 + H_2O,$$

the latter being converted into paramidophenolsulphonic acid and the former into azoresorufin by the excess of sulphuric acid. Sulphurous anhydride is always evolved during the reaction, and thus the nascent hydrogen required is accounted for.

The authors have also studied the action of the isomeric nitrophenols and of the homologues of nitrobenzene when heated with resorcinol and concentrated sulphuric acid. Paranitrotoluene and resorcinol yield a dimethyl ether of azoresorufin together with paramidophenolsulphonic acid, and not amidocresolsulphonic acid as might be expected. Of the three isomeric nitrophenols, the para-derivative alone yields a colouring matter analogous to resorufin, but all three yield amidophenolsulphonic acids. Only the mononitroso-derivatives of resorcinol and orcinol appear to yield these colouring matters, the dinitroso-derivatives showing no such reaction.

When paramidophenolsulphonic acid is subjected to dry distillation, it yields a dark violet-coloured sublimate, which appears to be identical with Liebermann's phenol colouring matter, $C_{18}H_{15}HO_3$. Neither the ortho- nor the meta-compound give any such sublimate.

α-Amidoresorcinolsulphonic acid, obtained by the reduction and subsequent sulphonation of Weselsky and Benedict's nitroresorcinol, [OH : OH : NO_2 = 1 : 3 : 4], appears to be identical with the acid described by Hazura (Abstr., 1883, 1114), but the author's specimen crystallised in green lustrous scales, whilst Hazura's yielded reddish prisms. This acid when dry-distilled yields azoresorcinol or azoresorufin, according to the temperature employed.

v-Amidoresorcinolsulphonic acid, prepared from Weselsky and Benedict's nitroresorcinol, [OH : OH : NO_2 = 1 : 3 : 2], and which therefore has not a hydroxyl-group in the para-position to the nitro-group, yields no colouring matter when heated. The acid crystallises in small colourless needles or prisms soluble in boiling water. Its solution reduces an ammoniacal silver solution in the cold.

From the results of their own and other investigators' work, the authors conclude that the nitrogen-atom in Liebermann's colouring matter is in the para-position to one of the hydroxyls, and that in polyhydric phenols only those can form these compounds in which two hydroxyl-groups are in the meta-position relatively to one another.

L. T. T.

β-Metaisocymenesulphonic Acid. By W. Kelbe and N. v. Czarnomski (*Ber.*, **17**, 1746—1748).—The author, some time ago, (Abstr., 1882, 619) described a bromisocymenesulphonic acid obtained by dissolving β-bromisocymene in fuming sulphuric acid. The author now finds that this acid yields β-metaisocymenesulphonic acid on reduction. He has proved the identity of this last-named acid with that obtained by direct sulphonation of isocymene by a comparison of their salts. The salts and derivatives prepared were:—$(C_{10}H_{13}SO_3)_2Ba + 8H_2O$; $(C_{10}H_{13}SO_3)_2Cu + 3\frac{1}{2}H_2O$; $C_{10}H_{13}SO_3Na + 3H_2O$; $C_{10}H_{13}SO_3NH_4$ melting at 162°; $(C_{10}H_{13}SO_3)_2Pb + 8H_2O$; $(C_{10}H_{13}SO_3)_2Ca + 5\frac{1}{2}H_2O$.

When treated at 40° with bromine dissolved in hydrobromic acid, this acid yields principally a bromisocymenesulphonic acid crystallising with 3 mols. H_2O, together with small quantities of bromisocymene.

L. T. T.

Behaviour of Tannin and Oak-bark Tannin towards Various Reagents. By C. Etti (*Ber.*, **17**, 1820—1823).—When boiled with dilute sulphuric acid under ordinary pressure, tannin takes up water and forms gallic acid, whilst "oak-bark tannin" gives up water and forms an anhydride. The same effects are produced by solutions of the caustic alkalis, except that the anhydride produced is of a different nature. Heated with dilute sulphuric acid at 130—140° under pressure, oak-bark tannin only gives traces of gallic acid. Tannin remains unchanged at 200°, oak-bark tannin loses a constant weight of water at 130—140°, and is converted into an anhydride. With acetic anhydride, tannin forms acetotannins, whilst oak tannin gives anhydrides and acetylised anhydrides. When boiled with aqueous ammonia in an atmosphere of hydrogen, tannin yields gallamide and an acid ammonium gallate in almost theoretical quantity; oak tannin yields nothing but indefinite resinous compounds.

It is thus clear that these two compounds are not identical, and that oak bark does not contain ordinary tannin.

From the analogy of the formation of gallamide and ammonium gallate by the action of ammonia on tannin, to that of lactamide and ammonium lactate from the action of ammonia on lactic anhydride, CHMe(OH).COO.CHMe.COOH, the author is inclined to look upon tannin as $C_6H_2(OH)_3.COO.C_6H_2(OH)_2.COOH$. L. T. T.

Synthesis of Diphenylethane from Ethylidene Chloride. By R. D. Silva (*Bull. Soc. Chim.*, **41**, 448—449).—Priority is claimed for the synthesis of diphenylethane from ethylidene chloride and benzene in presence of aluminium chloride, which has recently been announced by Angeblis and Anschütz (Abstr., 1884, 753), the author's results having been published in 1881 (*Bull. Soc. Chim.*, **36**, 66). By passing the vapour of ethylidene chloride into a mixture of benzene and aluminium chloride heated at 70°, ethylbenzene is obtained as well as unsymmetrical diphenylethane, from which it differs by containing one C_6H_4 residue less. This body is not formed in the preparation of symmetrical diphenylethane, but in the preparation of unsymmetrical diphenylpropane a notable quantity of cumene is obtained; this hydrocarbon stands in the same relation to diphenylpropane that ethylbenzene does to diphenylethane. W. R. D.

Acridines. By A. Bernthsen (*Annalen*, **224**, 1—56).—Most of the acridine and phenylacridine-derivatives have been previously described by the author (*Annalen*, **192**, 1; Abstr., 1883, 580, 1099, 1133, 1134, 1183). The best yield of acridine is obtained by the action of zinc or aluminium chloride on a mixture of chloroform and diphenylamine.

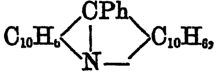
In addition to the methods which have been previously given (*loc. cit.*), phenylacridine can also be prepared by acting on a mixture of diphenylamine and benzotrichloride with zinc chloride. Phenylacridine boils above 400°. Hydrophenylacridine easily loses 2 atoms of hydrogen. Phenylacridine yields *di*- and *tri*-nitro-derivatives, which are converted into the corresponding amido-compounds by reduction with tin and hydrochloric acid. The salts of these bases dye silk and wool. Phenylacridinedisulphonic acid, which has not yet been obtained in the pure state, dissolves in water, forming a brownish-yellow solution, which exhibits an intense green fluorescence. The sodium salt crystallises in colourless needles. It is decomposed by fusion with potash, yielding, amongst other products, a yellow colouring matter.

Methylacridine, $C_{13}H_8NMe$, melting at 114°, unites with methyl iodide, forming a crystalline compound which is deposited from aqueous or alcoholic solutions in red needles. The crystals melt at 185° with decomposition. *Dimethylacridinium hydroxide*,

$$C_{14}H_{11}NMe.OH,$$

forms a grey powder, which is decomposed by exposure to the air. The hydrochloride crystallises in prisms which are freely soluble in water. It melts with decomposition between 130° and 135°. Cautious oxidation with potassium permanganate appears to convert methylacridine into quinolinetricarboxylic acid. Strong nitric acid transforms it into trinitroacridinecarboxylic acid, $C_{13}H_5(NO_2)_3N.COOH$. Butylacridine and acridylbenzoic acid have been already described (this vol., p. 1183). W. C. W.

Phenyl-β-naphthacridine. By C. Ris (*Ber.*, **17**, 2029—2032).—*Phenyl-β-naphthacridine*, $C_{27}H_{17}N$ =



$$C_{10}H_6\left\langle\begin{array}{c}CPh\\ |\\ N\end{array}\right\rangle C_{10}H_6$$

is obtained by heating a mixture of β-dinaphthylamine with three times its weight of benzoic chloride for eight hours at the boiling point of the mixture. It is also formed by the action of zinc chloride on benzoyldi-β-naphthylamine at 240°, and on a mixture of β-dinaphthylamine and benzoic acid at 280°. It crystallises in nearly colourless needles, melts at 297°, and sublimes in needles. It is readily soluble in hot benzene and glacial acetic acid, sparingly soluble in ether and alcohol. 100 parts of alcohol at 18° dissolve 0·04 part, and 100 parts of benzene 0·29 of phenyl-β-naphthacridine. The substance has been previously obtained by Claus and Richter (this vol., p. 1358). The *hydrochloride*, $C_{27}H_{17}N,HCl$, forms a yellow crystalline powder. The *platinochloride*, $(C_{27}H_{17}N)_2,H_2PtCl_6$, crystallises in brilliant yellow plates. The sulphate forms tufts of yellow crystals. A. J. G.

The Question of the Ammonium Bases derived from Acridine and Quinoline. By A. Bernthsen (*Ber.*, **17**, 1947—1957).—A reply to Claus (this vol., p. 1359), in which the author reaffirms the accuracy of the constitution assigned by him to methylphenylacridine-ammonium hydroxide (Abstr., 1883, 1133), and criticises the views of Claus as to the nature of the bases obtained by the action of silver oxide on the alkyl haloid addition-products of quinoline.

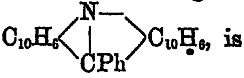
A. J. G.

Preparation of Propyl and Amyl-naphthalene. By L. Roux (*Bull. Soc. Chim.*, **41**, 379—382).—These compounds can be prepared by Friedel and Crafts' aluminium chloride reaction. 200 grams of naphthalene and 120 grams of α-propyl bromide are heated in an apparatus with reflux condenser, and as soon as the mixture commences to distil 10 grams of aluminium chloride are added in very small quantities at a time. When the theoretical quantity of hydrobromic acid has been evolved, the mixture is cooled, and from 300—400 grams of carbon bisulphide added. The liquid is then treated with water, the carbon bisulphide decanted and distilled to dryness from a water-bath. The residue is fractionally distilled in a vacuum. In this way a highly refractive, aromatic liquid is obtained which boils at 262—267°. It is insoluble in water, but soluble in benzene and alcohol. The purified compound crystallises from benzene or alcohol in slender yellow needles melting at 89—90°. This hydrocarbon is probably isopropylnaphthalene, for it has been shown that under the influence of aluminium chloride the propyl-group becomes an isopropyl-group. By a similar method, amylnaphthalene is obtained from amyl chloride boiling at 100—102°, and naphthalene. It is a colourless liquid boiling at 288—292°; the picric acid compound melts at 105—110°. This hydrocarbon appears to be isomeric with the two amylnaphthalenes already obtained; the one by the action of hydriodic acid and phosphorus on lapachic acid, the picric acid compound of which melts at 140—141°; the other by Fittig's method, the picric acid compound of which melts at 85—90°. In the preparation of both propyl- and amyl-naphthalene, isodinaphthyl is formed by the reducing action of aluminium chloride. This secondary reaction occurs exclusively when amyl chloride is allowed to fall drop by drop into a mixture of 100 grams of naphthalene and 25 grams of aluminium chloride heated at 120°. Under these conditions pentane, boiling at 29—34°, and isodinaphthyl are formed according to the equation, $2C_{10}H_8 + C_5H_{11}Cl = HCl + C_5H_{12} + (C_{10}H_7)_2$, but no amylnaphthalene.

W. R. D.

Action of Phosphorus Pentachloride and Pentoxide on Benzoyl-β-Naphthylphenylamine and on Benzoyldi-β-naphthylamine. By A. Claus and C. Richter (*Ber.*, **17**, 1590—1597).—*Benzoyl-β-naphthylphenylamine*, β-$C_{10}H_7.NPh\overline{Bz}$, is readily obtained by heating a mixture of benzoic chloride and β-naphthylphenylamine at 50—60°; it crystallises from alcohol in colourless lustrous needles melting at 147—148°. It is insoluble in water, sparingly soluble in cold alcohol, readily in benzene and acetic acid. It is decomposed by boiling alcoholic potash, yielding benzoic acid in theoretical quantity, whilst the naphthylaniline is converted into a brown resinous mass. The action of phosphorus pentachloride on benzoyl-β-naphthylphenylamine takes place much more readily than with the corresponding diphenyl-derivative (Abstr., 1882, 1060), and is best effected in chloroform solution; hydrochloric acid is evolved with formation of phosphorus trichloride, and the compound β-$C_{10}H_6Cl.NPh\overline{Bz}$ is produced. This is insoluble in water, soluble in alcohol, ether, chloroform, benzene, and glacial acetic acid; it crystallises in colourless needles melting at 152°. That the substitution takes place in the naphthyl-group is proved by the following facts:—On again treating the substance with the pentachloride, a higher chlorinated derivative is not formed; benzoyldi-β-naphthylamine when treated as above is readily converted into a dichlorinated derivative, whilst benzoyldiphenylamine yields no substitution-derivative with phosphorus pentachloride unless the mixture is heated above 150° (*Ber.*, **15**, 1285). *Benzoyldi-β-naphthylamine*, $(\beta$-$C_{10}H_7)_2N\overline{Bz}$, obtained by heating β-dinaphthylamine with benzoic chloride at 120°, crystallises in white needles and melts at 173°. It yields benzoic acid and a resinous mass on saponification. The dichlorinated derivative, $(\beta$-$C_{10}H_6Cl)_2N\overline{Bz}$, crystallises from alcohol, benzene, and chloroform in small white needles melting at 203°; it also yields benzoic acid on treatment with alkalis.

By the action of phosphorus pentoxide on the β-naphthyl-derivative, water is abstracted and bases produced which belong to the acridine series. *Phenyl-β-naphthacridine*,



$C_{10}H_6\left\langle\begin{matrix}N\text{—}\\|\\CPh\end{matrix}\right\rangle C_{10}H_6$, is obtained by extracting with potash solution the melt from dinaphthylamine (1 part), benzoic acid (1 part), and phosphoric anhydride ($1\frac{1}{2}$—2 parts), the residue being then washed, dried, and sublimed. It forms bright yellow needles melting at 294°; its basic properties are very feeble. The *hydrochloride* crystallises in long golden-red lustrous needles which are decomposed by water or alcohol; the *platinochloride*, $(C_{27}H_{17}N)_2,H_2PtCl_6$, forms yellow needles, and the *chromate* reddish-brown needles. *Phenylbenzo-β-naphthacridine*,  $C_6H_4\langle{}^{N—}_{CPh}\rangle C_{10}H_6$, obtained from β-naphthylphenylamine and benzoic acid, sublimes in almost colourless needles melting at 198°. The *hydrochloride* melts at 235°, and can be crystallised from water or alcohol containing a little free acid; the *platinochloride*, $(C_{23}H_{15}N)_2,H_2PtCl_6$, forms lustrous yellow needles. When the above bases are heated in sealed tubes with methyl iodide, both yield compounds crystallising in red needles. No additive product, however, could be obtained from phenylacridine and benzyl chloride even at 200°, whilst at 210—220° phenylacridine hydrochloride is produced. In conclusion, the authors object to the view held by Bernthsen (*Annalen*, **124**, 1), that the alkyl-derivatives of phenylacridine are quaternary ammonium bases. A. K. M.

Orthonitrosonaphthols. By H. Goldschmidt and H. Schmid (*Ber.*, **17**, 2066—2069).—Goldschmidt has shown (this vol., 735 and 1137) that both β-nitroso-α-naphthol and α-nitroso-β-naphthol are converted by the action of hydroxylamine hydrochloride at 150° into a substance of the formula  $C_{10}H_6\langle{}^{N}_{N}\rangle O$ [1 : 2], that must be regarded as the anhydride of a body derived from naphthalene dihydride by replacement of 4 hydrogen-atoms by 2 isonitroso-groups. The authors have succeeded in isolating this isonitroso-compound by the action of hydroxylamine hydrochloride on both the orthonitrosonaphthols at the temperature of 100°. *Diisonitrosonaphthalene dihydride*, $C_{10}H_8N_2O_2 = C_{10}H_6(NOH)_2$, [1 : 2] crystallises in yellow needles, melts at 149°, but shows signs of decomposition at 140°; is soluble in hot water and benzene. It dissolves in alkalis with reddish-yellow colour, yields a red sodium salt, and an orange-red silver salt. It dissolves in concentrated sulphuric acid with a dark-brown coloration; the compound is reprecipitated on adding water. It is readily converted into the anhydride, $C_{10}H_6N_2O$, by the action of acetic chloride by heating the solution in sulphuric acid, or still more readily by heating the solution in alkalis.

The two orthonitrosonaphthols do not behave alike towards alkaline solutions of hydroxylamine, α-nitroso-β-naphthol giving mainly the anhydride $C_{10}H_6N_2O$, whilst with β-nitroso-α-naphthol little more than a trace of this compound is obtained. A. J. G.

Phenylhydrazine-derivatives of Hydroxynaphthaquinone. By T. Zincke and H. Thelen (*Ber.*, **17**, 1809—1813).—When a cold alcoholic solution of hydroxynaphthaquinone is mixed with a cold, aqueous, alcoholic, or acetic solution of phenylhydrazine, *hydroxynaphthaquinonehydrazine*, $C_{10}H_5(OH)O : N_2HPh$, is formed. It crystallises in glistening orange crystals which are easily soluble in ether, boiling alcohol, or acetic acid, and melts with decomposition at 230°. It forms well characterised compounds with metals, alcohol radicles, and acetyl. The *barium* derivative, prepared by precipitating the ammoniacal solution of the hydrazide with barium chloride, crystallises in brownish-gold scales or long red needles soluble in alcohol: the first-named form is the less stable and usually passes gradually into the needles. Their formula is $(C_{16}H_{11}N_2O_2)_2Ba + 10H_2O$. When dehydrated by heating, it is insoluble in alcohol, but is rendered soluble again by moistening. The *sodium salt* crystallises in small orange needles soluble in alcohol; the *calcium salt* forms orange needles; the *silver salt* a reddish-brown amorphous precipitate which immediately blackens on heating. The other metallic salts are orange or red precipitates, the *lead* and *mercury salts* being insoluble in alcohol. The *acetate*, $C_{10}H_5(O\overline{Ac})O : N_2HPh$, formed by boiling the hydrazide with acetic anhydride, forms long red needles melting at 178—179°, and soluble in alcohol and boiling acetic acid. The *ethyl-derivative*, $C_{10}H_5(OEt)O : N_2HPh$, is formed by treatment of an alcoholic solution of the potassium salt with ethyl bromide, by boiling the free hydrazide with alcohol and sulphuric acid, or by heating it with alcohol and ethyl iodide. It forms orange needles which are easily soluble in boiling alcohol and acetic acid, and melt at 172—173°. The *methyl-derivative* forms small red needles melting at 174—175°. When an alcoholic solution of the hydrazide is boiled with benzaldehyde, a deep-red crystalline compound of the formula

$$[C_{10}H_5(OH)O.N_2Ph]_2CHPh$$

is formed. It is sparingly soluble in the usual solvents, and forms well characterised metallic derivatives, the *potassium* and *sodium* derivatives crystallising in small orange needles soluble in alcohol. When suspended in carbon bisulphide, the hydrazide may be easily brominated, and if equal molecular weights of bromine and the base are used, *monobromohydroxynaphthaquinonehydrazine* is formed: this crystallises in dark-red needles which melt with decomposition at 196—198°, and are easily soluble in boiling acetic acid, sparingly so in alcohol. It forms metallic derivatives, and as it is not decomposed by dilute acids or alkalis the position of the bromine could not be determined. Strong hydrochloric acid decomposes it, but the reaction is of a complex character, dark coloured, amorphous, and uncrystallisable compounds being formed.

As the hydrazide is so easily converted into the ether by boiling with alcohol and sulphuric acid, the same reaction was tried with hydroxynaphthaquinone, when the authors found that here also the formation of the ether took place readily. L. T. T.

Derivatives of Naphthoic Acid. By A. G. Ekstrand (*Ber.*, **17**, 1600—1605).—By the action of fuming nitric acid on α-naphthoic acid, a mixture is obtained from which the author has succeeded in isolating a *dinitro-α-naphthoic acid*, $C_{10}H_5(NO_2)_2.COOH$; this melts at

263—265°, crystallises from alcohol in small prisms or needles, dissolves readily in warm alcohol and glacial acetic acid, sparingly in ether and benzene, slightly also in hot water. On sublimation, it is obtained in yellowish-white needles. The *calcium salt*,

$$[C_{10}H_5(NO_2)_2.COO]_2Ca,3H_2O,$$

crystallises in needles moderately soluble in warm, sparingly in cold water (1 in 138). The *ethyl-derivative*, $C_{10}H_5(NO_2)_2.COOEt$, crystallises from alcohol in slender needles melting at 143°. The dinitronaphthoic acid (or acids) is accompanied by an indifferent substance, which appears to be dinitronaphthalene. It is separable by alcohol into two portions, the more soluble of which melts at 155—160°, and the less soluble at 170°. When β-naphthoic acid is treated in the same way as the α-acid, it yields a mixture of *dinitro-β-naphthoic acids*, but no dinitronaphthalene. By crystallisation from alcohol and mechanical separation of the different forms of crystals, two dinitro-β-naphthoic acids have been isolated. One of these melts at 226°, crystallises in long slender silky needles, and dissolves readily in alcohol, ether, and glacial acetic acid, sparingly in benzene; its *ethyl salt*, $C_{10}H_5(NO_2)_2.COOEt$, melts at 141°, forms long silky needles readily soluble in warm alcohol. The second *dinitro-β-naphthoic acid* melts at 248°, and crystallises in small hard rectangular prisms; it is readily soluble in warm alcohol, glacial acetic acid, and ether, sparingly in benzene; the *calcium salt* forms prismatic needles, moderately soluble in hot water; the *ethyl salt*, $C_{10}H_5(NO_2)_2.COOEt$, forms small hard wedge-shaped crystals melting at 165°, and sparingly soluble in alcohol. *Monochloro-α-naphthonitrile*, $C_{10}H_6Cl.CN$, is obtained by passing chlorine into a solution of α-naphthonitrile in carbon bisulphide to which some iodine has been added. It crystallises from alcohol in needles melting at 145°. On heating it with concentrated hydrochloric acid in a sealed tube, *chloro-α-naphthoic acid*,

$$C_{10}H_6Cl.COOH,$$

is obtained, and crystallises in colourless lustrous needles, readily soluble in alcohol, sparingly in glacial acetic acid and in benzene; this acid is also formed by the action of chlorine, in the presence of iodine, on a solution of α-naphthoic acid in glacial acetic acid. The *calcium salt*, $(C_{10}H_6Cl.COO)_2Ca,2H_2O$, forms colourless needles, soluble in 116 parts water at the ordinary temperature; the *ethyl-derivative*, $C_{10}H_6Cl.COOEt$, crystallises in quadratic plates melting at 42°. *Dichloro-β-naphthoic acid*, $C_{10}H_5Cl_2.COOH$, is prepared by passing chlorine in excess into a solution of β-naphthoic acid in glacial acetic acid containing also iodine; the crystals are separated from the mother-liquor and boiled with alcohol; the residue consisting of dichloronaphthoic acid melts at 291°, is very sparingly soluble in alcohol, and still less soluble in glacial acetic acid; it crystallises in colourless needles. One or more other and more readily soluble chlorine-derivatives are also produced. The *calcium salt*,

$$(C_{10}H_5Cl_2.COO)_2Ca,2\tfrac{1}{2}H_2O,$$

of the above acid forms small prisms, soluble in 3018 parts of water at the ordinary temperature; the *ethyl salt*, $C_{10}H_5Cl_2.COOEt$, crystallises in long needles melting at 66°. A. K. M.

Amides of α- and β-Naphthoic Acids. By T. LEONE (*Gazzetta*, 14, 120—124).—Rakowski (*Ber.*, 5, 318) found that the product insoluble in water, obtained in the saponification of α-cyanonaphthalene with alcoholic potash, is not naphthalene, as Merz and Mulhaüser supposed (*ibid.*, 3, 709), but the amide of α-naphthoic acid, and he gives the melting point as 128°, whilst Hofmann (*Compt. rend.*, 66, 476) gives the melting point of the amide as 207°.* The author having occasion to prepare a large quantity of naphthoic acids determined to clear up the discrepancy.

The α-cyanonaphthalene employed was prepared by distilling an intimate mixture of potassium ferrocyanide and α-naphthalenesulphonate in equal parts; the crude distillate was boiled with alcoholic potash until ammonia ceased to be given off, the alcohol evaporated, and the residue taken up with water. Only a very small portion remained undissolved, and this, when distilled with water, yielded naphthalene, which passed over with the steam, and a residue containing sulphur, but no nitrogen; this substance was proved to be originally present in the crude cyanonaphthalene. If pure α-cyanonaphthalene be used there is no residue if the digestion with alcoholic potash be continued until ammonia is no longer given off; this requires some days. If, however, the action is not continued so far, there is a product formed, insoluble in water, and which, on examination, was found to be the amide of α-naphthoic acid, $C_{10}H_7.CONH_2$. It forms colourless needles which, after being carefully purified, melt at 202°. The author finds that the saponification of the nitrile takes place in two stages; it is first converted into the amide, and this is subsequently decomposed, yielding α-naphthoic acid and ammonia; by stopping the action at the proper time the whole of the nitrile will be found to be transformed into the amide.

This is represented in the equations:—

$$C_{10}H_7.CN + H_2O = C_{10}H_7.CONH_2 \text{ and}$$
$$C_{10}H_7.CONH_2 + KHO = C_{10}H_7.COOK + NH_3 + H_2O.$$

The β-cyanonaphthalene was prepared in like manner to the α-derivative, and the action of alcoholic potash on it is perfectly similar but more rapid. The amide of β-naphthoic acid obtained by stopping the action before saponification is complete, crystallises in plates which melt at 192°, and are soluble in alcohol, ether, benzene, &c. It is in every respect identical with the compound described by Vieth (*Annalen*, 180, 320). C. E. G.

Dinaphthylsulphone. By A. W. HOFMANN (*Ber.*, 17, 1921—1922).—The author has succeeded in isolating the β-dinaphthylsulphone of Stenhouse and Groves from the bye-products obtained in the preparation of naphthalenesulphonic acid; their α-dinaphthylsulphone was also obtained, but only in small quantity. L. T. T.

---

* In *Ber.*, 1, 38, Hofmann gives the melting point as 244°. This appears to be a typographical error, but unfortunately it has been reproduced in most of the text-books.—C. E. G.

Wormseed Oil. By C. HELL and H. STÜRCKE (*Ber.*, **17**, 1970—1975).—The ethereal oil of wormseed, the flower buds of *Artemisia Vahliana*, has been submitted to numerous investigations with varying results; in particular, Kraut and Wahlfors (*Annalen*, **128**, 293) found the chief constituent to be an oil, $C_{10}H_{18}O$, converted by phosphoric anhydride into cynene, $C_{10}H_{16}$, whilst Faust and Homeyer (this Journal, 1875, 371) found the product of the action of phosphoric anhydride to be identical with cymene, thus giving the parent compound the formula $C_{10}H_{16}O$.

The fraction of wormseed oil distilling between 172—175° was rectified over soda; it then boiled constantly at 172·5—173°, and had a very faint yellow colour. By renewed distillation over sodium, it was obtained absolutely colourless, and then boiled at 172·6° (uncorr.), and had a sp. gr. of 0·9255 at 16°. A part of the oil was still further purified by treatment with potassium permanganate, distillation with steam, and rectification over sodium; it boiled at 172·5° (uncorr.), had the sp. gr. 0·9275 at 16°, 0·8981 at 50°, and 0·8553 at 100°. On analysis it gave numbers agreeing with the formula $C_{10}H_{18}O$. Vapour-density determination gave 4·98 and 5·03, calc. for $C_{10}H_{18}O = 5·33$. When heated with phosphoric anhydride, it yielded a small quantity of hydrocarbons boiling between 120—166°, apparently paraffins, cynene, and polymerised cynenes, mainly dicynene. *Cynene*, $C_{10}H_{16}$, is a mobile colourless liquid of aromatic odour, recalling that of oil of lemons; it boils at 174 5° under 731 mm. pressure (uncorr.), has sp. gr. 0·85 at 15°, 0·8238 at 50°, and 0·7851 at 100°. Vapour-density = 4·35, calc. = 4·7. On mixing cynene with concentrated sulphuric acid (slightly fuming) the liquid becomes dark brown, and, especially on heating, sulphurous anhydride is freely evolved; the sulphonic acid formed was found to be *cymenesulphonic acid*, thus explaining the results obtained by Faust and Homeyer.

Dicynene, $C_{20}H_{32}$, is a yellowish oil of pale blue fluorescence. It distils between 328—333°; vapour-density = 9·1 and 9·2 calc. = 9·4.

A. J. G.

Action of the Haloïd Acids on Wormseed Oil. By C. HELL and A. RITTER (*Ber.*, **17**, 1975—1980).—By the action of hydrochloric acid gas at 10—12° on the fraction of wormseed oil distilling between 172° and 173° (see preceding Abstract), a mass of prismatic or tabular crystals is obtained. Analysis confirms the formula, $C_{10}H_{18}O,HCl$, assigned to the compound by Volckel (*Annalen*, **87**, 315). It melts at 30—35°; loses hydrochloric acid on exposure to air, and is decomposed into its components by heating or by treatment with water. At high temperatures, the reaction takes a different course, cynene dihydrochloride being formed with separation of water; the best yield of the hydrochloride is obtained at 40—50°.

Cynene dihydrochloride, $C_{10}H_{18}Cl_2$, crystallises in colourless silky lancet-shaped tables, melts at 50—51°, is soluble in alcohol, ether, chloroform, benzene, light petroleum, and glacial acetic acid. It is stable in air, and is not decomposed by water. It has a camphor-like odour, and volatilises completely at ordinary temperatures. On dry distillation it is decomposed into cynene and hydrochloric acid; it also yields cynene on long boiling with water or aqueous potash. The action of hydrochloric acid on wormseed oil is therefore represented by the equations: $C_{10}H_{18}O + HCl = C_{10}H_{18}Cl.OH$ and $C_{10}H_{18}Cl.OH + HCl = C_{10}H_{18}Cl_2 + H_2O$. The formation of the compound,

$$C_{10}H_{18}Cl.OH,$$

seems to show the absence of a CO-group in wormseed oil, and this is further confirmed by the indifference of the oil towards hydroxylamine; it is very probable that the oxygen is in a state of union similar to that in which it occurs in ethylene oxide. A. J. G.

Camphor. By H. GOLDSCHMIDT and R. ZÜRRER (*Ber.*, **17**, 2069—2073).—Nägeli has shown (Abstr., 1883, 728; this vol., 610 and 1190) that camphor is converted by hydroxylamine into camphoroxime, $C_{10}H_{17}NO$, this, by the action of acetic chloride into an anhydride, $C_{10}H_{15}N$, which, finally by heating with alcoholic potash, is converted into isocamphoroxime. The authors show that the last two compounds are respectively the nitrile and the amide of a new acid, campholenic acid. The anhydride (nitrile), $C_{10}H_{15}N$, like other nitriles, unites with hydroxylamine to form a compound, $C_{10}H_{18}N_2O$, crystallising in white plates and melting at 101°. It is soluble both in acids and in alkalis.

Campholenic acid, $C_9H_{15}.COOH$, is prepared from the nitrile, $C_{10}H_{15}N$, by long boiling with alcoholic potash, &c. It is a colourless oil of a peculiar odour, boils at 254—255°, is insoluble in water, and has marked acid properties. It is isomeric with Montgolfier's camphic acid (Abstr., 1878, 891). The ammonium salt is converted into isocamphoroxime by heating it for some hours at 150°. Isocamphoroxime is converted into the nitrile, $C_{10}H_{15}N$, by distillation with phosphoric sulphide.

In the expectation that carvoxime would behave like camphoroxime, it was treated with acetic chloride, but was found to yield not an anhydride but an acetyl-derivative, $C_{10}H_{14}NO\overline{Ac}$, a yellow oil decomposing on heating. A. J. G.

Sylvic and Pimaric Acids. By C. LIEBERMANN (*Ber.*, **17**, 1884—1887).—Silvic and pimaric acids, when dissolved in acetic anhydride and treated with sulphuric acid, give a very similar colour reaction to quinovic acid, except that the shade is bluer and rather more evanescent.

When treated with hydriodic acid and amorphous phosphorus, these bodies behave in a manner similar to pyroquinovic acid. The hydrocarbon produced is a colourless thick liquid, boiling between 320° and 330°, but always with slight decomposition. In properties, it resembles Deville's colophene (*Annalen*, **37**, 162), produced by the dry distillation of colophonium. The analytical results are very close to those required for colophene, but agree better for the formula $C_{20}H_{34}$. The hydrocarbons obtained from pimaric and sylvic acids are identical in all their properties except their rotatory power. These acids may, therefore, be considered to be derivatives of a terpene.

Kraut has lately obtained a new acid from a Siamese gum-benzoïn, which resembles sylvic and pimaric acids in some respects, but differs from them in composition and melting point, which lies above 100°. With hydriodic acid, it gives a terpene ($C_{10}H_{16}$) which is solid in the cold, and boils above 360°. L. T. T.

Juglone. By A. Bernthsen (*Ber.*, 17, 1945—1947).—*Juglone* or *Nucin* has been studied by Reischauer and Vogel (Abstr., 1878, 233), who assign to it the formula $C_{18}H_{12}O_5$. Their analytical results, and also the author's, agree much better with either $C_{14}H_8O_4$ or $C_{10}H_6O_3$, and the latter would appear to be correct, as juglone is apparently a hydroxynaphthaquinone. It crystallises in long brilliant clear red needles, and melts at 145—147°. On distilling juglone with zinc-dust, it yields naphthalene (?) It resembles the quinones in its behaviour, being converted into a substance of phenol-like nature on reduction with zinc and hydrochloric acid, stannous chloride, or sulphurous acid. This substance is soluble in alkalis, and is then readily reoxidised. Aniline reacts with juglone in a manner similar to its behaviour with ordinary hydroxynaphthaquinone, forming a red substance soluble in alcohol. Juglone crystallises unaltered from dilute nitric acid; acid of sp. gr. 1·15 converts it into a readily soluble acid. Reischauer's analysis of the copper-compound of juglone agrees better with the formula $(C_{10}H_5O_3)_2Cu$ than with $C_{18}H_{10}O_5Cu$, the formula he assigned to it. A. J. G.

Derivatives of Quercetin. By C. Liebermann (*Ber.*, 17, 1680—1684).—It has been shown by Herzig (this vol., p. 846) that quercetin can be converted into a hexamethyl- and hexethyl-quercetin, and these further into diacetyl-derivatives; he concluded, therefore, that quercetin contains eight hydroxyl-groups, and assumed that the acetyl-derivative described by Liebermann and Hamburger (*Ber.*, 12, 1178) is an octacetyl-quercetin, and not a diacetyl-compound as stated by them. The author has repeated his previous experiments, and by decomposing the acetyl-derivative by means of dilute sulphuric acid, and then weighing the recovered quercetin, he obtains results agreeing with the octacetyl-compound, thus confirming Herzig's experiments. The percentage of carbon and hydrogen also agrees better with octacetyl- than with diacetyl-quercetin. The author has also re-examined the compounds previously described as dibromo-quercetin and dibromodiacetyl-quercetin, and finds them to be respectively *tribromo-quercetin*, $C_{24}H_{13}Br_3O_{11}$, and *tribromoctacetyl-quercetin*,

$C_{24}H_5Br_3O_4\overline{Ac}_8$. A. K. M.

An Alcohol from Birdlime. By J. Personne (*Compt. rend.*, 98, 1585—1587).—Birdlime is obtained by the fermentation, under special conditions, of the inner bark of the holly, and is a greenish, viscous, tenacious substance. When dried at 100°, it loses 26—27 per cent. of water, and if the residue is treated with chloroform or light petroleum, about 23 per cent. of vegetable and inorganic matter, consisting mainly of calcium phosphate, remains undissolved. The solution is evaporated to dryness, and the residue heated at 120° for some time to expel the last traces of the solvent.

The purified birdlime thus obtained is an ethereal salt or a mixture of ethereal salts of an alcohol which seems to be homologous with benzylic alcohol. In order to isolate this alcohol, the birdlime is subjected to prolonged treatment with alcoholic potash. An elastic substance resembling caoutchouc, and soluble in chloroform, separates out, and the liquid portion is poured into a large quantity of water. The gelatinous matter which separates is washed with water, treated with acetic acid to remove traces of alkali, again washed with water, dissolved in boiling alcohol of 90°, and purified by filtration through animal charcoal and repeated crystallisation from boiling alcohol.

The alcohol thus obtained crystallises in slender silky needles, insoluble in cold water, but soluble in all proportions in boiling light petroleum, alcohol of 90°, chloroform, and ordinary ether. It is almost insoluble in alcohol of 80°, but its solubility increases with the concentration of the alcohol. It melts at 175°, sublimes at 115° under a pressure of 100 mm., and boils above 350°. Its vapours have no aromatic odour. The new alcohol, which the author calls *ilicic alcohol*, has the composition $C_{25}H_{44}O$. It yields an acetate melting at 204—206°, and exists in the birdlime in combination with one or several acids, which seem to belong to the fatty series. C. H. B.

The Bitter Principle of Hops. By H. BUNGENER (*Bied. Centr.*, 1884, 431).—The author has succeeded in isolating from the lupulin of hops, a crystalline body which is insoluble in water, and possesses all the properties of the acid obtained by Lemers. The lupulin is cleansed from coarser impurities by passing it through a sieve, then digested with light petroleum for 24 hours in a stoppered flask, the dark solution filtered off by the aid of suction, and distilled down until a dark brown liquid remains in the flask; on cooling, this solidifies to a crystalline cake, which after purification by several recrystallisations becomes an almost colourless mass. It melts at 92—93°. It is easily soluble in alcohol, ether, benzene, chloroform, carbon bisulphide, and glacial acetic acid, less so in cold petroleum, and not at all in water. Analysis agrees best with the formula $C_{25}H_{35}O_4$. J. F.

Artificial Production of Diastase. By C. SCHNEIDER (*Bied. Centr.*, 1884, 432).—The diastase formed during the changes which take place in albumin while the seed corn is germinating, has been assigned a formula by some experimentalists, the author thinks incorrectly. He doubts if the soluble ferments which we call diastase have a definite composition, and thinks our knowledge of the substance meagre, and its artificial production a remote possibility. J. F.

Chlorophyll. By A. MAYER (*Bied. Centr.*, 1884, 390—394).—The author names the true chlorophyll corpuscles trophoplasts, and the colourless trophoplasts he names anaplasts, which last comprehends the starch formers of Schimper, and in order to distinguish the morphological relation between the organs, the colouring corpuscles receive the name of chromoplasts, and the chlorophyll that of autoplasts. The anaplasts are found in those plant cells which are in darkness, or in relatively feeble light if the plant is under the influence of direct light; the presence of colourless trophoplasts in the epidermis cells of plants growing in full light leads to the belief that it is here the transformation of the chlorophyll corpuscle takes place, and that it is intimately connected with the amount of light present. There are, however, some unaccountable exceptions: the anaplasts are found abundantly in the cells of the unlighted portion of the plant, both in presence and absence of starch corpuscles. The coloured trophoplasts or chromoplasts exist abundantly in the flower leaves, adding to the attractions which lead to fertilisation by insects. In appearance they are generally round, but often spindle-shaped. There appear to be only two colours, yellow and orange, all the others being formed from them by action on the other constituents of the cell. The author declares the lipochlor of Pringsheim to be non-existent, and the hypochlorin of the same observer to be identical with chlorophlan, but agrees with Pringsheim's view of the structure of the autoplasts. Crystalloïd bodies of a long needle-like spindle form are often found in connection with the anaplasts. Schimper considers these bodies as the actual anaplasts, the author, as being a product of them and starch corpuscles.

The spindle-shaped substances which are found in the chloroplasts are stages in the transformation of the colour-substance (xanthophyll). The condition of these bodies is changeable, the autoplasts increasing by fissure. J. F.

Chlorophyll. By A. F. W. SCHIMPER (*Bied. Centr.*, 1884, 394—396).—The author differs from Mayer in some of his views respecting chlorophyll, particularly as regards the crystalloïd bodies found both in the coloured and colourless corpuscles. According to Meyer they are a reserve of nitrogenous matter obtained from the plastide; Schimper declares them to be that substance itself. J. F.

Action of Alkaline Hypochlorites and Hypobromites on Pyrroline. By G. CIAMICIAN and P. SILBER (*Ber.*, **17**, 1743—1745) —10 grams pyrroline were added slowly with constant agitation to 1 litre of a solution of sodium hypochlorite containing 50 grams of active chlorine. The solution was allowed to remain for some hours, and was then steam-distilled. A mixture of unchanged pyrroline and chlorinated pyrrolines passed over. The residual liquid was acidified with dilute sulphuric acid, and again steam-distilled, when tetrachloropyrroline passed over. The residue from this second distillation was filtered from separated carbon, and then extracted with ether. On evaporating the etheric solution, dichloromaleïc acid is left; this yielded dichloromaleic anhydride on distillation.

When treated with potassium hypobromite, pyrroline yields brominated pyrrolines, together with dibromo-maleïnimide. L. T. T.

Synthesis of Pyrroline-derivatives. II. By L. Knorr (*Ber.*, 17, 1635—1642).—The author previously described the formation of *phenyl-β-imidobutyric acid*, NPh : CMe CH$_2$.COOH, by the condensation of aniline with ethyl acetoacetate (this vol., p. 1198), and this led him to assume the probability of Duisberg's ethyl paramidoacetaocetate (obtained from ammonia and ethyl acetaoacetate), being *ethyl β-imidobutyrate*, NH : CMe.CH$_2$.COOEt. To test this he has examined the action of nitrous acid on the two compounds.

Phenyl-β-imidobutyric acid is converted by nitrous acid into *isonitrosoanilacetone*, NPh : CMe.CH : NOH. This crystallises in splendid white needles, melting at 180°; it dissolves readily in ether and hot alcohol, sparingly in cold alcohol, and is insoluble in water, acids, and alkalis; it is not attacked by boiling hydrochloric acid, and is distinguished from isonitrosoacetone by its insolubility in alkalis. When heated above its melting point, it detonates. When ethyl β-imidobutyrate, prepared according to Duisberg's instructions, is submitted to the action of nitrous acid, ethyl isonitroso-β-imidobutyrate, NH : CMe.C(NOH).COOEt, is obtained, and on reducing this with zinc-dust and acetic acid *ethyl dimethylpyrrolinedicarboxylate*, $C_{12}H_{17}NO_4$, is formed; this melts at 130°, is insoluble in water, acids, and alkalis, moderately soluble in alcohol and ether. On saponification with alcoholic potash, potassium ethyl dimethylpyrrolinedicarboxylate is obtained as the chief product, together with a small quantity of potassium dimethylpyrrolinedicarboxylate. If the saponification be effected at 150—160° in sealed tubes, dimethylpyrroline is obtained. The *monethylic dimethylpyrrolinedicarboxylate* crystallises in slender needles, melting above 200° with evolution of carbonic anhydride; it is insoluble in water, sparingly soluble in cold, moderately in hot alcohol and ether; the lead and silver salts form white amorphous precipitates. *Dimethylpyrrolinecarboxylic acid* crystallises from water or ether in dense lustrous prisms; it is moderately soluble in water and alcohol, less so in ether; it melts at 197°, with violent evolution of carbonic anhydride; its lead and silver salts are crystalline. *Dimethylpyrroline*, C_6H_9N, after purification by distillation in steam, forms a nearly colourless oil, having an odour resembling that of chloroform, is almost insoluble in water, but readily soluble in alcohol and ether; it combines with mercuric chloride, and is converted by acids into a brownish-red resin. It is uncertain whether it is isomeric or identical with the dimethylpyrroline obtained by Weidel and Ciamician from animal tar.

The author finds that on reducing ethyl isonitrosoacetoacetate by means of zinc-dust and acetic acid, a compound is obtained melting at 134°, and strongly resembling ethyl dimethylpyrrolinedicarboxylate. Its composition agrees with the formula $C_{12}H_{16}O_5$, but further experiments are necessary to prove it to be a furfurane-derivative.

A. K. M.

Pyridine-derivatives. By W. Koenigs and R. Geigy (*Ber.*, 17, 1832—1838).—In a former communication (this vol., p. 1195), the authors described the formation of a mixture of di- and tri-chloropyridine by the action of phosphoric chloride at 200° on anhydrous barium pyridinedisulphonate. The dichloropyridine is found chiefly in the aqueous part of the distillate, and is purified by help of its mercuriochloride. *Dichloropyridine*, $C_5H_3NCl_2$, crystallises in silky scales which melt at 66—67°. It is freely soluble in alcohol, moderately so in water. It has slightly basic properties, dissolves readily in hydrochloric acid, and with mercuric chloride forms a compound which crystallises in long needles. It is easily soluble in boiling alcohol, and melts at 183°. The *platinochloride*,

$$(C_5H_3NCl_2)_2,H_2PtCl_6 + 2H_2O,$$

forms yellow needles. The crystalline portion of the distillate from the action of phosphoric chloride consists chiefly of *trichloropyridine*, which melts at 49—50°, and crystallises in long flat needles, easily soluble in boiling alcohol, almost insoluble in water. It has much feebler basic properties than dichloropyridine, and is almost insoluble in hydrochloric acid. It forms a compound with mercuric chloride which melts, with decomposition, at 209°, and is easily soluble in boiling alcohol, insoluble in water. When trichloropyridine is boiled with sodium ethylate, *dichlorethoxypyridine*, $C_5H_2NCl_2.OEt$, is formed; this is volatile in steam, and the crystals melt at 31°. From analogy to the easy replacement of chlorine by ethoxyl in α-chloroquinoline, the authors are inclined to consider that the third chlorine-atom in trichloropyridine occupies the α-position. *Monhydroxydichloropyridine* is obtained by the saponification of the ethoxy-compound with hydrochloric acid at 150°. It forms long lanceolate crystals, melts at 171°, and is easily soluble in boiling water, in alkalis, alkaline carbonates, and acids. It gives no coloration with ferric chloride, but gives a precipitate with silver nitrate. *Dihydroxypyridine*, $C_5H_3N(OH)_2$, is obtained by fusing potassium pyridinedisulphonate with potash. It crystallises from water in long yellow needles, with $\frac{1}{2}H_2O$. The anhydrous compound melts at 255°, and is sparingly soluble in alcohol and the other usual solvents, but dissolves readily in acids and alkalis. An aqueous solution gives an intense brownish-red coloration with ferric chloride, whilst with phosphotungstic acid it yields a yellow precipitate soluble in boiling water. With mercuric and cadmium chlorides, lead acetate, and silver nitrate, it forms white, sparingly soluble compounds. The *hydrochloride*, $C_5H_5NO_2,HCl$, crystallises in yellow needles, easily soluble in alcohol and water. Blackening and decomposition begin at 140°, but the mass only completely melts at 207°. The *neutral sulphate* forms deliquescent plates. Platinic and auric chlorides yield no precipitates. The *sodium salt* produces sparingly soluble precipitates with lead, calcium, barium, and silver salts; the silver salt blackens very quickly. When dihydroxypyridine is heated with zinc-dust, a strong odour of pyridine is produced, but it is scarcely acted on by sodium-amalgam, or by tin and hydrochloric acid.

The mother-liquors from the preparation of barium pyridinedisulphonate were converted into the potassium salt, and this salt, when fused with potash, yielded β-hydroxypyridine, $C_5H_4N.OH$, lately described by O. Fischer and E. Renouf (this vol., p. 1050). This shows that the product of the action of boiling strong sulphuric acid on piperidine contains β-pyridinemonosulphonate, but its presence is probably due to the action of sulphuric acid on pyridine, small quantities of which are produced by the oxidation of some of the piperidine by the sulphuric acid at the high temperature of the reaction, and not by the direct action of the acid on piperidine.

The fusion of the sulphonates should be carried out with potash, as more bye-products are produced when soda is used, and the yield is not so good. L. T. T.

Derivatives of Hydroxypyridine from Pyridinesulphonic Acid. By O. Fischer and E. Renouf (*Ber.*, **17**, 1896—1899).—In a previous communication (this vol , p. 1050), the authors described the above β-hydroxypyridine. The melting point of the pure body is 124·5°. The *platinochloride* yields yellow needles easily soluble in water and alcohol; the *oxalate* soft yellowish needles melting at 175°, and easily soluble in water, sparingly in absolute alcohol: the *picrate* yellow needles, sparingly soluble in alcohol; the *methiodide* yellowish-white needles, easily soluble in water and alcohol, insoluble in ether; the *methochloride* colourless needles, which yield a platinochloride crystallising in orange-coloured needles. *β-Ethoxypyridine*, prepared by the action of ethyl bromide on the potassium-compound of hydroxypyridine, is a colourless oil, which is volatile in steam. It yields a platinochloride crystallising in prisms of melting point 192°. *Acetoxypyridine*, $C_5H_5N.O\overline{Ac}$, is obtained by boiling the hydroxy-compound with acetic anhydride. It is an almost colourless oil, boiling at 210° (uncorr.), and has a pleasant odour. It is easily soluble in acids and water, and the aqueous solution has a neutral reaction. The *hydrochloride* and *platinochloride* are both easily soluble in water and alcohol, the oxalate rather less so. *Dibromoxypyridine* is obtained by treating the hydroxy-compound with bromine-water. It forms soft colourless needles, easily soluble in water and alcohol, sparingly so in benzene. An aqueous solution gives a violet colour with ferric chloride. The *hydrobromide*, *hydrochloride*, *oxalate*, and *picrate*, are sparingly soluble; the *sulphate* and *platinochloride* easily soluble. Tin and hydrochloric acid act very slowly on β-hydroxypyridine, ammonia, and *probably* pyridine being formed; but the latter in such small quantity that the authors have not yet been able to conclusively prove its presence. L. T. T.

Derivatives of Orthhydroxyquinoline. By O. Fischer and E. Renouf (*Ber.*, **17**, 1642—1646).—The azo-compound, $C_{15}H_{11}N_3SO_4$, obtained from diazobenzenesulphonic acid and orthhydroxyquinoline is an orange dye forming magnificent crystalline alkali salts. On reducing the azo-compound with stannous chloride, and subsequently decomposing the yellow tin compound with sulphuretted hydrogen, amidohydroxyquinoline hydrochloride is formed, from which the base may be obtained by adding soda and extracting with ether. *Amidohydroxyquinoline* is somewhat unstable, but yields stable salts; the *sulphate*, $C_9H_8N_2O,H_2SO_4$, forms sparingly soluble silky needles; the *hydrochloride*, $C_9H_8N_2O,2HCl$, is very readily soluble. *Quinolinequinone*, $C_9H_5NO_2$, is prepared by oxidising amidohydroxyquinoline sulphate with chromic mixture, and when purified by crystallisation from benzene or alcohol forms soft flat needles having a peculiar green lustre. It decomposes at 110—120°. Its basic properties are but feeble, its salts being decomposed by water. Quinolinequinone is decomposed by soda, baryta-water, sodium carbonate solution, and even by barium carbonate. The *anilide of quinolinequinone*, $C_{15}H_{10}N_2O_2$, is prepared by boiling an alcoholic solution of the quinone with an excess of aniline. It is very similar to the corresponding naphthaquinone derivative obtained by Zincke (*Ber.*, **12**, 1644); it crystallises in small copper-coloured scales with green lustre, dyes deep copper-red, and yields violet solutions with cold dilute mineral acids; it seems to melt a little above 190°. *Quinolinequinol* is prepared by the action of sulphurous acid on an alcoholic solution of the quinone. It is moderately soluble in water, and crystallises from benzene in slender needles; it yields stable salts, the *sulphate* crystallising in soft orange-yellow needles, sparingly soluble in water, and decomposing when heated to about 220°; the *hydrochloride* forms more readily soluble orange-coloured needles. Ferric chloride converts quinolinequinol into the quinone even in the cold.

With regard to the constitution of the above compounds, it is assumed from their analogy with the corresponding naphthol derivatives, that the side groups occupy similar positions, so that in amidohydroxyquinoline the amido- and hydroxy-groups occupy the para-position in the benzene nucleus. That the substitution occurs only in the benzene nucleus is proved by the oxidation of amidohydroxyquinoline to pyridinedicarboxylic acid.

Parahydroxyquinoline and metahydroxyquinoline also yield orange-coloured azo-dyes, and it is intended to prepare from these the derivatives corresponding with the above. A. K. M.

Diquinoline from Benzidine. By W. Roser (*Ber.*, **17**, 1817—1820).—Employing Skraup's method (Abstr., 1883, 85 and 92), the author heated a mixture of nitrobenzene and benzidine with glycerol and sulphuric acid. Dinitrodiphenyl may be used in place of nitrobenzene, and hydrazobenzene in place of benzidine.

Diquinoline, $C_{18}H_{12}N_2$, thus prepared, crystallises in small yellow plates which melt at 178°, and is easily soluble in boiling water and in benzene; sparingly in alcohol and ether. The *sulphate* crystallises in short needles; the *hydrochloride* in concentrically grouped needles; the *chromate* and *platinochloride* both form sparingly soluble yellow crystalline powders. Fuming nitric acid yields the sparingly soluble *nitrate*, but has no further action on the base even when heated with it. When bromine-water is added to a solution of the hydrochloride a *tetrabromo-addition product*, $C_{18}H_{12}N_2Br_4$, is formed, which on being boiled with water gives up bromine and regenerates diquinoline. A reduction product of diquinoline, obtained by boiling with tin and hydrochloric acid, could not be obtained in a crystalline form. A *disulphonic acid*, $C_{18}H_{10}N_2(SO_3H)_2$, is formed when the base is heated with fuming sulphuric acid at 190°. It is insoluble in water and alcohol, but dissolves in ammonia to form a characteristic *ammonium salt*, which crystallises in glittering, white, sparingly soluble needles. The *potassium* and *sodium salts* are both very sparingly soluble, the latter crystallising with 5 mols. H_2O. The *magnesium salt* is precipitated in the form of small needles when a mixture of solutions of the ammonium salt and of magnesium sulphate is heated. When fused with caustic potash, the disulphonic acid yields a very unstable *dihydroxydiquinoline*, which forms a red colouring matter with diazo-compounds. Diquinoline unites readily with the haloid salts of the alcohol radicles, forming easily crystallisable additive products. The *dimethiodide*, $C_{18}H_{12}N_2(MeI)_2$, forms small yellow crystals which are easily soluble in water, sparingly so in alcohol, and melt with decomposition at 300°; the *diethiodide* forms yellow needles soluble in water and melting with decomposition at 270°; on oxidation with potassium permanganate it yields a red substance of acid properties, which is now under investigation. Weidel's isomeric α-diquinoline (Abstr., 1882, 69) forms only additive products with 1 mol. methyl iodide, &c. The metallic salts of α-diquinoline are very unstable and are decomposed even by water; those of the present compound, on the other hand, are quite stable, so that, although resembling one another in many points (melting point, sulphonic acids, crystalline form, &c.), these two compounds are certainly not identical.

From the method of formation, the conjugation of the two quinoline nuclei in this compound must take place between the benzene-rings, whereas in Weidel's diquinoline it is probable (from analogy with the formation of dipyridine by the action of sodium on pyridine), that the conjugation takes place between the pyridine-rings.

L. T. T.

Formation of Diquinoline by Aid of Heat. By J. Zimmermann and A. Müller (*Ber.*, 17, 1965—1966).—By passing the vapour of quinoline through iron tubes heated to a dull red heat, the authors obtained a diquinoline, $C_{18}H_{12}N_2$, identical with the base described by Japp and Graham (Trans., 1881, 174) as diquinolyline. A. J. G.

Peculiar Method of Formation of Diquinoline. By O. Fischer and H. v. Loo (*Ber.*, 17, 1899—1902).—Orthoquinolinesulphonic acid when subjected to dry distillation yields *β-diquinoline*, identical with that described by Japp and Graham (Trans., 1881, 174), and by Weidel (*Monatsh.*, 2, 501). The yield was 10 per cent. of the sulphonic acid employed. It sublimes in beautiful iridescent scales, and forms a characteristic sulphate, $C_{18}H_{12}N_2,H_2SO_4$. The *hydrochloride* forms hard stellate clusters of needles; the picrate yellow needles sparingly soluble in benzene.

Anaquinolinecarboxylic acid, $C_{10}H_7NO_2$, is obtained by the oxidation of β-diquinoline with chromic acid. It crystallises in tufts of pale yellow needles; melts at 255—257°, and decomposes into quinoline and carbonic anhydride at a few degrees higher. The *platinochloride* has the formula $(C_{10}H_7NO_2)_2,H_2PtCl_6$. The *alkali salts* are easily soluble, the *copper*, *lead*, and *cadmium salts* are amorphous, the *calcium salt* yields silky needles. This acid is therefore different from all the six quinolinecarboxylic acids at present known.

The same diquinoline is also obtained, but in much smaller proportion, by the dry distillation of meta- and para-quinolinesulphonic acids. L. T. T.

Formation of Quinaldine. By G. SCHULTZ (*Ber.*, **17**, 1965).—The author considers Dobner and Miller to be in error in supposing the solid bases obtained by them (*Ber.*, **17**, 1698) as bye-products in their method of preparing quinaldine, to be intermediate products in the formation of quinaldine, inasmuch as that they are not converted into quinaldine by boiling with hydrochloric acids. A. J. G.

Quinaldine Bases. By O. DOEBNER and W. v. MILLER (*Ber.*, **17**, 1698—1712).—In a previous paper (this vol., p. 183), the authors mentioned the formation of secondary products in the preparation of quinaldine; these are principally ethylaniline, boiling at 205°, and tetrahydroquinaldine, boiling at 246—248°. If aniline, paraldehyde and hydrochloric acid are allowed to react in the cold, very little quinaldine is produced, a mixture of amorphous bases being obtained which yields quinaldine when heated. The same product is obtained on warming an *aqueous* solution of aniline, paraldehyde, and hydrochloric acid.

Nitro-derivatives of quinaldine are prepared by dissolving quinaldine (100 grams) in the equivalent quantity of nitric acid, and adding the solution to a mixture of sulphuric (600 grams) and fuming nitric acids (600 grams). The product contains ortho- and metanitroquinaldine. *Orthonitroquinaldine*, $C_{10}H_8N.NO_2$, crystallises from dilute alcohol in long needles, melting at 137°; it dissolves readily in alcohol, ether, and benzene, sparingly in cold but more readily in hot water. The *hydrochloride*, $C_{10}H_8N_2O_2,HCl$, crystallises in large vitreous prisms which are decomposed by water with separation of the base; the *platinochloride*, $(C_{10}H_8N_2O_2)_2,H_2PtCl_6$, crystallises from hot concentrated hydrochloric acid in small needles. *Orthamidoquinaldine*, $C_{10}H_{10}N_2$, melts at 56°, is sparingly soluble in water, very readily in alcohol, ether, and hot light petroleum, and crystallises from the latter in long prisms; the *hydrochloride*, $C_{10}H_{10}N_2,HCl$, crystallises from alcohol in golden-yellow needles; the platinochloride is obtained as a yellow precipitate, which is decomposed on standing, more rapidly on warming. *Metanitroquinaldine*, $C_{10}H_8N_2O_2$, is much more readily soluble in dilute alcohol than the ortho-derivative, and crystallises in long slender needles melting at 82°; it is sparingly soluble in water, readily in ether and in acids. The *hydrochloride*, $C_{10}H_8N_2O_2,HCl$, crystallises in prisms, and dissolves readily in water without decomposition; the *platinochloride*, $(C_{10}H_8N_2O_2)_2,H_2PtCl_6$, crystallises in nodules or in needles. *Metamidoquinaldine*, $C_{10}H_8N.NH_2$, is readily soluble in hot water, alcohol, and benzene, sparingly in ether, more readily in light petroleum; the dry base has a greenish lustre, the ethereal solution a bluish-green fluorescence. It crystallises from water with 1 mol. H_2O, which it loses at 100°, and when anhydrous it melts at 104—105°. The hydrochloride, $C_{10}H_{10}N_2,HCl$, crystallises from alcohol in red curved needles, soluble in water with yellowish-red coloration.

By the action of fuming sulphuric acid on quinaldine, three sulphonic acids are produced, all of which probably contain the sulphonic group in the benzene nucleus. The chief product is named by the authors *β-quinaldinesulphonic acid*, $C_{10}H_8N,SO_3H$; it is sparingly soluble in cold, more readily in hot water, and crystallises in monoclinic prisms. The barium and silver salts are sparingly soluble, the sodium and potassium salts readily soluble. The other two acids are *ortho-* and *para-quinaldinesulphonic acids.* The *ortho-* acid is more readily soluble in cold water than the β-acid, and is readily soluble in hot water; it crystallises in long, flat, triclinic prisms. When fused with potash, it yields orthhydroxyquinaldine, melting at 74°. *Paraquinaldinesulphonic acid* is distinguished from its isomerides by its greater solubility in water. It is much more advantageously prepared by heating sulphanilic acid (100 grams), with paraldehyde (80 grams), and hydrochloric acid (100 grams). It forms small monoclinic crystals, and yields parahydroxyquinaldine, melting at 213°, on fusion with potash.

Orthohydroxyquinaldine, $OH.C_6H_3<\begin{matrix}N:CMe\\CH:CH\end{matrix}>$, may also be obtained by heating orthamidophenol hydrochloride (200 grams) with paraldehyde (200 grams) and crude concentrated hydrochloric acid (150 grams); the product is diluted with water, filtered, saturated with sodium carbonate, and steam-distilled. It crystallises from dilute alcohol in colourless prisms, melts at 74°, and boils at 266—267°; it is sparingly soluble in water, readily in benzene, ether, and hot alcohol. It forms salts with bases and with acids, but is insoluble in alkaline carbonates; the hydrochloride, nitrate, and sulphate are readily soluble; the *platinochloride,* $(C_{10}H_9NO)_2,H_2PtCl_6 + 2H_2O$, crystallises in clusters of yellow needles, sparingly soluble in cold water.

Tetrahydrorthohydroxyquinaldine, $C_{10}H_{12}N.OH$, obtained by the action of tin and hydrochloric acid on hydroxyquinaldine, is a liquid boiling at 278—282°. Benzoic and acetic chlorides react energetically with orthohydroxyquinaldine, yielding benzoic and acetic derivatives. The *methyl-derivative,* $C_{10}H_8N.OMe$, may be obtained from methyl iodide and hydroxyquinaldine, but more advantageously by heating a mixture of orthanisidine (2 parts), hydrochloric acid (4 parts), and paraldehyde (3 parts). It melts at 125°, boils at 282°, is sparingly soluble in water, readily in alcohol, ether, and hot benzene. The hydrochloride, sulphate, and nitrate are readily soluble; the chromate crystallises in long orange-red needles, sparingly soluble in cold water; the *platinochloride,* $(C_{11}H_{11}NO)_2,H_2PtCl_6$, forms sparingly soluble yellow needles. *Tetrahydrorthomethoxyquinaldine,* $C_{10}H_{12}N.OMe$, boils at 270°, is sparingly soluble in water, readily in alcohol and ether; its salts give a magenta coloration with ferric chloride; a nitroso-derivative can be obtained. The hydrochloride, $C_{10}H_{12}N.OMe,HCl$, is readily soluble in water, and sublimes at about 150° in stellate crystals. On heating the hydro-base with methyl iodide at 100°, the tertiary base, $C_{10}H_{11}MeN.OMe$, is produced; this boils at 260—262°, yields a soluble hydrochloride, and furnishes a green dye when heated with benzotrichloride and zinc chloride. The *platinochloride,* $(C_{12}H_{17}NO)_2,H_2PtCl_6$, forms stellate clusters of yellow needles.

Parahydroxyquinaldine may be obtained, in the same way as the isomeric ortho-compound, from paraquinaldinesulphonic acid, and from paramidophenol, aldehyde, and hydrochloric acid. It is not volatile in steam, but may be distilled with very slight decomposition;

it forms spear-shaped crystals, melts at 213°, dissolves very sparingly in cold water, readily in alcohol and ether, and is also soluble in acids and alkalis. The *platinochloride*, $(C_{10}H_9NO)_2,H_2PtCl_6 + 2H_2O$, forms stellate clusters of yellow needles. *β-Hydroxyquinaldine*, $C_{10}H_8N.OH$, obtained from β-quinaldinesulphonic acid, crystallises in colourless silvery scales, softens at about 220°, melts at 232—234°, and can be distilled with slight decomposition; it is almost insoluble in boiling water, sparingly in cold but more readily in hot alcohol, readily in ether. The sulphate and *hydrochloride*, $C_{10}H_9NO,HCl + 2H_2O$, crystallises in long lemon-yellow needles, sparingly soluble in cold water; the *platinochloride*, $(C_{10}H_9NO)_2,H_2PtCl_6 + 2H_2O$, also forms yellow needles. β-Hydroxyquinaldine is soluble in dilute alkalis, but insoluble in alkaline carbonates; it is distinct from the γ-compound obtained by Knorr (this vol., p. 335), and probably contains the hydroxyl-group in the meta-position.

Trimethylquinaldine, $C_{10}H_6NMe_3$, prepared from crystallised cumidine (Abstr., 1883, 324), paraldehyde and hydrochloric acid, is an oil boiling at 297—300°, and solidifying at 20°; it is insoluble in water, readily soluble in alcohol and ether. The *chromate*, $(C_{13}H_{15}N)_2,H_2Cr_2O_7$, crystallises in long golden-yellow needles. *α-Naphthaquinaldine*,  $C_{10}H_6<\begin{matrix}N:CMe\\CH:CH\end{matrix}>$, is prepared by heating α-naphthylamine (1 part), with paraldehyde (1 part), and hydrochloric acid (2 parts), at 100—110°. It is a heavy liquid, boiling above 300°; the hydrochloride, nitrate, and sulphate are readily soluble in water, and in very dilute solution exhibit blue fluorescence. The *platinochloride*, $(C_{14}H_{11}N)_2,H_2PtCl_6 + 2H_2O$, crystallises in concentrically grouped needles; the *chromate*, $(C_{14}H_{11}N)_2,H_2Cr_2O_7$, forms yellow crystals. *β-Naphthaquinaldine* forms large colourless needles, melts at 82°, and boils above 300°; it dissolves sparingly in water, readily in alcohol and ether. The *platinochloride*, $(C_{14}H_{11}N)_2,H_2PtCl_6 + 2H_2O$, and the *chromate*, $(C_{14}H_{11}N)_2,H_2Cr_2O_7$, both form yellow sparingly soluble needles.
A. K. M.

Homologues of Quinaldine. By O. DOEBNER and W. v. MILLER (*Ber.*, **17**, 1712—1721).—The method previously given for the preparation of quinaldine (this vol., p. 183) may be employed for the production of its homologues, provided the aldehydes used contain primary alcohol radicals, that is, $CH_2R.CHO$. From propaldehyde, aniline, and hydrochloric acid, a base, $C_{12}H_{13}N$, is obtained which melts at 56°, boils at 268—269° (bar. = 711 mm.), and has the characteristic odour of quinaldine; it is sparingly soluble in water, readily in alcohol, benzene, and ether, and crystallises from the last solvent in large well-formed monoclinic prisms. The sulphate and hydrochloride crystallise from alcohol in small prisms extremely soluble in water. The *platinochloride*, $(C_{12}H_{13}N)_2,H_2PtCl_6$, crystallises in bright-yellow needles, the *picrate*, $C_{12}H_{13}N,C_6H_3N_3O_7$, in yellow crystals, and the *chromate*, $(C_{12}H_{13}N)_2,H_2Cr_2O_7$, in small yellowish-brown prisms. The *methiodide*, $C_{12}H_{13}N,MeI$, forms lemon-yellow needles very readily soluble in hot water or hot alcohol, but insoluble in ether; it melts at 196° with partial decomposition. On oxidising the base $C_{12}H_{13}N$ with chromic acid dissolved in sulphuric acid, an acid, $C_{11}H_9NO_2$, is formed melting at 140° and yielding a sparingly soluble *copper salt*, $(C_{11}H_8NO_2)_2Cu$. When heated with soda-lime, this acid furnishes a methylquinoline boiling at about 250° (*i.e.*, higher than quinaldine) and the *platinochloride* of which crystallises in orange-yellow needles of the composition $(C_{10}H_9N)_2,H_2PtCl_6 + 2H_2O$. This is no doubt β-methylquinoline, $C_6H_4<\begin{matrix}-N:CH-\\CH:CMe\end{matrix}>$, and therefore the acid must be regarded as a *methylquinolinecarboxylic acid*, and the base $C_{12}H_{13}N$ as an *ethylmethylquinoline*. The formation of the latter from propaldehyde being analogous to that of quinaldine from acetaldehyde, it is extremely probable that an intermediate product, ethylmethylacroleïn, CHEt : CMe.COH, is first formed, and then unites with aniline to form *α-ethyl-β-methylquinoline*, $C_6H_4<\begin{matrix}-N:CEt-\\CH:CMe\end{matrix}>$. The constitution of the acid $C_{11}H_9NO_2$ must then be $C_6H_4<\begin{matrix}-N:C(COOH)\\-CH:CMe-\end{matrix}>$. The reduction of ethylmethylquinoline takes place less readily than is the case with quinaldine; the *hydrogenated base*, $C_{12}H_{17}N$, obtained is a colourless liquid of agreeable odour, boiling at 260—262°; it gives a red coloration with ferric chloride, and combines with nitrous acid to a yellowish-red nitroso-compound. The platinochloride is a bright yellow crystalline precipitate; the hydrochloride is sparingly soluble (distinction from ethylmethylquinoline), and crystallises in tufts of needles. *Propylaniline*, NHPhPr, and the above hydrobase are obtained as secondary products in the preparation of ethylmethylquinoline. Propylaniline boils at 214—216°, and yields a crystalline nitroso-derivative, the platinochloride of which crystallises in long concentric prisms. *Propylethylquinoline*, $C_{14}H_{17}N$, obtained from normal butaldehyde, aniline, and hydrochloric acid, boils at 290° and yields a crystalline picrate. *Butylpropylquinoline*, $C_{16}H_{21}N$, prepared from isovaleraldehyde, $CHMe_2.CH_2.CHO$, and aniline, forms a bright yellow oil, boils at 293—294°, and yields crystalline salts; the *nitrate* is almost insoluble in cold water, the *hydrochloride* and *sulphate* are readily soluble; the *platinochloride*, $(C_{16}H_{21}N)_2,H_2PtCl_6$, forms sparingly soluble yellow prisms, and the picrate, $C_{16}H_{21}N,C_6H_3N_3O_7$, large yellow plates. *Hexylamylquinoline*, $C_{20}H_{29}N$, obtained from œnanthaldehyde and aniline, is a colourless oil boiling between 320° and 360°. It is not dissolved by concentrated hydrochloric acid, but is soluble in concentrated sulphuric and nitric acids, the addition of water, however, reprecipitates it from these solutions. The sulphate separates from its alcoholic solution in needles or wart-like crystals; the *picrate*, $C_{20}H_{29}N,C_6H_2(NO_2)_3.OH$, crystallises in yellow needles, sparingly soluble in water and cold alcohol; the *platinochloride*, $(C_{20}H_{29}N)_2,H_2PtCl_6$, forms large yellow plates. The *hydrogenated base*, $C_{20}H_{33}N$, is obtained as a secondary product; it yields no crystalline picrate and no platinochloride.

The resemblance which the above bases show in their chemical behaviour indicates that they have a similar constitution, their general formula being accordingly $C_6H_4<\begin{matrix}N:C(CH_2R)\\-CH:CR-\end{matrix}>$. A table is appended showing the formulæ 1, of the aldehydes experimented on; 2, of the hypothetical intermediate alkylacroleïns; and 3, of the quinaldine-bases formed from them. A. K. M.

Constitution of Quinizine-derivatives (III). By L. Knorr (*Ber.*, **17**, 2032—2049).—The author applies the term quinizine-derivatives to a new class of compounds derived from a hypothetical base, *quinizine*, of the formula  , of which the first representative methyloxyquinizine formed by condensation from phenylhydrazine and ethyl acetoacetate, has been already described (this vol., pp. 302, 1153); the formula  then assigned to it is further confirmed by the following considerations. The formation of this body occurs in two stages. The intermediate compound, ethyl phenylhydrazineacetoacetate, formed in the cold with elimination of water, must be represented by either one of the formulæ

$$<\begin{matrix}NPh\\NH\end{matrix}>CMe.CH_2.COOEt;\quad NHPh.N:CMe.CH_2.COOEt.$$

The dimethyloxyquinizine formed by replacing the hydrogen-atom attached to nitrogen by methyl does not yield methylaniline when decomposed either by heating with hydrochloric acid at 200° or by distillation with zinc-dust. Secondary hydrazines do not yield the corresponding alkyl quinizines by condensation with ethyl acetoacetate. These facts render the second formula improbable. In the second stage of the reaction, at 100°, ethyl phenylhydrazinacetoacetate suffers further condensation with elimination of alcohol; without doubt, here the ethoxy-group combines with a hydrogen-atom from the benzene-ring, and not with one from the neighbouring methylene-group, it being found in methyloxyquinoline that the latter must remain intact, as the isonitrosomethyloxyquinoline obtained by the action of nitrous acid on the base is identical with that obtained by direct condensation from phenylhydrazine and ethyl isonitrosoacetoacetate. The chemical behaviour of methyloxyquinoline is in complete accordance with this formula. It is at once acid and base, the acid properties disappearing on substitution of alcohol radicles for the hydrogen of the imido-group. The methylene-group is no longer capable of having its hydrogen replaced by metals, but otherwise shows the greatest resemblance in behaviour to that possessed by it in acetoacetates.

Dimethyloxyquinizine (antipyrine).

$$C_9H_6N(\colon NMe).MeO\ [NMe : Me : O = 1', 2' : 2' : 4'].^*$$

This compound has been already shortly described (*loc. cit.*). It is distinguished from its isomerides by containing the second methyl in the imido-group. Under the name of antipyrine it is now used extensively in Germany as a febrifuge.

Isonitrosoantipyrine, $C_{11}H_{11}N_3O_2$, is prepared by the action of nitrous acid on a solution of antipyrine. It forms green crystals, explodes when heated at 200°, is insoluble in water and dilute acids, soluble in alkalis and acetic acid, moderately soluble in alcohol, sparingly soluble in chloroform and ether. By reduction with zinc and acetic acid, it is converted into an oily base that has not been further investigated.

Nitroantipyrine, $C_{11}H_{11}N_2O.NO_2$ $[NO_2 = 3']$, is obtained by gently heating a solution of antipyrine in concentrated nitric acid or by the action of nitric acid on isonitrosoantipyrine. It crystallises in white needles, melts at 270—280°, is insoluble in water and alkalis, sparingly soluble in strong nitric and hydrochloric acids, from which it is reprecipitated unchanged on addition of water.

Benzylidineantipyrine is obtained as hydrochloride by the action of concentrated hydrochloric acid on a solution of antipyrine in benzaldehyde. It has the formula $C_{29}H_{28}N_4O_2 = CHPh(C_{11}H_{11}N_2O)_2$, the benzylidine being most likely united to the antipyrine-groups at the [3′] positions as the compound does not react with nitrous acid. The free base forms lustrous crystals and melts at 201°. The hydrochloride crystallises in long, interlaced, silky needles.

By heating antipyrine with hydrochloric acid at 200°, it suffers complete decomposition, yielding, amongst other products, much aniline and small quantities of methylamine. By distillation with zinc-dust, antipyrine yields benzene, aniline, a base boiling at 86—87° (still under investigation), and other products.

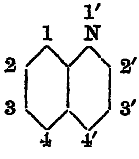
Isonitrosomethyloxyquinizine,

$$C_9H_4N(\colon NH)Me(NOH)O\ [= 1', 2' : 2' : 3' : 4'],$$

is obtained by the action of nitrous acid on methyloxyquinizine or by direct condensation from phenylhydrazine and ethyl isonitrosoacetoacetate. It crystallises in orange-yellow needles, melts at 137°,

---

[*] In the notation of the quinoline series, 1 . 2 . 3 . 4 refer to the positions in the benzene-ring, and 1′ . 2′ . 3′ . 4′ to the corresponding positions in the basic ring containing the nitrogen, where N = 1′, as shown in the annexed symbol:—



In the quinizines where the $\colon$ NH or other similar group is united to both 1′ and 2′, the constitutional formula is written $\colon NH = 1', 2'$, &c.—C. E. G.

slowly sublimes below 100°, and is decomposed when heated above the melting point. It is sparingly soluble in water and acids, readily in hot glacial acetic acid and alcohol, moderately in ether. It is a strong acid, dissolves in alkalis with yellowish-red coloration, and yields a yellow crystalline sodium salt.

Isonitrosomethyldioxyquinizine,

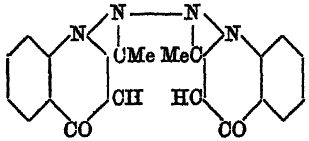
$$C_9H_4(:NOH)Me(NOH)O\ [= 1', 2' : 2' : 3' : 4'],$$

is prepared by mixing an alkaline solution of methyloxyquinizine with excess of sodium nitrite and pouring the mixture into dilute sulphuric acid. It crystallises in brilliant prisms, melts at 135°, is soluble in alcohol and ether, insoluble in acids, soluble in alkalis to a yellow liquid. Nitric acid readily converts both this and the preceding compound into a blue compound, most probably identical with diquinizine-blue.

By the action of nitric acid on methyloxyquinizine, an oil can be obtained which is probably methyldioxyquinizine; it is very readily oxidised to di-quinizine-blue, and is converted into nitrosomethyldioxyquinizine by the action of nitrous acid. It could not be obtained in a pure state.

Di-methyloxyquinizine, $C_{20}H_{18}N_4O_2$, is formed by heating a mixture of methyloxyquinizine and phenylhydrazine to boiling. As it is also formed by condensation from ethyl diacetosuccinate and phenylhydrazine (p. 1382), it must be regarded as formed by the union of 2 mols. of methyloxyquinizine with elimination of 2 atoms of hydrogen, the position of union being [3′ : 3′]. It crystallises in rhombic forms, is insoluble in nearly all solvents, except alkalis, and has both acid and basic properties. Heated with methyl iodide and methyl alcohol, it yields *diantipyrine*, $C_{22}H_{22}N_4O_2$, melting at 250°. The corresponding ethyl compound, $C_{21}H_{26}N_4O_2$, melts at 240—250°. These bases are distinguished from antipyrine by their sparing solubility in water.

Diquinizine-blue, $C_{20}H_{16}N_4O_2$, is obtained as already mentioned by oxidation of many of the quinizine-derivatives: it is best prepared by mixing di-methyloxyquinizine in alkaline solution, with excess of sodium nitrite solution, and pouring the mixture into dilute sulphuric acid, when it separates in flocks which can be crystallised from chloroform. It forms blue needles, is insoluble in water, dilute acids, and dilute alkalis, sparingly soluble in alcohol and ether. It dissolves in chloroform and concentrated sulphuric acid, the solutions having an indigo-blue colour, and giving a spectrum similar to that of indigo. It does not dye fibres. It is decomposed on boiling it with strong alkali or acids, and is decolorised by chlorine and nitric acid. Reducing agents convert it into di-methyloxyquinizine. The author assigns to it the constitution



A. J. G.

Action of Substituted Acetoacetates on Phenylhydrazine.

By L. KNORR and A. BLANK (*Ber.*, **17**, 2049—2052).—These quinizine-derivatives are prepared in similar manner to that described for methyloxyquinizine (this vol., p. 302).

2′. 3′-*Dimethyloxyquinizine*, $C_9H_5N(:NH)Me_2O$ [Me : Me = 2′ : 3′], prepared from phenylhydrazine and ethylic methylacetoacetate, forms a crystalline powder and melts at 127—132°. It is isomeric with antipyrene. Heated with methyl iodide and methyl alcohol, it yields a base melting at 84°, and analogous to antipyrine. A diquinizine is not formed by heating it with excess of phenylhydrazine. Oxidising agents, best nitrous acid, convert it into *azodimethyloxyquinizine*, $C_9H_5NMe_2O:N—N:C_9H_5NMe_2O$, which crystallises in long needles, melts at 164°, is soluble in alcohol and glacial acetic acid, insoluble in water, acids, and alkalis.

2′. 3′-*Methylethyloxyquinizine*, $C_9H_5N(:NH)MeEtO$, prepared from phenylhydrazine and ethylic ethylacetoacetate, crystallises in needles with 1 mol. H_2O, melts when anhydrous at 108°, is readily soluble in chloroform, alcohol, benzene, and hot water, less soluble in ether and light petroleum. By the action of oxidising agents, it is converted into azoethylmethyloxyquinizine, $C_{24}H_{26}N_2O_4$, melting at 160°.

The action of ethylic acetosuccinate on phenylhydrazine unassisted by heat gives rise to *ethylic phenylizinacetosuccinate*, $C_{16}N_{22}N_2O_4$ (m. p. 80°), which by heating at 150° is converted into alcohol and *ethylic methyloxyquinizinacetate*, $C_{14}H_{16}N_2O_3$, forming crystals melting at 138°. It is saponified by heating with sulphuric acid, and yields the free acid. *Methyloxyquinizinacetic acid*,

$$C_9H_5N(:NH)Me(CH_2.COOH)O \; [1', 2' : 2' : 3' : 4'],$$

thus obtained, crystallises in needles, and melts at 178°.

A. J. G.

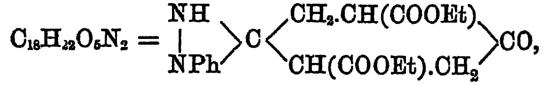
Action of Ethylic Succinosuccinate on Phenylhydrazine.

By L. KNORR and C. BÜLOW (*Ber.*, **17**, 2053—2057).—Knorr has described (this vol., p. 1154) a yellow substance of the formula

$$C_{20}H_{16}N_4O_2,$$

diquinizinhydrobenzene, which forms the main product of the action of ethylic succinosuccinate on phenylhydrazine. By working under varied conditions, the authors have now succeeded in obtaining by this reaction nearly all the substances whose formation could be theoretically predicted.

Ethylic phenylizinsuccinosuccinate,

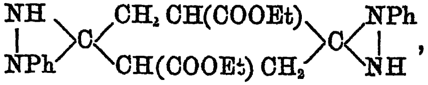


$$C_{18}H_{22}O_5N_2 = \left.\begin{matrix} NH \\ | \\ NPh \end{matrix}\right\rangle C \left\langle\begin{matrix} CH_2.CH(COOEt) \\ CH(COOEt).CH_2 \end{matrix}\right\rangle CO,$$

is prepared by heating on the water-bath an excess of ethylic succinosuccinate with Fischer's phenylhydrazine reagent. It is only formed in small quantity, diquinizinehydrobenzene being the main product. It crystallises in interlaced needles, melts at 159—160°, is soluble in alcohol, insoluble in water, and has basic properties.

Ethylic diphenylizinsuccinosuccinate,

$C_{24}H_{28}N_4O_4$ =

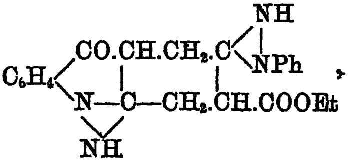


$$\begin{matrix}NH\\|\\NPh\end{matrix}\!>\!C\!<\!\begin{matrix}CH_2\,CH(COOEt)\\CH(COOEt)\,CH_2\end{matrix}\!>\!C\!<\!\begin{matrix}NPh\\|\\NH\end{matrix},$$

is obtained amongst other products by heating for some hours a solution of phenylhydrazine (2 eq.) with ethylic succinosuccinate (1 eq.) in presence of acetic acid. It forms a yellow crystalline powder, melts at 205—206°, gives off a green vapour on heating, and dissolves in acids with a beautiful carmine-red coloration. It is decomposed by boiling with strong acids, without separation of phenylhydrazine, and does not yield a colouring matter on treatment with nitrous acid.

Ethylic phenylizinquinizinhydrobenzenecarboxylate,

$C_{22}H_{22}N_4O_3$ =

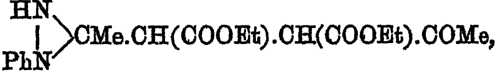


is formed at the same time as the last substance, and can be separated by boiling with toluene, in which it is soluble. It crystallises in yellow needles, melts at 211—212°, is insoluble in water and alcohol, soluble in alkalis with yellow coloration, in acids with pale-rose coloration. By oxidation with nitrous acid or exposure to air its acid solution acquires an emerald-green tint, which by further oxidation turns dirty green. It gives off a green vapour when heated.

Dimethyldiquinizinhydrobenzene, $C_{22}H_{25}N_4O_2$, prepared by heating the sodium salt with methyl iodide, crystallises in yellowish needles, is soluble in chloroform and toluene, the solutions showing a fluorescence resembling that of uranium glass; it is but sparingly soluble or insoluble in most other solvents. The corresponding diethyl-compound resembles the foregoing in both preparation and properties.

By the action of nitrous acid on an alkaline solution of diquinizinhydrobenzene, a blue colouring matter of the formula $C_{20}H_{14}N_4O_2$ is obtained; when heated, it gives off purple-red vapours, and in part sublimes undecomposed. The same vapours and sublimate are obtained by heating diquinizinhydrobenzene. A. J. G.

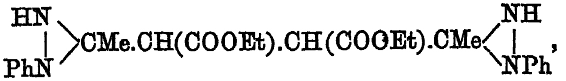
Action of Ethylic Diacetosuccinate on Phenylhydrazine. By L. KNORR and C. BÜLOW (*Ber.*, 17, 2057—2060).—*Ethyl phenylizindiacetosuccinate,*



$$\begin{matrix}HN\\|\\PhN\end{matrix}\!>\!CMe.CH(COOEt).CH(COOEt).COMe,$$

is obtained by heating equal parts of phenylhydrazine and ethyl diacetosuccinate at 180°, and is separated from the di-methyloxyquinizine formed at the same time by boiling with alcohol, in which the latter is insoluble. It forms large crystals, melts at 91°, is insoluble in alcohol, light petroleum, and glacial acetic acid, and insoluble in water.

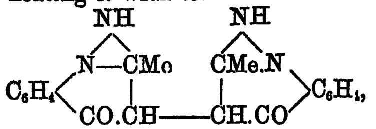
Ethyl diphenylizindiacetosuccinate,



$$\left.\begin{array}{l}\mathrm{HN}\\ \mid\\ \mathrm{PhN}\end{array}\right\rangle \mathrm{CMe.CH(COOEt).CH(COOEt).CMe}\left\langle\begin{array}{l}\mathrm{NH}\\ \mid\\ \mathrm{NPh}\end{array}\right.,$$

is best prepared by heating equal parts of phenylhydrazine and ethyl diacetosuccinate on the water-bath. It crystallises in lance-like forms, is insoluble in water, alcohol, acids, and alkalis, and is converted into di-methyloxyquinizine by heating it with toluene at 180°.

Di-methyloxyquinizine,



obtained as above mentioned, is identical with the di-methyloxyquinizine prepared by heating methyloxyquinizine with phenylhydrazine (p. 1379). A solution of the sodium salt gives white precipitates with silver, lead, mercury, and nickel salts, a deep-blue precipitate with copper salts, a brownish-red precipitate with uranium salts, a blackish-brown precipitate with ferric salts, and a steel-blue precipitate with ferrous salts. A. J. G.

Cystine and Cysteïne. By E. Baumann (*Zeit. Physiol. Chem.*, 8, 299—305).—If tinfoil is added to a hydrochloric acid solution of cystine, there is at first no disengagement of gas, the lævorotatory power also gradually diminishes until it reaches a point where no further change takes place. Only a minimal quantity of sulphuretted hydrogen is formed, which is not in accordance with the statements of Dewar and Gamgee. The hydrochloride of the new base cysteïne is obtained by evaporating the filtrate, after removal of the tin by sulphuretted hydrogen. The base itself can be best prepared by carefully neutralising the alcoholic solution of the hydrochloride, washing with alcohol, and drying in a vacuum. It differs from cystine, being soluble in water, ammonia, acetic and mineral acids, and forms a fine indigo-blue colour with ferric chloride, which rapidly vanishes, cystine being precipitated; this is also true of the hydrochloride, although the colour is much weaker. When treated with potash, it furnishes the same decomposition-products as cystine, and is also very readily oxidised, cystine being the product formed. The author has assigned to it the formula $C_3H_7NSO_2$; cystine being $C_6H_{12}N_2S_2O_4$.

Concentrated hydriodic acid fails to form thiolactic acid as expected, by the displacement of NH_2 by H. J. P. L.

Cinchona Alkaloïds. By W. J. Comstock and W. Königs (*Ber.*, 17, 1984—1996).—In earlier communications (Abstr., 1880, 673, 1882, 224), Königs has shown that cinchonine when treated with phosphoric chloride and oxychloride is converted into cinchonine chloride, from which by boiling with alcoholic potash a nonoxygenated base, cinchine, $C_{19}H_{20}N_4$, is obtained; and that this when heated with concentrated hydrochloric acid at 220—230° is converted into apocinchine, $C_{18}H_{17}NO$, with separation of methyl chloride and ammonia.

Cinchonidine chloride, $C_{19}H_{21}N_2OCl$, is prepared by the action of phosphoric chloride and oxychloride on cinchonidine hydrochloride; it crystallises well, and melts at 108—109°. Heated with alcoholic potash it yields cinchine.

Quinine chloride, $C_{20}H_{23}N_2OCl$, is prepared by dissolving quinine hydrochloride (3 parts) in chloroform, and adding the liquid to finely powdered phosphoric chloride covered with chloroform; the mixture is heated for some time, then cooled in water, the chloroform decanted off, and the aqueous solution precipitated with ammonia. The base may be crystallised by adding ether to its solution in benzene; it forms colourless crystals, melts at 151°, and gives a green coloration with chlorine-water and ammonia, the coloration being much less intense than that obtained with quinine. Its solution in dilute sulphuric acid is not fluorescent.

Chinine, $C_{20}H_{22}N_2O$, prepared by the action of alcoholic potash on quinine chloride, forms colourless crystals containing 2 mols. H_2O, and melting at 81—82°; it is soluble in water, ether, and light petroleum. The sulphate is readily soluble, and of neutral reaction. The solution in dilute sulphuric acid shows decided fluorescence, of a greener tint than that of quinine.

Oxidation-products of Cinchine, Cinchonine, and Quinine.—It has been shown that on oxidation with chromic acid cinchonine yields, together with carbonic anhydride and a little formic acid, a quinolinecarboxylic acid—cinchonic acid—(Königs, Abstr., 1879, 471; Skraup, *ibid.*, 656), and that quinine yields a methoxyquinolinecarboxylic acid—quinic acid—(Skraup, Abstr., 1879, 809), but of the bye-products little is known except that Weidel and Hazura obtained a small quantity of nitrohydroxyquinoline from the mother-liquors of cinchonic acid, by boiling them with nitric acid; and on distilling them with zinc-dust small quantities of β-ethylpyridine, quinoline, and a very little pyridine were formed (Abstr., 1883, 222).

In the authors' experiments, after removal of the cinchonic or quinic acid from the oxidation products, bromine-water is added, when from cinchonine and cinchine they obtained the insoluble tribromoxylepidine, and a soluble bromine-compound of the formula $C_9H_{13}Br_2NO$. In the case of quinine, the latter compound alone is obtained. *Tribromoxylepidine*, $C_{10}H_6Br_3ON$, can be crystallised from boiling alcohol; it does not melt at 280°, but can be sublimed in small quantity. It is sparingly soluble in boiling alcohol, chloroform, or benzene, more readily in hot acetic acid, insoluble in water, scarcely soluble in ammonia, sparingly in boiling aqueous soda; when it is boiled with sodium-amalgam and water, quinoline and hydroquinoline are formed in small quantity. Hydriodic acid converts it, in small part, into quinoline or lepidine. The soluble bromine-compound, $C_9H_{13}Br_2NO + \frac{1}{2}H_2O$, crystallises in colourless prisms, melts with decomposition at 250°, is very readily soluble in hot water, sparingly soluble in boiling alcohol, nearly or quite insoluble in chloroform, benzene, and ether. The aqueous solution has an acid reaction, gives a precipitate with phosphotungstic acid, a resinous precipitate with potassium mercuric iodide, soluble in excess, and with gold chloride, a resinous precipitate that can be crystallised in flat ruby-red needles. Silver nitrate added to a hot aqueous solution precipitates half the bromine, a compound being formed whose aurochloride crystallises in clear yellow needles of the formula

$$C_9H_{12}BrNO,HAuCl_4 + H_2O.$$

Long boiling with excess of silver nitrate removes nearly the whole of the bromine. Dibromocinchonine was submitted to oxidation, to see if these bromo-derivatives would be formed, but the products were found to be cinchonic and hydrobromic acids. By boiling it with alcoholic potash, a base free from bromine (a dihydrocinchonine, $C_{19}H_{20}N_2O$?) was obtained; this crystallises in needles, melts at 202—203°, sublimes without decomposition, and is readily soluble in alcohol. A. J. G.

Quinine and Homoquinine. By O. HESSE (*Annalen*, **225**, 95—108).—The author at the outset claims for himself the first notice of the presence in the bark of the *China cuprea* of an alkaloïd which, if not identical with, at least closely resembles quinine. To this substance the name homoquinine has been given (comp. Howard, Trans., 1882, 67). Objection is raised to Howard's statement that plants in the course of their growth are capable of the mutual conversion of quinine and cinchonidine, for all experiments in this direction have failed, so that the formation of quinine and cinchonidine must be considered to be independent phenomena.

Homoquinine is best obtained by dissolving the crude alkaloïd in dilute sulphuric acid, reprecipitating by ammonia, then shaking up with ether, from which homoquinine separates out in the crystalline form. On repeating this process twice, the alkaloïd is obtained practically pure. In a former paper the author assigned to homoquinine the formula $C_{19}H_{22}N_2O_2$ (Abstr., 1883, 601; *Ber.*, **15**, 857); the numbers obtained in more recent analyses are best in accordance with a formula $C_{20}H_{24}N_2O_2$. Homoquinine crystallises in concentrically grouped needles. belonging to the rhombic system, containing between 2 and 2½ mols. H_2O; on exposure to the air they gradually deliquesce, but may be heated to 100° without melting. Homoquinine is less soluble in ether than quinine; it is readily soluble in alcohol, the solution having a strongly alkaline reaction and an intensely bitter taste. With acids, the alkaloïd forms both neutral and acid salts, which differ from the corresponding salts of quinine by their greater solubility. The *neutral hydrochloride* forms an amorphous powder, the *acid hydrochloride* colourless prisms; the *platinochloride* crystallises in small orange-red prisms, the *neutral sulphate* in short six-sided colourless prisms; the thiocyanate is an amorphous powder.

In the specific rotatory power of the sulphate (1·25 grams dissolved in 10 c.c. normal hydrochloric acid and 25 c.c. water), ($t = 15$, $l = 220$) $[\alpha]_D = -235·6$, due allowance being made for the proportion of water contained in the crystalline salt; this value is practically identical with that of quinine sulphate. The neutral tartrate crystallises in tufts of needles containing 2 mols. H_2O.

It was found possible to convert homoquinine into quinine by dissolving the alkaloïd in hydrochloric acid, precipitating with soda, shaking up with ether, and adding sulphuric acid. On frequent repetition of the process, homoquinine is converted entirely into quinine sulphate. This result explains how homoquinine for some time eluded the observation of chemists. A few remarks are also added on the formation, under certain conditions, from quinine of an anhydride which behaves as a definite alkaloid, but can be reconverted into quinine, so that it would appear most probable that there exist several modifications of quinine, of which one is homoquinine.

V. H. V.

Bromo-derivatives of Dimethylpiperidine. By G. MERLING (*Ber.*, 17, 2139—2143).—*Bromodimethylpiperidineammonium bromide*, $NMe_2(C_5H_9Br)''Br$, is obtained together with dimethylpiperidine dibromide hydrobromide by the action of bromine on dimethylpiperidine, both dissolved in carbon bisulphide. The separation of the two products is effected by treatment with hot absolute alcohol, in which the former is very sparingly, the latter compound readily soluble. The ammonium bromide, which is formed in much the largest quantity, forms groups of colourless crystals, is readily soluble in water, but only very sparingly in alcohol, insoluble in ether. It is not decomposed by aqueous potash. By treatment with silver chloride and addition of platinic chloride, an orange-yellow platinochloride, $(C_5H_9Br\colon NMe_2Cl)_2,PtCl_4$, is precipitated. By digesting the aqueous solution with moist silver oxide ($\frac{1}{2}$ mol. proportion) a liquid of strongly alkaline reaction is obtained, probably due to the formation of the hydroxide, $C_5H_9Br\colon NMe_2\,OH$. This solution slowly loses its alkaline reaction when evaporated in a vacuum, the change taking place rapidly on heating. This change is due to an intermolecular action in which a new bromide of the formula

$$NMe(C_5H_7Me)'',HBr,$$

or $C_6H_8\colon NMe_2Br$, has been found, and is obtained on evaporation as a white deliquescent mass which can be converted into a platinochloride of the formula

$$(C_5H_7Me\colon NMe)_2,H_2PtCl_6,\text{ or }(C_6H_8Cl\colon NMe_2)_2,PtCl_4.$$

By further digestion of the solution after it has become neutral, with a fresh quantity of moist silver oxide, a strongly alkaline solution is again obtained; this, when evaporated in a vacuum, yields a viscous brownish syrup which appears to be an ammonium base, as methyl iodide has no act on on it. On distillation, it splits up into water and a new base of the formula $C_5H_7Me\colon NMe$. This base is specifically lighter than water, in which it is nearly insoluble, boils at 137—142°, and absorbs carbonic anhydride on exposure to the air. The platinochloride is soluble in water and alcohol. The base unites with methyl iodide with almost explosive violence, yielding a compound of the formula $C_5H_7Me\colon NMe_2I$, readily soluble in water, sparingly soluble in alcohol.

Dimethylpiperidine dibromide hydrobromide crystallises in lustrous plates; the numbers obtained on analysis were very unsatisfactory. By the action of potash on an aqueous solution of the substance, an oily base is separated, showing that the substance cannot be an ammonium bromide. A. J. G.

α-Isopropylpiperidine. By A. Ladenburg (*Ber.*, **17**, 1676—1679).—Ladenburg and Schrader recently described two isopropylpyridines, one of which was shown to belong to the γ-series (this vol., p. 1048), whilst the constitution of the second one was not established. The higher fraction containing it yields picolinic acid on oxidation, showing that it contains α-isopropylpyridine. In order to separate the two bases more perfectly than can be effected by fractioning, the author converts them into the corresponding piperidine-bases, and separates these by means of their platinochlorides. A concentrated aqueous solution of the isopropylpiperidine hydrochloride is mixed with the calculated quantity of platinic chloride, the mixture warmed to dissolve the precipitate, and evaporated to a syrup. When cold, a mixture of ether (2 parts) and alcohol (1 part) is added to precipitate the salt of the β-base, whilst that of the α-base remains in solution. α-Isopropylpiperidine, $C_8H_{17}N$, separated from the purified platinochloride, boils at 162—164°, is sparingly soluble in cold, and still less in hot water. It closely resembles conine in its odour, physiological and other properties, as seen from the following table, the conine employed in the experiments being specially purified by the author.

	Conine.	α-Isopropylpiperidine.
Sp. gr. at 0°	0·8625	0·8660
Hydrochloride	m. p. 218°	m. p. 206°
	Both crystallise in needles, are stable in the air, and dissolve readily in water and alcohol.	
Hydrobromide	m. p. 207°	m. p. 216°.
	Both crystallise in prisms, are stable in the air, and are readily soluble.	
Platinochloride	Very soluble in water, crystallise with difficulty, soluble also in mixture of alcohol and ether.	
Action of mercuric chloride on the solution of the hydrochloride	None.	None.
Action of gold chloride	Oily precipitate in both cases.	
Action of picric acid	Both yield an oily precipitate in concentrated solution, no precipitate in dilute solution.	

The small differences are probably connected with the optical inactivity of the artificial base, and will possibly vanish if it be split up into its active constituents, and the dextrorotatory component isolated. A. K. M.

The Liquid Alkaloïd from Lupinus Luteus. By G. BAUMERT (*Annalen*, **224**, 321—330).—The author discusses the results of Siewert's investigations (*Landw. Versuchs-Stat.*, **27**, 52), Beyer's (*ibid.*, **14**, 161), Schulz's (*Landwirtschaft Jahrbuch*, 1879, 37), and Liebscher's (*Bericht landwirtschaftlichen Inst. Univ. Halle*, **2**, 70) on the alkaloids contained in the yellow lupine, and maintains that his own experiments (*Ber.*, **14**, 1150, 1321, 1880; **15**, 631, 1951, 2745; *Annalen*, **214**, 361; *Landw. Versuchs-Stat.*, **27**, 15, and 30) prove that the liquid portion of the alkaloids yields a platinochloride of the constant composition $C_{16}H_{30}N_2,H_2PtCl_6 + 2H_2O$. The liquid alkaloid, which is termed *lupinindine*, $C_8H_{15}N$, appears to form a crystalline hydrate, $C_8H_{15}N,H_2O$. The liquid portion probably consists of a mixture of lupinidine and its hydrate. It does not contain a mixture of different bases as stated by Siewert and Schulz (*loc. cit.*)

The low boiling fraction of the crystalline alkaloids from the lupine contains *lupinine*, $C_{21}H_{40}N_2O_2$. W. C. W.

Action of Acetic Chloride and Anhydride on Lupinine. By G. BAUMERT (*Annalen*, **224**, 313—321).—A mixture of lupinine hydrochloride and diacetyllupinine hydrochloride is formed by the action of acetic chloride on lupinine. A better yield of the acetyl-derivative is obtained by substituting acetic anhydride for the chloride. The product of the reaction is mixed with ether, and the excess of acetic anhydride decomposed by water. After neutralising the free acid with sodium carbonate, soda is added, and the mixture is then well shaken in order that the acetic derivative may dissolve in the ether. On evaporating the ethereal extract, diacetyllupinine remains as a heavy oil insoluble in water. It dissolves readily in hydrochloric acid, and with platinum chloride yields a platinochloride, $C_{21}H_{38}\overline{Ac}_2N_2O_2,H_2PtCl_6$, crystallising in rhombic plates.

W. C. W.

Colchicine. By S. ZEISEL (*Compt. rend.*, **98**, 1587—1588).—The crystals obtained by Houdé from a chloroform solution of colchicine were described by the author in 1883 (*Monatsh. Chem.*). They are not, however, pure colchicine as Houdé supposes, but are a compound of colchicine and chloroform, and the latter can only be removed by dissolving in water and boiling for some time. Dilute mineral acids decompose colchicine into *colchiceine* and methyl alcohol. Colchiceine, when heated with concentrated mineral acids at 110—120°, yields a new base, *apocolchiceine*, methyl alcohol, and acetic acid. When oxidised, colchicine yields a crystalline product, and when reduced in acid or alkaline solution, it yields amorphous products which are difficult to purify. C. H. B.

Investigations on Sinapine. I. Sinapic Acid. By I. REMSEN and R. D. COALE (*Amer. Chem. J.*, **6**, 50—60).—Sinapine thiocyanate was first prepared by Henry and Garot from white mustard seed, and has since been investigated by Babo and Hirschbrunn. 100 lbs. of seed are pressed to remove oils, then extracted with alcohol, and after concentration mixed with a small quantity of an alcoholic solution of potassium thiocyanate, whereupon crystals of the sinapine thiocyanate slowly separate. This method is superior to that given by von Babo and Hirschbrum, the product weighing 80 grams. The substance, after recrystallisation, is almost white, and melts at 176°. By boiling with baryta-water, it is resolved into sincaline and sinapic acid, which is precipitated as the barium salt. The sinapic acid may be isolated by the action of hydrochloric acid and recrystallisation from alcohol and water. It melts at 185·6—192°. Analyses agree with the original formula $C_{11}H_{12}O_6$; the substance is partly decomposed by boiling with water. Crystalline salts cannot be prepared, but by digesting the acid with calcium and barium carbonates, the existence of the salts $(C_{11}H_{11}O_5)_2Ca$ and $(C_{11}H_{11}O_5)_2Ba$ was demonstrated; the above-mentioned insoluble barium salt is $C_{11}H_{10}O_5Ba$. Acetic chloride has no action on sinapic acid, but acetic anhydride converts it into the body $C_{10}H_{10}O_2(\overline{OAc}).COOH$, melting at 281°; hence sinapic acid is monobasic, but contains one phenolic hydroxyl, and the possibility of it being derived from the phthalic acids is excluded. Fused with potash, sinapic acid yields a dark-coloured product, apparently containing pyrogallol, and hence it is probably butylenegallic acid,  $COOH.C_6H_2(OH)<\genfrac{}{}{0pt}{}{O}{O}>C_4H_8$. The synthesis of sinapic acid is being attempted. H. B.

Albuminoïds. By DANILEWSKY (*Bull. Soc. Chim.*, **41**, 254—255). —The basicity of myosin depends on the number of amidogen-groups which it contains, and their number varies in myosins of different origin. It always contains a small quantity of magnesium and phosphoric acid, which appear to be combined with organic radicals; although these inorganic constituents may be removed by treatment with dilute acids, the myosin is thereby converted into syntonin. The latter does not exist in living tissues. Syntonin can be converted into myosin, and if the syntonin is optically active the resulting myosin is likewise, and *vice versâ*. Optically active myosin and syntonin are rendered optically inactive by boiling for some time with a 10 per cent. solution of hydrochloric acid. Besides myosin, muscular tissue contains a feeble base, analogous to nuclein, which the author has designated *myostroïne*. At a high temperature, and in presence of dilute acids, this compound yielded syntonin (derived from myosin, which it contained), *chondropeptone*, and *lecithin*, the last of which can also be obtained from the nucleïn of cow's-milk and yeast. Myosin and myostroïne constitute 70 per cent. of the solid residue of muscle. This total quantity is uniformly found in muscle from different sources, but the proportion of the two constituents is subject to considerable variation. It appears that the more active the work done by the muscle, the greater is the proportion of myostroïne which it contains, this compound having been formed at the expense of the myosin. W. R. D.

Hemialbumose or Propeptone. By R. HERTH (*Monatsh. Chem.*, 5, 266—327).—The incomplete digestion of albumin by pepsine yields solutions containing an albumin, which Schmidt and Muhlheim (*Arch. Anatom. Physiol.*, 1879, 40) style *propeptone*, and which Salkowski (*Virchow's Arch.*, 81, 1880) has shown to be identical with Kuhne's *hemialbumose* (this vol., p. 854). This paper contains an account of the author's investigation of this substance, from the results of which the following conclusions, as to the nature of hemialbumose, are drawn. Hemialbumose is a definite body, in composition it is identical with fibrin; it is as insoluble in water as coagulated albumin. Pure hemialbumose is almost insoluble in solutions of common salt, its solubility increasing from a certain limit with the amount of salt in solution. Hemialbumose exhibits a great tendency to combine with acids and alkalis. The compounds with acids are insoluble in salt solutions, consequently it is precipitated as an acid compound by the addition of solutions of sodium chloride and acids. The characters of the solutions of hemialbumose and of the precipitates obtained from its solutions depend on its reaction with alkalis, acids, and salts. Its solutions are coagulated by heat; in this respect it exhibits a gradual change, which is to be attributed to the influences of the solvents. Hemialbumose cannot be regarded as the product of the decomposition of albumin. P. P. B.

New Forms of Albumose. By W. KÜHNE and R. CHITTENDEN (*Amer. Chem. J.*, 6, 31—51).—The authors have already suggested (*Zeits. f. Biol.*, 19, 159) that hemialbumose is not a simple body, and the terms "soluble" and "insoluble" were applied to it. Noticing an inconstancy in the manner of precipitation by sodium chloride, a new method of preparation was devised, whereby four different forms of albumose are separated. *Protalbumose*, precipitated by excess of sodium chloride, soluble in cold and hot water. *Deuteroalbumose*, precipitated by excess of sodium chloride, insoluble in cold and in boiling water, but on the other hand soluble both in dilute and strong solutions of sodium chloride. *Heteroalbumose*, similar to deuteroalbumose, but insoluble in solutions of sodium chloride. *Dysalbumose*, not precipitated by excess of sodium chloride, but precipitated by sodium chloride and acids; soluble in pure water. Detailed methods are given for preparing these bodies by pepsin digestion from raw fibrin and from Witte's so-called peptone. The mean composition of five samples of protalbumose and their rotatory power are given in the table:—

C......	50·89	50·39	50·54	51·50	50·55
H......	6·83	6·74	6·69	6·80	6·85
N......	17·12	17·12	17·34	17·13	17·01
S......	1·17	1·07	1·17	0·94	1·07
O......	23·99	24·68	24·26	23·63	24·52
$[\alpha]_D$....	−72·64°	−79·05°	−77·90°	−73·18°	−71·40°

The variation of the angle of rotation is due, at least in part, to the reagents used to render the solutions transparent. The behaviour with a number of reagents is given. Deuteroalbumose has the composition—

C......	50·47	50·84
H......	6·81	6·85
N......	17·20	17·14
S......	0·87	1·07
O......	24·65	24·10
$[\alpha]_D$....	−74·41°	−79·11

And both protalbumose and deuteroalbumose are to be considered as first hydrates of albumin. H. B.

Solubility of Vegetable Proteïn-compounds in Water containing Hydrochloric Acid. By H. Ritthausen (*J. pr. Chem.* [2], **29**, 360—365).—The solvent action of water containing $\frac{1}{1000}$ to $\frac{2}{1000}$ part hydrochloric acid on wheat-gluten was first noticed by Bouchardat (*Compt. rend.*, **14**, 962). The author finds that large quantities of the albuminoïds of some Leguminosæ may be dissolved by this means, and that the greater part is reprecipitated on neutralising with an alkali. The dry precipitate gave all the reactions of undecomposed albuminoïds, being wholly and readily soluble in caustic potash, hydrochloric acid, and more or less in water containing 5 per cent. of sodium chloride. The following proportions of albuminoïds were extracted from the various leguminous seeds examined :—

Peas yielded	9	per cent.	albuminoïds.
Vicia faba	12	„	„
Yellow lupins........	32	„	„
White beans	10	„	„
Vicia sativa..........	10	„	„

Studies on Peptonisation. By T. Chandelon (*Ber.*, **17**, 2143—2151).—In these experiments, barium peroxide was suspended in an aqueous solution of albumin, and a slow stream of carbonic anhydride passed into the liquid, so that the albumin should be subjected to the continual action of freshly-formed (nascent?) hydrogen peroxide. After 48 hours, the liquid no longer coagulated on heating, and was found to contain—(1) a proteïn-substance closely resembling casein in most properties, but distinguished from it by its rotary power (− 69·52), and by the non-occurrence of coagulation on heating in sealed tubes at 135° ; (2) a substance closely resembling propetone; (3) a substance having all the reactions of peptone. As, in the electrolysis of water, hydrogen peroxide is known to be continually formed, an aqueous solution of albumin, acidulated with very dilute acetic acid, was submitted to electrolysis. The products in this case were syntonin, propeptone, and peptone. The author draws attention to the similarity of these products to those obtained with peptic ferments (syntonin, propeptone, and peptone in the case of pepsin and globulin, propeptone and peptone in the case of trypsin), and to the confirmation it affords of the theory that peptonisation is a phenomenon of hydration. A. J. G.

Corneïn. By C. F. W. Krukenberg (*Ber.*, **17**, 1843—1846).—The substance to which this name was given by Valenciennes is prepared from the skeleton of the asteroid polypes and other of the lower animal organisms. The skeleton is first treated with cold hydrochloric acid, to remove the inorganic part, and then digested for several days at 38° successively with active peptic and tryptic digestive fluids. *Cornein* is left as a horn-like residue, and this, when digested with dilute sulphuric acid for several days, yields a hygroscopic substance, which may be obtained crystallised in prisms. *Cornikrystallin* thus prepared is insoluble in concentrated sulphuric acid, in which it may be preserved for years without change. The author has prepared and analysed cornein from *Rhipidogorgia flabellum*, *Gorgonia verrucosa*, and *Antipathes* (spec. ?), and obtained concordant results agreeing with the formula $C_{31}N_9H_{44}O_{13}$.

L. T. T.

Physiological Chemistry.

Elimination of Nitrogen in the Free State from the Animal Body. By M. GRUBER (*Zeits. f. Biol.*, **19**, 563—568).—From the results of his former experiments, the author concluded that the intake and output of nitrogen balanced one another. Objections have, however, been raised, as his experimental dog lost during the course of the experiment 920 grams body-weight. He has, however, repeated the experiment, maintaining the dog at an almost constant body-weight, with the same results, viz., the intake and output of nitrogen balance each other. Rohmann found that only a part of nitrates and nitrites, when given to animals, appeared in the urine, and concluded from this that they were converted into ammonia, and in turn decomposed into nitrogen and water. This, however, does not, as the author points out, affect the question, as no nitrates or nitrites are formed in the body, and only a very small quantity of these would be contained in the food taken. J. P. L.

Determination of the Rate of Consumption of Oxygen in the Tissues by means of the Spectroscope. By A. DENNIG (*Zeits. f. Biol.*, **19**, 483—500).—The forefinger, usually of the left hand, was bound round with a caoutchouc band; then the period that elapsed from the moment of binding until the disappearance of the two absorption-bands of the oxhæmoglobin was noted.

In the same individual the time varies, according to the hour of the day at which the observation is made. At night it is between 135—146 seconds, in the morning 114—152, and in the afternoon only 92. Children always give much lower figures. Muscular activity, not only walking, but exercising the arms, voluntarily stopping respiration, warming the hand, all produce a diminution of the period, cooling on the other hand increases it even to 300 seconds

In a series of observations made by the author on patients suffering from various ailments, a diminution of the period occurs throughout. J. P. L.

Biological Function of Phosphoric Acid. By A. MAIRET (*Compt. rend.*, **99**, 243—246).—The elimination of phosphoric acid is connected with general nutrition, the elimination of phosphates, both of the alkalis and alkaline earths being greater the greater the decomposition of albuminoids, or in other words, the greater the elimination of nitrogen. The effect of muscular exertion on the elimination of phosphoric acid depends on the state of nutrition. Phosphoric acid is used up, and if the exertion is proportionally greater than the amount and quality of the food assimilated, the elimination of nitrogen and alkaline phosphates in the urine is increased; but if the diet is rich and abundant, muscular exertion has no effect on the amount of phosphates eliminated in the urine. C. H. B.

Assimilation of Maltose. By A. DASTRE and E. BOURQUELOT (*Compt. rend.*, **98**, 1604—1607).—Solutions of maltose were injected into the blood of the dog, both alone and mixed with glucose or saccharose, and the proportion of the sugars in the urine was estimated. No maltose was excreted in the saliva. The results of the experiments show that maltose is directly assimilated with very nearly the same facility as glucose. C. H. B.

Effect of Coffee on the Composition of the Blood and on Nutrition. By COUTY, GUIMARAES, and NIOBEY (*Compt. rend.*, **99**, 85—87).—The authors have extended Guimaraes' researches on the physiological action of coffee, using the methods adopted by Couty and D'Arsonval in their investigations on maté (*Compt. rend.*, **94**). They find that coffee diminishes considerably the proportion of gases in the blood, but does not affect the proportion of carbohydrates consumed. In other words, it diminishes the activity of the simple combustions which produce carbonic anhydride. On the other hand, coffee increases very considerably the amount of urea in the blood, and stimulates those complex animal processes which use up nitrogenous substances. It increases the formation and excretion of urea, and also the assimilation of nitrogenous foods such as beef. The tension of the blood, the biliary and salivary secretions, and the temperature, are slightly increased, and the movements of the heart and respiratory organs become somewhat more frequent.

It follows that coffee is a complex aliment, which acts mainly by indirectly modifying the phenomena of nutrition and the general functions. It renders the organism capable of consuming and destroying larger quantities of nitrogenous substances, and may consequently be regarded as an indirect source of available energy. C. H. B.

Pathological Formation of Fat. By LEBEDEFF (*Bied. Centr.*, 1884, 356).—The modern theories propose as the source of the abnormal formation of fat in the liver in cases of phosphoric poisoning—(1) the fat of the food; (2) the carbohydrates; (3) the albuminoïds. The first case is most unlikely, as the deposition occurs when a minimum of food is given; (2) the same argument holds good; (3) against this proposal the author, with the aid of experiments, urges that the fat which is deposited three days after the taking of phosphorus amounts to eighty times the quantity which could be produced by the albumin present. The action of phosphorus on the blood causes want of oxygen, suppression of blood-corpuscles, consequently formation of compounds the result of incomplete combustion, physical alteration of the blood, and deposition of incompletely oxidised fat in the liver. The explanation of the migration of fat from the subcutaneous connective tissue into the liver is as follows:—The fat in the connective tissue is not so firmly deposited as that in the parenchymatous tissue, and this is demonstrated by the fact that it is almost impossible to remove the fat from the latter by ether, whereas from the former it is readily removed. Such being the condition of affairs, this fat can be readily removed, passes into the blood, and because of the presence of phosphorus it is not oxidised, and is consequently deposited in the liver. If there is no fat capable of being transmitted in this manner, atrophy of the liver ensues. E. W. P.

Action of Heat on the Animal System. By H. Senator (*Bied. Centr.*, 1884, 502).—Heat raises the pressure of the blood, but part of this rise may be due to the movement of the animal under experiment, part to nervous irritation. Breathing is at first more rapid and deeper, later on more rapid only. At high temperatures albumin appears in the urine. E. W. P.

Influence of Stature on the Interchange of Matter and Energy. By M. Rubner (*Zeits. f. Biol.*, 19, 535—562).—Among many factors which influence the degree of decomposition of matter, the effect of stature has hitherto been least studied. Regnault and Reiset have shown that small animals consume more oxygen relatively than large ones. In the present paper, the author has endeavoured to solve the question for a particular kind of animal, the dog. Different sized dogs were kept under the same conditions of exercise and temperature. The consumption of albumin was determined from the nitrogen found in the urine; and the consumption of fat from the carbon of the carbonic acid expired, and the carbon contained in the urine after subtracting that belonging to the proteid decomposed. The total interchange of matter is calculated in proportion to the calorific values of the compounds consumed. 1 gram of nitrogen corresponds with 25·64 calories, 1 gram of fat with 9·686. The following averages, (p. 1394) reckoned from the amount of urea excreted, were obtained from the experimental results after reducing them to a uniform temperature of 15°.

With the decrease of body-weight, there is a gradual increase of the intensity of combustion. The reason of the high figures obtained in the case of small animals is solely, as the author shows, due to their relatively large surface; the decomposition increases as the surface increases, that is to say, for every square centimetre of surface an equal number of heat-units are given off, consequently the total interchange of matter in starving animals is proportional to their surface.

Body-weight of dog.	Calories per day per kilogram.	Relative formation of heat.
31·2	35·68	100
24·0	40·91	114
19·8	45·87	128
18·2	46·2	129
9·6	65·16	182
6·5	66·07	184
3·2	88·07	247

Large and small dogs consume different quantities of food stuff, because the impulses given off by the skin caused by the cooling of the surface increase the activity of the cells. For equal surfaces approximately isodynamous quantities of matter are consumed. The author concludes that variations produced by loss of heat in every warm-blooded animal are the sole cause of the differences observed between the material consumed and energy expended. From comparisons made by Voit and Kuhein on the consumption of material in starving animals, it is shown that small animals consume more albumin in proportion to fat than large ones, because they possess less fat.

J. P. L.

The Excretion of Urea and Inorganic Salts with the Urine under the Influence of an Artificially Increased Temperature. By C. F. A. KOCH (*Zeits. f. Biol.*, 19, 447—468).—Several experiments have been made before to determine whether high temperatures caused by artificial means influence the excretion of urea in the same manner as fever; the results, however, were very contradictory. Neumayer and Schleich found that an important increase took place when either men or animals were subjected to warm baths; Bartels, Kaup, and Senator, on the other hand, came to the opposite conclusion, Kaup even observing a slight diminution.

The author has repeated Schleich's experiments, at the same time extending his observations to the excretion of the inorganic salts (phosphates, chlorides, and sulphates). In fever, the chlorides almost wholly disappear. The results are mostly of a negative character. The urea was not increased in any experiment; the phosphates and chlorides show a slight decrease of only very short duration, whilst the sulphates are unaffected. As an increase in the carbonic acid expired takes place in high temperatures, experiments were made to determine whether any direct relation existed between the amount of carbonic acid expired and urea excreted. No such relation could be found.

J. P. L.

Formation of Urea from Sarcosin. By E. SALKOWSKI (*Zeits. Physiol. Chem.*, 8, 149—157).—A controversy between the author and Schiffen upon the formation of urea from sarcosin. J. P. L.

Influence of Intellectual Activity on the Elimination of Phosphoric Acid by the Urine. By A. MAIRET (*Compt. rend.*, 99, 282—285).—The effect of intellectual exertion, like that of muscular exertion, is closely connected with the sufficiency or insufficiency of the diet of the individual. The general result is a diminution in the quantity of nitrogen and alkaline phosphates eliminated by the urine, the amount of diminution depending on the duration of the intellectual effort. When the diet is insufficient relatively to the work done, an additional effect is produced, and the amount of phosphates of the alkaline earths eliminated is increased. For one and the same diet, the more severe the intellectual effort, the greater is the increase in the elimination of earthy phosphates. With a purely vegetable diet, this increase is particularly well marked. It follows from these results that phosphoric acid is intimately connected with the nutrition and activity of the brain, and that when the brain works it absorbs alkaline phosphates and gives up phosphates of the alkaline earths. Intellectual activity retards general nutrition.

A comparison of these results with those relating to the effect of muscular exertion (this vol., p. 1392) shows that intellectual and muscular activity produce exactly opposite effects; the former diminishes the elimination of nitrogen and alkaline phosphates and increases the elimination of earthy phosphates, whilst the latter diminishes the elimination of earthy phosphates, but increases the elimination of alkaline phosphates and of nitrogen. The effect of general nutrition is exerted alike on both classes of phosphates and on nitrogen.

C. H. B.

Formation of Mercapturic Acid in the Organism, and its Detection in the Urine. By E. Baumann (*Zeit. Physiol. Chem.*, 8, 190—197).—The urine of animals after feeding with chloro- or bromobenzene does not originally contain the substituted chloro- or bromophenylmercapturic acid, but a body strongly lævorotatory, which on treatment with acids yields mercapturic acid. The author has obtained the potassium salt of this compound, but cannot isolate the free acid, as it is at once decomposed into mercapturic acid and an acid soluble in water and alcohol, which reduces Fehling's solution, and is probably a glyceronic acid. The following is the general method for detecting the mercapturic acid:—The urine is precipitated with lead acetate, the excess afterwards removed with sulphuretted hydrogen, the filtrate boiled for ten minutes with strong soda and a few drops of Fehling's solution, then acidified with hydrochloric acid. If mercapturic acid be present, a yellow caseous precipitate of the copper compound of the mercaptan will be formed. By this reaction it was found that only the halogen-derivatives of benzene and naphthalene formed any considerable quantity of mercapturic acid. Benzonitrile gives no trace, but forms, as Giacosa conjectured, the phenolic ethereal sulphate which splits up yielding the nitrile of salicylic or parhydroxybenzoic acid.

J. P. L.

Inflammable Gases in the Animal Organism. By B. Tacke (*Ber.*, 17, 1827—1830).—In order to determine whether the inflammable gases generated in the digestive organs of animals pass out of the body by the anus or through the blood by the lungs, the author has made a series of experiments on rabbits. The bodies of the rabbits were surrounded with water, in order to prevent as far as possible the diffusion of these gases through the skin. As the result of these experiments the author finds that, in the case of rabbits, by far the greater part of the inflammable gases emitted from the body passes out through the lungs, but that a small quantity also passes out by the anus. The author believes that if any oxidation of these inflammable gases takes place during their passage through the blood and lungs, the amount of gas so oxidised is exceedingly small. L. T. T.

Analyses of Human Milk. By H. Struve (*Bied. Centr*, 1884, 503).—Healthy human milk contains 3—5 per cent. butter-fat, and is of a sp. gr. 1·031—1·035. When treating the milk with ether, a gelatinous mass is removed, but the quantity is very fluctuating. E. W. P.

Influence of Pilocarpine and Atropine on Lactation. By F. Hammerbacher (*Bied. Centr.*, 1884, 503).—The action of these two drugs is to lower for the time the yield of milk, but their action is very transient. E. W. P.

Employment of Milch Cows for Labour. By V. Baro (*Bied. Centr.*, 1884, 502).—It is not advisable to work milch cows when oxen are obtainable, as the former loose more flesh than the oxen, and the yield of milk decreases. E. W. P.

Annual Report of Experimental Dairy Farm at Kiel. By M. Schrodt (*Bied. Centr.*, 1884, 417).—The report gives the extremes of sp. gr., fat, and dry substance during the year; the average of the whole year for day's milk was 12·30 per cent. dry substance, 3·52 per cent. fat. The variations between morning and evening milk are not unimportant, the dry substance and fat differing from 0·5 to 1 per cent., and sometimes more.

		Sp gr.	Dry substance.	Fat.
Morning milk	stall fed......	1·0295—1·0331	11·52—12·63	3·01—3·79
	grass fed	1·0307—1·0335	11·24—13·22	2·57—3·05
	stall fed......	1·0318—1·0338	11·80—12·57	3·17—3·81
Evening milk	stall fed......	1·0302—1·0330	11·53—12·83	3·11—4·05
	grass fed	1·0289—1·0339	11·28—13·92	2·96—4·77
	stall fed......	1·0321—1·0339	12·20—13·11	3·37—4·15
Day's milk, stall fed		1·0300—1·0331	11·32—12·87	2·74—4·14

J. F.

Composition of Cow's Milk in Holland. By D. Gabel (*Bied. Centr.*, 1884, 420).—The milk of Dutch cows is known to be poor in fat. 18—20 litres are generally required to make half a kilogram of butter. The following table shows the composition of the milk of a large and carefully conducted dairy at the Hague :—

Month.	No. of expts.	Sp. gr.	Degrees of creamometer.	Solids.	Fat.
May	10	1·0313	9·06	12·16	2·82
June	5	1·0312	7·00	12·10	2·71
July	6	1·0308	8·10	11·88	2·57
August	6	1·0306	8·60	11·95	2·55
September	4	1·0316	9·50	12·25	2·90
October	3	1·0306	12·00	12·20	2·75
November.......	5	1·0310	11·00	12·04	2·60
December.......	4	1·0313	11·20	12·10	2·70
January	3	1·0316	10·50	11·67	2·60
February	4	1·0306	11·50	12·20	2·88
March..........	4	1·0316	10·00	12·30	2·83

J. F.

Composition of the Ash of Cow's Milk. By M. SCHRODT and H. HANSEN (*Landw. Versuchs-Stat.*, **31**, 55—79).—The milk was taken from 10 cows, which had all calved between October and the beginning of the succeeding January; samples were taken at seven different times, from January till September, and analysed with special attention to the ash-constituents: the first three samples were taken while the cows were in the stable, and the rest of the time they were put out to grass. The following table gives the general result of the analyses:—

	1.	2.	3.	4.	5.	6.	7.
K_2O.........	25·81	26·91	25·18	26·30	26·17	22·55	24·90
Na_2O	11·78	10·39	10·09	11·97	11·42	10·65	10·26
CaO	19·71	21·81	21·09	21·26	20·93	23·57	21·77
MgO	2·77	2·75	2·75	3·15	1·78	2·66	1·90
Fe_2O_3	0·13	0·21	0·05	0·08	0·11	traces	0·10
SO_3	4·07	4·15	3·75	4·38	4·20	3·92	4·30
P_2O_5	23·11	23·11	24·61	22·41	23·59	26·51	25·41
Cl..........	16·15	13·15	15·94	14·16	14·81	13·48	14·52

From the above figures, it is readily seen that there is no marked change in the ash-constituents of the milk at varying periods of lactation. The small differences that are apparent seem to owe their origin to change of fodder rather than to the length of time that the cows had been milked. The increase of the amount of phosphoric acid and lime in the last four analyses is probably due to an increased secretion of caseïn in the milk during that time, the cows being then in the pasture. The experiments were continued with some of the cows for a few months more, when a more tangible depression in the quantity of potash was noted. The milk of several cows which had just calved showed also less alkali, but a considerable increase in phosphate of lime.

J. K. C.

Infection of Eggs by Chicken Cholera. By BARTHÉLEMY (*Bied. Centr.*, 1884, 419).—A hen with the disease, of which she afterwards died, laid 14 eggs which were set to be hatched, but they did not come to maturity—opened between the eighth and tenth day there was found a quantity of black blood, having the peculiar smell of blood from fowls dead of the disease; this blood contained numerous bacteria. It is clear that the secretions of the mother, containing the spores, passed into the substance of the egg, and the shells allowed sufficient oxygen to pass to enable them to develop. J. F.

Bacillus of Cattle Plague. By METZDORF (*Bied. Centr.*, 1884, 419—420).—The author has observed a distinctive bacillus in the blood of animals which died of the disease; it was also observed in the coats of the intestinal canal and the lymphatic glands; the microscopic examinations were made on the bodies immediately after death, so that there could not be any question of putrefactive germs. J. F.

Action of Potassium Ferricyanide on Blood. By v. MERING (*Zeits. Physiol. Chem.*, 8, 186—189).—Metahæmoglobin is formed by the action of ferricyanide of potassium, only when the red blood corpuscles have been destroyed, either by the addition of water, ether, chloroform, or alternately freezing and thawing, and have yielded their colouring matter to the surrounding fluid. In concentrated solutions, its action is preservative, the same as chloride of sodium and sulphate. J. P. L.

Poisonous Action of Urea. By GRÉHANT and QUINQUAUD (*Compt. rend.*, 99, 383—385).—When urea is injected in sufficient quantity under the skin of the frog, guinea-pig, rabbit, pigeon, and dog, it gives rise to tetanic convulsions, similar to those produced by strychnine, followed more or less rapidly by death. The amount of urea in 100 grams of the blood after death was 0·82 gram in the case of the guinea-pig; 0·661 gram in the case of the rabbit, and 0·6 gram in the case of the dog. The amount present in 100 grams of human blood in fatal cases of retention of urine, &c., varied from 0·21 gram to 0·41 gram.

When urea is injected under the skin, the whole of it is never completely absorbed before the animal dies, even if death does not take place until several hours after injection. Urea does not act directly on the muscular fibre, and does not diminish the energy of its contraction. C. H. B.

Do Bones contain Keratin? By H. E. SMITH (*Zeits. f. Biol.*, 19, 469—482).—Brœsike maintains that the membranes of the Haversian canals of the lacunæ and the canaliculi consist of keratin. The author, to test this assertion, determined anew some of the chief properties of keratin by experimenting on bodies containing it in a pure state. He found that it resisted both the action of pepsine and trypsine; a solution of caustic potash or soda of 20 per cent. dissolved it; 40 per cent. solutions had a weaker action, and a solution of $\frac{1}{3}$ to 1 per cent. scarcely any action at all. Bones, however, when digested with pepsine and trypsine, left but an unimportant residue, which, moreover, was completely soluble in a $\frac{1}{2}$ or 1 per cent. solution of caustic potash or soda, after removal of the fat by ether.

J. P. L.

Chemistry of Vegetable Physiology and Agriculture.

Action of Oxygen on the Activity of the Lower Organisms. By F. Hoppe-Seyler (*Zeits. Physiol. Chem.*, 8, 214—228).—From further researches conducted with the apparatus described in a previous paper, by means of which a continual supply of oxygen can be introduced into the fluid, the author has been led to the conclusion that when oxygen is continuously present, the only certain products formed, during the putrefaction of albuminous liquids, are carbonic anhydride, water, and ammonia, or some closely allied nitrogen compound; neither hydrogen or marsh-gas, indole, nor skatole are formed except perhaps in very small quantities; leucine and tyrosine, too, if formed at all, are only passing stages and do not exist permanently. Thus putrefactive bacteria behave as all other organisms, they assimilate oxygen and eliminate carbonic anhydride, water, and ammonia. In the absence of oxygen, all organisms show more or less evidence of fermentation, but whilst the ordinary putrefactive bacterium can live some time when oxygen is excluded or present in insufficient quantity, all other organisms die off. The bacterium of the cellulose fermentation resists the want of oxygen for a long time. Whether there are organisms that live in the absence of oxygen is not shown. Bacteria multiply quicker in the presence of an excess of oxygen than with an insufficiency.

J. P. L.

Influence of High Pressures on Putrefaction. By A. Certes (*Compt. rend.*, 99, 385—388).—Vegetable and animal infusions in fresh water and sea water putrefy under pressures of from 350 to 500 atmos., but the chemical changes which take place, and the organisms which are developed, seem to be different from those observed when the same solutions ferment under ordinary pressure. Blood containing the bacilli of anthrax lost none of its virulence by being subjected to a pressure of 600 atmos. for 24 hours.

C. H. B.

Cultivated Wine Yeast. By A. Rommier (*Compt. rend.*, 98, 1594—1596).—The true wine ferment on the skin of the grape requires a considerable time and a comparatively high temperature for its development, and before it attains its full activity other ferments and moulds develop and produce secondary fermentations which impair the quality of the wine. If, however, the fresh must is mixed with a suitable proportion of cultivated wine yeast (about

15 c.c. per kilo.), fermentation takes place rapidly even at temperatures as low as 15—22°, and is complete in about 7 days If the must is mixed with sugar, the latter is entirely decomposed, but in this case complete fermentation requires a much longer time. The rapidity with which the principal fermentation takes place under these conditions prevents the development of the secondary ferments, and the quality of the wine is much improved. The low temperature at which fermentation takes place, and the short time required for its completion, render this method especially valuable for the production of white wines. C. H. B.

Water Culture of Lupines. By Weiske (*Landw. Versuch-Stat.*, **30**, 437—444).—The fact of lupines producing a crop rich in nitrogen when grown in soils poor in that element has excited much interest, but the author believes that comparatively few cultural experiments have hitherto been made with them. His experiments consisted in growing two sets of plants, one in a nutritive solution containing nitrogen, the second in water free from it. The first set of experiments were unsuccessful, but the second yielded better results, six strong healthy plants were selected, three placed in cylinders containing the one, and three in cylinders filled with the other medium; this was done on 21st June, in the middle of July the plants in the non-nitrogenous fluid ceased growing, and gradually faded. The others on the contrary had finely formed roots, and continued to grow. Other four plants were then taken, two of them placed in cylinders with closely fitting lids bored to let the stem of the plant through, then carefully stopped with wadding so that the roots could not obtain nitrogen either from the air or water, two others were grown in porcelain dishes in filter-paper saturated with nitrogenous solution; after a short time one plant of each set died—as did the others later on: the author gives tabular results of analyses, but owing to comparative failure of the experiments they are not of much value. J. F.

Change in the Composition of Potatoes by Ripening. By Saare (*Bied. Centr.*, 1884, 322—324).—Measurements of the average size of starch cells are given, and they are for large cells 215 microm., the greatest difference being 80 microm. The smaller potatoes have round, whilst the larger have elongated cells; the smallest cells measured on the average 115 microm. The author divides the grains into firsts, seconds, and thirds, according to size, as follows: 21 microm., 21—12·5 microm., and under 12·5; these latter are lost to the manufacturers, being washed away. The percentage of these qualities varies in ripe tubers according to variety. During ripening, the total weight, size, and number of tubers, size of cells, sp. gr., dry matter, and starch steadily increase, whilst sugar and fibre decrease; when employing the table for calculating available starch from the sp. gr. of tubers, 1·5 per cent. must be deducted and placed to the account of loss: the number of large grains increases as the potato ripens. E. W. P.

Influence of Krugite on the Percentage of Starch in Potatoes. By KETTE (*Bied. Centr.*, 1884, 355).—The reduction of starch in potatoes by the use of kainite as manure is ascribed to the chlorine present, but if krugite, which contains but very little chlorine, is used, the results are the same—the starch falls considerably in percentage.

E. W. P.

Absorption of Nitrogen by Leguminous Plants. By BOUTELLEAU (*Bied. Centr.*, 1884, 420).—An old vineyard when cleared and manured, was cropped for two years with grain in such quantity that it was calculated all the nitrogen had been exhausted by the corn, yet the third year there was an abundant yield from lucerne and esparsette, sown between the drills.

Another field was well manured with stable manure, $\frac{1}{3}$ was planted with potatoes, $\frac{1}{3}$ with maize, and $\frac{1}{3}$ with vetches, the second year the whole field was sown with wheat, the part where potatoes had been yielded 30 hectolitres, after maize 28 hectolitres, after the vetches 35 hectolitres, although the vetches themselves contained more nitrogen than the maize.

J. F.

Absorption of Nitrogenous Foodstuffs by Plants. By W. O. ATWATER (*Ann. Chim. Phys.* [6], 2, 322—331).—This paper contains an account of a series of experiments carried on during the last seven years in various parts of the United States and Canada. Their object was to ascertain (1) the effect produced on different kinds of plants by the application of mineral manure, such as calcium superphosphate and potassium chloride; (2) the fertilising influence of nitrogen in the form of nitrates and ammoniacal compounds; and (3) the degree of absorption of nitrogen by the plants, from the soil or air.

The experiments were performed with maize, potatoes, and oats; the results may be summed up as follows:—

(1.) Maize absorbs large quantities of the phosphoric acid and potassium chloride manures, but relatively small quantities of nitrogenous substances; it possesses to a high degree the property of obtaining its necessary nitrogen from natural sources. In this respect, maize resembles the Leguminosæ rather than the cereal plants.

(2.) Potatoes seem to be affected by the superphosphates, potash salts, and the nitrogenous manures, and are less apt than maize to procure their nitrogen from natural sources.

(3.) Oats are more sensible than potatoes to a defect of nitrogen, and are more profited by the addition of that element in the form of manure.

V. H. V.

Influence of Water on the Growth of Plants. By HELLRIEGEL (*Bied. Centr.*, 1884, 475—484).—The questions to be answered were: How much water does a plant transpire under normal conditions? How much water must be present in the soil? And how is the proper quantity of water to be retained? Barley was sown in quartz sand, to which had been added sufficient plant-food, and the amount of water present was 60 per cent. of the whole retainable water. The observations showed that the evaporation was much more dependent on the temperature of the air than on the evaporating surfaces; a rising temperature with dryness increased the evaporation, and *vice versâ.* When the temperature remains constant, then the moistness of the air greatly affects the evaporation, which may in dry air be raised to double, and in moist air reduced to one-half that which is evaporated under normal conditions; but this alteration has no effect on the physiological functions of the plant so long as the condition of soil remains normal. A long account of the construction of the apparatus used in this research is given. The rapidity of the air currents has much influence on the evaporation, but the effect is much less than those exerted by warmth and moisture. To observe the effect of light, two healthy and well-grown barley plants were examined, the one under a bell-jar painted white, the other under a clear glass jar, both of them connected with the ventilating apparatus above referred to; other coloured shades were also employed, but all with a similar result, that light has a very considerable influence, but not so great as that exercised by heat and moisture.

Experimenting with sunflowers, the author finds that the rise of the sap is independent of the leaves, and that moisture is carried up by the roots, so long as there is a certain degree of water in the soil; the minimum of moisture seems to be slightly above 8 per cent. of the dried soil. E. W. P.

Formation of Diastatic Ferments in the Cells of the Higher Plants. By W. Detmer (*Ann. Agronomiques,* **10**, 280—281).—Ungerminated grains of wheat contain a little diastatic ferment, but the presence of oxygen is necessary to the further development of this ferment by germination. J. M. H. M.

Relation of Red Colouring Matter of the Phanerogams to the Migration of Starch. By H. Pick (*Ann. Agronomiques,* **10**, 274—276; from *Bot. Centralblatt,* **16**, 281, 314, 343, 375).—In many of the phanerogams, different organs or parts of organs are coloured red, either permanently or at certain periods of their life. The author brings together a number of observations on the formation and optical properties of this red colouring matter, and on its relation to the transportation of starch at certain phases of a plant's life. It seems probable that the colouring matter is derived from tannin, since it is especially noticeable in tannin-producing plants, and experiments seem to show that as the red colour of young leaves increases, so the tannin decreases. The colouring matter itself gives some of the reactions of tannin. In stems, leaves, and fruits (*e.g.*, apples), the red colour is only developed on the parts exposed to light, and young plants which remain uncoloured so long as they are kept in the dark, speedily redden on exposure to light, which may be white, blue, or red indifferently. The absorption-spectrum of the red colour is almost exactly complementary to that of chlorophyll. By exposing portions of a growing leaf of the castor-oil plant under ruby glass, or under a solution of the red colouring matter obtained from beetroot, the author shows that at the end of 15 minutes of sunlight the starch contained in the outer layers of cells has almost entirely migrated to the subjacent cells of the circulatory tissues. By exposure to direct solar light, on the contrary, it is the outer layers of cells which become charged with starch granules. By causing the leaf of a French bean to absorb a solution of sugar, starch may be made to accumulate in the cell layers; on exposing the leaf to red light this starch also migrates to the subjacent tissues.

With regard to the autumnal colouring of leaves, the lower temperature increases the formation of tannin, which becomes changed into the red colouring matter; the starch accumulates by preference in the coloured cells, and disappears with the fall of the leaf.

J. M. H. M.

Osmotic Functions of Living Parenchyma. By Westermaier (*Ann. Agronomiques*, **10**, 271—273).—An account of the part taken, according to the author's theory, by the ligneous parenchyma and medullary tissue in causing the ascent of the sap. An experiment with parenchyma is adduced in support of it. J. M. H. M.

Absorption of Water by Flower Petals. By A. Burgerstein (*Bied. Centr.*, 1884, 422).—The petals of several kinds of composite plants have the property of absorbing moisture, and the underside of the petals is more active than the upper. J. F.

Transpiration in Plants in the Tropics. By V. Marcano (*Compt. rend.*, **99**, 53—55).—The evaporation of water from the leaves of plants in the tropics is practically the same during the night as during the day. One-half to three-quarters of the total evaporation during the day takes place between 6 A.M. and mid-day, the maximum being reached between 10.15 A.M. and noon, whilst from noon to 6 P.M. there is very little evaporation. Evaporation is not sensibly affected by the hygrometric condition of the atmosphere. The maximum in the morning corresponds exactly with the minimum pressure of the sap. C. H. B.

Chemical Phenomena of the Respiration of Plants. By T. L. Phipson (*Chem. News*, **50**, 37).—The author showed in a previous paper (*Chem. News*, 1883) a simple apparatus by which unicellular algæ, supplied constantly with fresh spring-water and exposed to sunlight, gave a constant evolution of oxygen gas. When the carbonic anhydride of the spring-water is exhausted, fresh spring-water is let into the apparatus, whilst the old water is run off, and the evolution of oxygen continues. Instead of renewing the water, carbonic anhydride was supplied to the water after three or four days' running had exhausted its faculty of causing the algæ to give off oxygen. The faculty of evolving oxygen was restored, but not to any great extent, and it became less and less manifest with successive additions of carbonic anhydride.

Experiments show that plants exposed to sunlight are incapable of evolving oxygen in spring-water which has been thoroughly boiled for five minutes, then rapidly cooled and supplied, when cold, with small or large quantities of carbonic anhydride. Evidently something else is required by the plant, and this is hydrogen peroxide, which is decomposed by boiling the water. Its presence can be demonstrated in all spring-water, and it is as essential to the life of the plant as carbonic anhydride is. "Respiration" of plants is due to the reaction which occurs in the plant-cell, between carbonic anhydride and hydrogen peroxide, oxygen being evolved whilst ternary compounds are formed in the plant-cell.

When spring-water is boiled, the *air* collected (after absorption of carbonic anhydride) contains 30–33 per cent. of oxygen, instead of 21 per cent. This difference is chiefly due to oxygen in the state of hydrogen peroxide.

Manganese peroxide in spring-water exposed to strong sunlight can be made to "breathe" like the unicellular algæ. Unicellular algæ in spring-water which has been impregnated with carbonic anhydride after boiling (and so deprived of its hydrogen peroxide), and having abundant contact with the air, will, after several days' exposure to the sun, evolve small quantities of oxygen, showing that, in these circumstances, hydrogen peroxide is slowly formed again.

J. T.

Effect of Depth of Sowing on the Germination and Growth of Plants. By E. WOLLNY (*Bied. Centr.*, 1884, 293—299).—There are no definite results obtained by the experiments described, but the general outcome seems to be that the deeper the seeds or tubers are laid in the soil the more irregular and the later do the plants appear above ground, and there seems to be a definite depth for each kind of seed; but this is again dependent on weather and soil. In experiments with rye, it appeared that deeply sown seed suffered much more from winter cold that the shallow sown seeds, and when potatoes are set deep there is less chance of their being attacked by disease.

E. W. P.

Ratio of Nitrogen to Phosphoric Acid in Seeds. By E. HEIDEN and others (*Bied. Centr.*, 1884, 484—486).—W. Mayer and Arendt have both stated that there exists a definite ratio between the above components of seeds, and Siegert considers, in the case of wheat and rye, that the percentage is affected by manuring; Ritthausen and Pott are of similar opinion, whilst Kreusler and Kern believe that phosphates reduce the nitrogen in the seed. The author has experimented with oats, rye, vetches, and peas, and finds that straw crops are rendered richer in protein by the use of nitrogenous manures, but that by the use of phosphates alone the albumin is neither raised nor depressed. He finds also that the ratio of phosphoric acid to nitrogen in oats and rye is wider than is stated by Mayer, viz., 1 : 1·20—1 : 2·13 (oats) and 1 : 1·44—1·267 (rye). With the other crops, nitrogen does not increase the albumin, but phosphates lower it.

E. W. P.

Composition of American Wheat. By C. RICHARDSON (*Bied. Centr.*, 1884, 420—421).—The author has examined more than 200 samples of American wheat; it will be seen that it contains less moisture, cellulose, and albumin than European wheat. The principal ingredients fluctuate between the following limits :—

	Minimum.	Maximum.	Difference.
Water	6·05	13·52	6·47
Ash	0·80	2 98	2·18
Fat	1·39	3·93	2·54
Starch	67·95	78·95	11·00
Cellulose	0·44	2·76	2·32
Nitrogenous matter	8·05	17·10	9·05

The variations in the nitrogenous matter are large, but in other countries there are even greater differences, and the grain in North America has not yet attained its maximum of nitrogen.

The small amount of moisture is attributed to the American method of harvesting. With the exception of Minnesota, Dakota, and Colorado, American wheats are poorer in nitrogen than those of any other country; the grain from the Atlantic States is the poorest, and it is a curious fact that, as a rule, the grain from those States is smaller than in the Western and Pacific States. J. F.

Analysis of American Barley. (*Bied. Centr.*, 1884, 491.)—Analyses of several American barleys show that they are of a higher class than is generally supposed, and are capable of making quite as good malt as German and Austrian grain. E. W. P.

Occurrence of Vicin in Broad Beans (Vicia faba). By H. Ritthausen (*J. pr. Chem.* [2], **29**, 359—360).—This substance, $C_{28}H_{51}N_{11}O_{21}$, was formerly found by the author (Abstr., 1881, 1158) in the seed of *Vicia sativa*, he now finds it in *V. faba* and *V. minor*. The finely-ground beans are extracted with alcohol (85 per cent.), and the residue obtained after distilling off the alcohol is shaken up with ether to remove the fats, when a substance separates in thin colourless needles, which give the characteristic reaction for vicin, viz., after boiling with a few drops of hydrochloric acid, and allowing to cool, a deep blue solution is obtained on adding a trace of ferric chloride and then ammonia in excess. P. F. F.

Composition of Lupines. By E. Flechsig (*Landw. Versuchs-Stat.*, **30**, 415—447).—This paper is a report of numerous analyses of the seeds and stalks of lupines. Full details are given in tables which accompany it—one of them presents a summary of results (p. 1406). It will be observed that there is a great difference between the nitrogenous contents of the different varieties. *L. Cruikshanksii* heads the list with 47 13 per cent. proteïn, the lowest being *L. hirsutis* with only 27·81 per cent.; their contents in alkaloïds, estimated by Taüber, are also very variable. *L. albus*, which is unfitted for cattle food, because of its great bitterness, contains less than other varieties which are readily eaten; bitterness is therefore not a measure of the alkaloïds present; the amount of fat also is very variable, and varieties containing most of it have least woody fibre.

E. W. P.

Poisonous Effects of Arsenic, Zinc, and Lead, on Vegetable Organisms. By F. Nobbe and others (*Landw. Versuchs-Stut.*, **30**, 381—422).—These experiments were undertaken to ascertain the effects of applying those metals directly to plants in process of growth: the subjects of experiment were plants of peas, oats, maize, and buckwheat. The mode of culture was that known as water culture, in large glass cylinders supplied with the nutritive solution employed at the experimental station of Tharaud; the arsenic was added to the different vessels in the form of potassium arsenite, in four degrees of strength, viz., 3, 33, 333, 1000 mgrms. As per litre.

The plants were introduced into the vessels in a healthy condition, and similar plants were reserved as control. In all cases, the results were fatal, but the time varied not a little, the plants treated with the least quantity recovering for a brief period, but eventually succumbing. With all the plants, the upper leaves were first affected, the decay gradually attacking the stems; the appearance of the roots was peculiar, their growth ceased, and they became tinged with a yellow shade. Four plants of maize were taken and tested for arsenic; that treated with 3 mgrms. arsenic yielded none, that with 33 mgrms. nothing, with 333 mgrms. equal to 0·1 mgrm., and that with 1000 mgrms. 0·5 mgrm. AsO_3.

The authors think that the action of the arsenic consists either in causing an excessive transpiration from the plants, or that it prevents the absorption of moisture by the roots. This induced them to make further experiments with plants in a dark atmosphere saturated with moisture, which they obtained by growing them under bell-glasses with necessary precautions; as usual, growing similar plants to control the experiments. Both sets died, but those under glasses more slowly than the others, and the result leads the authors to believe the protoplasm of the root cells is the vulnerable point, the poison destroying the power of osmose by the roots.

Further experiments were made as to the limit of dilution which would be injurious to vegetation, and it was found that the presence of As 1 to 1,000,000 = 1 mgrm. of As per litre, exercised a decidedly injurious effect on the normal growth.

The authors next directed their attention to the quantitative estimation of the arsenic actually absorbed by the plants, and give the results in tables, which show the quantities to be extremely minute, the roots containing most and the leaves least.

In order to ascertain the rapidity of absorption, several experiments were made by submitting plants to the influence of the poison for periods varying from five minutes to an hour, then carefully washing the roots and replacing the plants in the normal solution, it was found that some possessed greater powers of resistance than others.

Experiments with salts of lead and zinc were made in a similar manner; the effects of the latter were very similar to those of arsenic, the death of the plant rapidly following considerable doses: the salts of lead are not so poisonous to vegetation as zinc; $\frac{1}{1000}$th part of the latter killed a plant in three days, while another plant treated with the lead salt of same strength lasted 41 days. Carbonate of zinc is the most injurious of all the salts tried, and the plants absorb more of the metal from it. The solutions were daily agitated, so that the roots came well into actual contact with the insoluble precipitates, in fact, were covered with the suspended matter. Both metals are therefore poisonous, and in small quantities act by decreasing the yield of the plant.

The article contains several tables of details and descriptions of the processes employed by the authors for the estimation of the three metals. J. F.

Behaviour of Zinc Salts with Plants and in the Soil. By A. BAUMANN (*Landw. Versuchs-Stat.*, **31**, 1—53).—In view of the conflicting statements made by various writers as to the action of zinc salts on plants, the author set himself to work to thoroughly investigate this subject. The experiments of Freytag had shown that in a soil containing 5 per cent. of zinc oxide various kinds of cereals flourish, and absorb also a small quantity of zinc, but no attention had been given to the nature of the soil used. The author began first by determining the action of zinc sulphate on plants grown in a nourishing solution containing calcium and potassium nitrates, iron and potassium phosphates, and magnesium sulphate. To these was added zinc sulphate in varying proportions, so that four solutions were obtained containing 10, 5, 1, and 0·1 mgrm. Zn per litre respectively.

Thirteen species of plants of seven different families were experimented on, and in each case the plants were chosen as nearly as possible alike, and one of each sort placed in the solution above described, but containing no zinc. The results showed that the action of zinc sulphate when given to the plant in solution is more injurious than has generally been supposed. All plants, with the exception of the Coniferæ, speedily die in a solution containing 10 mgrms. zinc to the litre, although traces of zinc in solution are harmless: the proportion in which all the plants throve undisturbed was 1 mgrm. per litre, the only exception being *Raphanus sativus*. The limit at which the injurious action begins lies between 1 and 5 mgrms. per litre; the only plant that survived a 5 mgrm. solution, with the exception of the Coniferae, was *Onobrychis sativa*. The latter also resisted longest the action of the 10 mgrms. solution, dying in 194 days, while *Trifolium pratense* died in 16 days, and the Coniferæ flourished undisturbed. Older plants of the same kind perish sooner than younger ones, probably because of the greater number of leaves in the former and the relatively increased transpiration, so that greater quantities of the poison are absorbed in a given time. The action of the zinc always shows itself by a change in the green colour of the leaves. When, however, the zinc solution is poured on to the soil, its action on plants growing therein may differ according to the nature of the soil: this was made evident by experiments with the same plants employed before, but grown in two kinds of soil—one a lime soil rich in humus; the other sandy, free from humus, and containing very little lime. The plants were set in pots, there being six experiments with each species, three in lime and three in sandy soil. Two pots (one of each kind of soil) were treated every day with distilled water, two with a solution of 20 mgrms. Zn per litre, and two with a solution of 40 mgrms. In the sandy soil, all the plants treated with zinc solution died, showing that the soil was not able to convert the zinc sulphate into insoluble and harmless forms. With the calcareous soil, however, the case was different; the plants throve better which had the zinc solution poured on them, doubtless because other elements, such as potassium, calcium, and magnesium were thereby converted into soluble forms. The action of the zinc seemed therefore to depend on the composition of the soil, and further experiments were made to ascertain the quantity of zinc rendered insoluble by passing through various soils. The results showed that the absorptive power of a pure humus soil is the greatest: wood humus absorbed 200 times as much as the sandy soil above referred to, and over 800 times the amount absorbed by a sandy soil from the keuper. Next to pure humus in absorptive power came a rich clayey soil containing lime, then the other soils according to their richness in humus and alkaline earths. Alumina appears to be a very active agent in rendering zinc sulphate insoluble, the sulphuric acid being also thrown down at the same time. The presence of zeolites in soils causes a decomposition of zinc sulphate, sulphates of calcium, magnesium, &c., going into solution. Direct experiments with calcium and magnesium carbonates showed that these have the power of precipitating the whole of the zinc from solution.

The question as to whether insoluble zinc salts, introduced as such into the soil, prove injurious to plants has been answered by all previous workers in the negative. The author tried the solubility of zinc carbonate and sulphide in water charged with carbonic acid, and found that solution took place in both cases to a considerable extent, so much so, that plants immersed in the liquid perished as in solutions of zinc sulphate: the action of the carbonic acid was, however, considerably lessened by the presence of other carbonates, so that this fact can have no bearing on the solution of zinc by water in the soil, at least not to any injurious extent: he concludes, therefore, that insoluble zinc salts in the soil are harmless to plants.

The specific action of zinc on the vegetable organism consists in a destruction of the chlorophyll colouring matter, and a consequent stoppage of the whole process of assimilation. J. K. C.

Ensilage. By WEISKE and others (*Bied. Centr.*, 1884, 464—469).—Lupines, maize, and lucerne were siloed in barrels, and after some time the silage was analysed and compared with the fresh substance.

The analyses were conducted in the usual way after the silage had been extracted with cold water and the volatile acids (butyric) estimated in the extract by volatilisation, and the non-volatile (lactic) by titration Below are given the analytical results.

Lupines (fresh) lost 3 per cent. water and 22 per cent. dry matter.

	Fresh.	Silage.

Holdefleiss examined two specimens of green maize silage which had lost, the one about 40—50 per cent. dry matter, the other about 10 per cent., and this latter had laid in cocks on the field for four weeks. He recommends this plan, as a good fodder is produced, and the harvesting does not clash with that of the potatoes and roots. Wood gives analyses of hay silo which contained 0·34—0·55 per cent. acetic acid. G. Nasir has followed Goffart's method, in which the silage does not become acid, and finds it successful. (See Fry's method in "Mark Lane Express," 1884. Abstractor.) E. W. P.

Presence of Mildew, &c., in Cattle-foods. By A. Emmerling (*Bied. Centr.*, 1884, 472—475).—Various forms of fungoid growths have been found in earth-nut and other cakes, and may be obtained by treating the powdered cake with a little water for 24 hours at 35°. The principal forms of schizomycetes observed were micrococcus, bacteria, and bacilli; at times leptothrix and cladothrix were observed, and in a few cases sarcina and spirilla. Of the 52 samples, 61 per cent. contained some of these growths; of cotton-cake and meal, 40 per cent. were infected, many containing a very high percentage of bacteria and bacilli, and it is to the presence of so many in this kind of food that the ills which often follow its use may be ascribed. Short accounts about several other cakes (linseed, &c.) are given. E. W. P.

Cotton-cake as Fodder for Milch-cows. By De la Tréhonnais (*Bied. Centr.*, 1884, 311).—Under adverse circumstances decorticated cotton-cake considerably raised the yield of milk. E. W. P.

Cultivation of Potatoes. By J. Timm and others (*Bied. Centr.*, 1884, 487—490).—Timm finds Chicago Early the heaviest cropper, and that Richter's Imperator is the best to grow for importation to England. An anonymous writer has tried growing large and small sets to discover which gives the best yield, and finds that it is best to set one large set (say 100 grams) instead of smaller sets of 25 grams; also that 4 sets of 25 grams apiece yield as well as one set of 100 grams. Märcker has come to a similar conclusion. E. W. P.

Horse-chestnuts as Cattle-food. By Kaehler (*Bied. Centr.*, 1884, 386).—According to the author, the fruit of the horse-chestnut deserves more attention as fodder than it has yet received; he has fed cattle with it for eight years, the only objection being the smallness of the supply. He gave each animal 2 metzen (about 7 litres) twice daily; they were eaten readily, especially when young, when they just commenced to fall. Swine did not take to them so readily, but the author thinks that if they were shelled and deprived of their bitter principle they would be eaten. A small stock of Southdown sheep was fed regularly every winter. Some of the chestnuts were dried and ground; they were then readily eaten by young cattle. Klein's analysis gave for the meal 10·06 per cent. of proteïn, 4·83 per cent. of ash. J. F.

Drying of Exhausted Beet-residues. By J. H. Reinhart (*Bied. Centr.*, 1884, 415).—The exhausted sections of beet are found to yield a very large proportion of their moisture to pressure, provided they have been previously torn so as to open the cells. A mass is thus obtained containing 20—40 per cent. dry matter, easily treated afterwards by ordinary means of drying, and capable of being made into convenient cakes, &c., for purposes of fodder. J. F.

How to bring Heavy Raw Soils into Cultivation. By E. Heiden and others (*Bied. Centr.*, 1884, 437—446).—These experiments were conducted during the years 1869—78, and had for their object the most economical and satisfactory treatment of uncultivated land, so as to render it fit for cropping. The manures were lime, potassium and ammonium sulphate, and calcium phosphate, the crops being cereals, leguminosæ, and potatoes. Full details of the experiments are given, accompanied by several tables. The results are as follows:—First season: lime in autumn, plough in and ridge, and in spring plant potatoes, but not straw crop, giving also nitrogen and phosphates; next follow with oats manured as for potatoes, afterwards vetches or peas with bone-meal, again leaving the ground in the ridge during winter. Fourth crop should be potatoes with potash as kainite, this mixed with soil should be ploughed in with stubble, and nitrogen and phosphates applied in spring. E. W. P.

Preparation of Farmyard Manure. By P. P. Dehérain (*Compt. rend.*, **99**, 45—47).—Straw oxidises only under the influence of an aërobic ferment, and seems to be free, as a rule, from active anaërobic ferments. Farmyard manure can undergo two kinds of fermentation, viz., neutral, in which carbonic anhydride, methane, and nitrogen are given off, and acid, in which carbonic anhydride, nitrogen, and hydrogen are evolved, and butyric acid is formed. Occasionally both kinds of fermentation take place at once, and the evolved gases contain both methane and hydrogen, but in such case one gas is always present in much larger proportion than the other. It seems probable that the anaërobic ferments present in farmyard manure are derived from the alimentary canals of the animals, and according to their relative abundance and the conditions in which they are placed, they produce one or the other kind of fermentation. C. H. B.

Fermentations of Farmyard Manure. By P. P. Dehérain (*Ann. Agronomiques*, **10**, 385—409).—*Aerobic Fermentation of Straw.*—At 40° straw cut into small pieces and moistened with water gives rise to an evolution of carbonic anhydride which is nearly constant for the first few days and then gradually diminishes. This action is due to microbes, for it is almost entirely prevented by chloroform. The liquid contains a multitude of small and very active vibrios. At 110° and 120°, however, slight oxidation occurs without the intervention of ferments.

Aerobic Fermentation of Manure.—The gases evolved by different layers of a manure heap in different stages of fermentation have been examined. The gas evolved near the top of a heap is composed of carbonic anhydride and nitrogen, that from the middle contains marsh-gas in addition, and that from the bottom, when there is no access of air, often contains nothing but carbonic anhydride and marsh-gas. The rise in temperature of a fermenting dung-heap is occasioned entirely by atmospheric oxidation, and does not take place if air be excluded, but the production of marsh-gas goes on in the absence of air. A drop of liquid from a fermenting dung-heap is found to be full of very active elongated microbes refracting light strongly when not exactly in focus; they are much larger than the organisms found in the infusion of straw. The oxidation of the carbon of this liquid is greatly diminished but not prevented by the addition of chloroform; the evolution of carbonic anhydride in a dung-heap appears therefore to be due partly to fermentation and partly to simple oxidation.

Anaerobic Fermentation of Straw.—If cut straw be placed in water and kept at 40—45° with or without the addition of alkaline phosphates, anaërobic fermentation occasionally takes place as soon as the oxygen of the liquid has been used up, and results in the production of hydrogen or marsh-gas. This fermentation is however exceptional.

The marsh-gas fermentation of farmyard manure may be observed by placing the manure in a flask and collecting the evolved gas over mercury. The evolution of gas proceeds for some days and then almost stops; it may be renewed by temporary exposure of the contents of the flask to the air; after a few days it will again stop, and may be renewed as before. If the flask is heated for some hours at 85°, or if chloroform is added, the production of marsh-gas ceases. The liquid portion of the manure contains short brilliant vibrios, accompanied by a great number of spores. An alkaline reaction is maintained throughout the fermentation. Occasionally hydrogen instead of marsh-gas is produced by the fermentation of farmyard manure; in this case an acid is developed, which appears to be butyric acid. The organism present in this case is exactly similar to that which is present when marsh-gas is produced, and does not resemble the ordinary butyric ferment. When a solution of sugar or dextrin with suitable minerals is fermented with a drop or two of the liquor from a manure heap, hydrogen is produced, but when paper is used instead of sugar or dextrin the fermentation is slower, and marsh-gas is evolved. Sometimes, however, the two gases appear together whichever material is employed. When straw is used as the subject of a fermentation excited by a drop of manure liquor, marsh-gas is more frequently produced, generally free from hydrogen, but sometimes mixed with it. As much as 500 c.c. of gas can be obtained from 10 grams of straw in 48 hours. On the whole it appears probable that there are two distinct ferments, one causing the evolution of hydrogen and the other that of marsh-gas, and that they are conveyed to the manure heap from the intestinal canals of farm animals. Tappeiner has found in the intestinal canal of the Herbivora organisms which attack cellulose, and cause the evolution of the two gases mentioned. J. M. H. M.

Loss of Nitrogen during the Fermentation of Farmyard Manure. By H. Joulie (*Ann. Agronomiques*, 10, 289—301).—Six mixtures were made of broken straw 75 grams, horse-droppings 50 grams, putrid urine (human) 300 c.c., and distilled water 275 c.c. Each of these mixtures was placed in an inverted bell-glass furnished with a tubulure, through which passed a cork and glass tube to conduct away the excess of liquid into a conical beaker. To restrict evaporation, the bell-glasses were covered with glass plates. The first mixture received no addition. To the other five were added: (2), 10 grams of mineral phosphate of lime; (3), 10 grams mineral phosphate and 10 grams of gypsum; (4), 10 grams mineral phosphate and 10 grams calcium carbonate; (5), 10 grams calcium carbonate; and (6), 10 grams gypsum. A seventh mixture was also made of straw 150 grams, horse-droppings 200 grams, urine 400 c.c., water 850 c.c., and this mixture was placed in a larger bell-glass than the rest, so as to expose a greater surface to the air. The mixtures were allowed to remain from February 18th, 1883, to September 1st, 1883, and every two or three days the liquor in the beakers (representing the drainings from a dung-hill) was poured back over the manure in the bell-glasses. On April 15, there not being enough liquid to moisten the samples, 100 c.c. of water was added to each. On September 1st, 1883, the experiments were terminated by transferring the liquid portion of each mixture to a litre flask, and making up to the mark with the washings from the solid portion. The amount of dry matter contained in solid and liquid was estimated in each case, and compared with that originally present. The humus acids contained in the several liquors were also estimated by precipitation with hydrochloric acid, and the nitrogen present in the three forms (nitric, ammoniacal, and organic) was determined in both the solid and liquid portions of each sample. In addition, complete analyses were made of Nos. 1 and 7 (which received no addition), proving them to have the same general composition as well fermented farmyard manure, except that they were deficient in potash and magnesia, in consequence of the substitution of human urine for that of cattle. The same changes, in fact, had been produced as occur in the fermentation of dung, the length of time during which the experiments lasted compensating for the lower temperature at which they were carried on. The loss per cent. of dry solid matter present, and the amount of brown humus acids formed are shown in the annexed table :—

	Loss per cent. of dry matter introduced.	Brown acids per cent. of organic matter introduced.
No. 1. Without addition........	53·71	1·386
„ 2. With phosphate	57·93	0·924
„ 3. With phosphate and gypsum............	49·74	traces
„ 4. With phosphate and carbonate	56·35	0·924
„ 5. With carbonate..........	58·00	0·963
„ 6. With gypsum	52·61	traces
„ 7. Without addition........	56·20	1·309

Gypsum, therefore, in the proportions used, almost totally prevents the formation of the brown humus acids.

The amount and distribution of the nitrogen present in the materials and in each fermented sample, are shown in the annexed table :—

		Nitrogen, grams.

There is thus in every case a large loss of ammoniacal nitrogen, ranging from 49·47 to 85·30 per cent. of the quantity introduced. On the other hand, there is a gain of organic nitrogen, ranging from 35·15 to 63 per cent. of the original quantity. A portion of the ammoniacal nitrogen has therefore become fixed on the organic matter, mostly in the insoluble form. The following table shows the proportion of original ammoniacal nitrogen which had become thus transformed, and, on balance, the proportion absolutely lost:—

	Ammoniacal nitrogen per cent. of that introduced.		
	Disappeared.	Transformed.	Absolutely lost.
No. 1. Without addition	49·96	24·82	25·14
„ 2. With phosphate	49·47	20·09	29·38
„ 3. With phosphate and gypsum	71·43	17·09	54·34
„ 4. With phosphate and carbonate	61·40	17·83	43·57
„ 5. With carbonate	70·41	13·84	56·57
„ 6. With gypsum	67·34	19·98	47·36
„ 7. Without addition	85·30	44·54	40·76

This important and absolute loss of nitrogen, ranging from 25·14 to 56·57 per cent. of the ammoniacal nitrogen originally present, must be due either to volatilisation of ammonium carbonate or to destruction of ammonia by the fermentative action of microbes. Seeing that the temperature in these experiments was much lower than prevails in a dung-heap, and that evaporation was restricted as much as possible, the author concludes that the loss in actual practice is still larger. A comparison of experiment 7 with experiment 1 proves that this loss is greatly increased by the larger surface exposed to the air in a thin layer of manure.

Of the substances so often recommended to be added to manure-heaps as absorbents of ammonia, it is seen that gypsum, at any rate, exercises a positively injurious effect, whether used alone or in conjunction with mineral phosphate. This effect is accompanied by a slight nitrification, and an almost total absence of soluble brown acids—the liquors in experiments 3 and 6 being almost colourless. The loss of nitrogen is also increased by carbonate of lime.

J. M. H. M.

Loss of Nitrogen during the Fermentation of Farmyard Manure. By C. Brame (*Compt. rend.*, 99, 390—392).—The floor of the stable is dug out to a depth of 0·6—1·5 metre, the sides of the excavation plastered to render them air-tight, a layer of light soil, 0·3—0·4 metre in depth, is placed on the floor, and over this a layer of straw, furze, &c., to a depth of 0·06—0·1 metre. The liquid excrement from the animals filters through the straw, &c., into the soil beneath, which, after a time, becomes black, and forms an excellent manure. The upper part of the straw remains dry, and the health of the animals is improved. By this method the loss of ammonia during fermentation is practically prevented. C. H. B.

Loss of Nitrogen by Organic Matter during Putrefaction. By A. Morgen (*Landw. Versuchs-Stat.*, **30**, 429—436).—The author refers to König's researches on this subject, with the general results of which he agrees. Nitrogen certainly escapes in a gaseous form which cannot be retained, like ammonia and nitric acid, by ordinary reagents, and he recommends farmers to add either gypsum or earth containing humus to fermenting bone-meal, fish guano, and such like matters, and to keep the heap moist.

The author believes the theory of the process to be that ammonia is formed during putrefaction, in the presence of oxygen. If no absorbent is present, such as gypsum, kainite, earth, &c., and if the moisture is insufficient, the decomposition continues, and the oxygen burns up the ammonia into nitrogen and water; in the presence of suitable absorbents, the process is arrested at the formation of ammonia. The author refers to the researches of Carius, de Saussure, and Armsby, as supporting his view that the process is one of oxidation caused by free access of air to the decomposing mass.

J. F.

Comparative Nitrifying Action of certain Salts. By P. Pichard (*Ann. Agronomiques*, **10**, 302—315).—The salts experimented with were the carbonates and sulphates of potassium, sodium, calcium, and magnesium. Each of these salts was added, in something like the proportion actually found in soils to a mixture of powdered arachida cake with pure siliceous sand, the arachida cake representing the nitrogenous organic matter of soil, and being present in such quantity as to give N = 0·15 per cent. of the mixture. In two instances, the arachida cake was replaced by ammonium sulphate. The mixtures were made up May 30, 1883, and were placed in glass vases and kept moistened with water and sheltered from rain and dust. On August 30, slight nitrification had taken place in the mixtures containing ammonium sulphate, but not in those containing arachida cake. The author attributes this slight nitrification of the ammonium sulphate to simple oxidation. On August 31, about 0·75 per cent. of dry soil was added to each vase in order to start nitrification. On March 15, 1884, the quantity of nitrate formed in each mixture was estimated in an aqueous extract by the indigo process. The percentage of total nitrogen added, which had nitrified by this time, was in the mixture containing potassium carbonate 4·96, sodium carbonate 2·14, calcium carbonate 26·15, magnesium carbonate 24·47, potassium sulphate 12·59, sodium sulphate, 15·61, calcium sulphate 28·82, magnesium sulphate 3·94. In all the above mixtures, the sand employed was coarse. In a similar set of vases in which fine sand was employed, the percentages of total nitrogen nitrified were as follows: with potassium sulphate 20·86, sodium sulphate 24·96, calcium sulphate 46·29, magnesium sulphate 11·55, no salt added, 4·86. The two mixtures containing ammonium sulphate instead of arachida cake yielding the following results: coarse sand with calcium carbonate

3·86 per cent. of the nitrogen nitrified, with magnesium carbonate 3·18 per cent. The remainder of the ammonia in both those cases had disappeared, the author supposes by conversion into carbonate and volatilisation. These experiments seem to the author to demonstrate the very great superiority of calcium sulphate as a nitrifying agent, and he arranges the salts experimented with in the order of the figures given above.* He also draws a number of conclusions as to the employment of gypsum and its mode of action as a dressing for soils. J. M. H. M.

Comparison of Peat and Straw Litter. By M. FLEISCHER (*Bied. Centr.*, 1884, 500).—Under nine cattle was strewn, for six days, 250 kilos. of rye straw, and for another six days 187·5 kilos. of peat litter; the cattle were fed with chaff, hay, roots, and grains. The litters yielded, of dry matter, 17·98 per cent. (straw) and 17·11 per cent. (peat). The whole was analysed, and the results are given in the original, which show that the peat is better adapted than the straw to retain the easily soluble nitrogenous matter. E. W. P.

Utilisation of Human Excreta. By K. ENGLER (*Bied. Centr.*, 1884, 411—412).—This paper is a report of the working of a process in use at Freiburg for the treatment of sewage. The solid matters are precipitated by a preparation of manganese, and subjected to a modified process of distillation. The poudrette obtained contains 2·1 to 3·0 per cent. of nitrogen. The water from the operation contained 12½ to 15½ per cent. of solid matter with ammonia 0·02 per cent. This water is run into deep pits. As yet, the wells in their neighbourhood have not been contaminated. J. F.

Chili Saltpetre for Sugar-beet. By F. MÜLLER and others (*Bied. Centr.*, 1884, 303).—Müller remarks that the start given to the roots by this manure enables them to resist the attacks of insects. Eggers applied Chili saltpetre to some roots, to others ammonia and phosphates, all of equal money value. All roots suffered from wire-worm, and the saltpetered roots polarised lower in the middle of September, but in October no difference could be distinguished between these and the other crop, except that the yield was higher where the Chili saltpetre had been used. In the succeeding year, as the saltpetre seemed to have lowered the percentage of sugar, part of it was replaced by phosphates, but with a similar result. Kahmann thinks this manure of no great value. Deecke finds the character of the soil an important factor, humous soils requiring ammonia, cold poor soils Chili saltpetre. Weinrich considers the ratio of nitrogen to phosphoric acid may be 2 : 3 without harm ensuing; but all concur in considering that roots manured with Chili saltpetre ripen the soonest. E. W. P.

---

* The author does not seem to have made any examination for *nitrites* in his mixtures. Judging from the extent of nitrification, nitrites must have been present in most, if not in all, and their presence entirely vitiates any conclusions drawn from estimations by the indigo process as to the comparative amounts of nitrogen nitrified.—J. M. H. M.

Chili Saltpetre for Barley. By Klawitter (*Bied. Centr.*, 1884, 355).—The application of this manure to barley in Posen was followed by an increased yield when 1 centner per morgen was given at one time; to apply one-half that quantity at sowing and the other half as top dressing was of no advantage. E. W. P.

Manufacture of Bone-meal. By J. König (*Bied. Centr.*, 1884, 300—303).—Bone-meal prepared by the old and new methods, removal of the fat by steam, and removal by means of benzene, are compared, with the result that the modern process yields a manure freer of fat, and therefore far more valuable as a manure, and at a lower price; moreover the percentages of nitrogen and phosphates are raised. E. W. P.

Manurial Experiments at Reims. By A. Manteau (*Bied. Centr.*, 1884, 383—386).—Ten farmers in the vicinity of Reims agreed to carry out certain experiments on similar lines. The soil of each plot was analysed by Joulie, and ten mixtures of manures were made up and applied, so as nearly as possible to supply the deficiency of fertilising ingredients in the soils. The whole of the plots were then sown with wheat.

Unfortunately the season in which the experiment was carried out was most unfavourable, the winter being very wet, the spring cold, and the summer rainy, so that the results differed very little in all the plots. The results might have been valuable had the season been normal. J. F.

Manuring Barley. By H. Wäterling (*Bied. Centr.*, 1884, 305). A mixture of 100 kilos. Chili saltpetre with 50 kilos. superphosphate per morgen brought the highest yield of grain and straw, whilst "super" alone brought less than the unmanured land. This heavy manuring paid for itself and left a surplus, which was not the case with the other plots. E. W. P.

Potatoes with Lime as a Manure. By E. Heiden and others (*Bied. Centr.*, 1884, 449—453).—Potatoes are subject to "scab," of which there are two forms; the one due to *Rhizoktonia solani* (Kuhn) consists of slight elevations on the skin, and does not deteriorate the tuber, whilst the other penetrates deeper, forming depressions penetrating below the skin. The origin and prevention of this latter form of disease is as yet unknown. It has heretofore been ascribed to lime, but fresh lime in the soil does not produce the disease, although in the second year of liming the disease appears. Some (Heiden) hold that the decomposition of the ammonium salts in the soil by the lime is the cause, but the quantity of free ammonia likely to be present (0·003 per cent.) is too small to cause corrosion (Märcker). Schulze states that potatoes manured with farmyard manure are most liable to the disease. Heiden finds that lime greatly assists potatoes, in that it sets free ammonia, which is then converted into nitrates. Märcker adds that this aid to ripening has been often observed, and it also is produced by marling, but he doubts the explanation, for

nitrates retard instead of assisting the ripening process. In the place of Heiden's theory, he proposes as a reason that lime assists the formation of carbonic anhydride; this then sets free a larger quantity of soluble nutriment, and also phosphates, which are known to assist ripening.
E. W. P.

Beet Culture with Artificial Manures. By PETERMANN (*Ann. Agronomiques*, 10, 241—262; *Bied. Centr.*, 1884, 370—383).—The experiments detailed in this paper were conducted on the loam soil of Gembloux, containing per hectare to a depth of 20 cm. about 800 kilos. N, 1700 kilos. P_2O_5, 2000 kilos. K_2O, 6200 kilos. CaO, and 4400 kilos. MgO. Over 90 per cent. of the phosphoric acid is soluble in ammonium citrate. Nitrogenous manures are usually found very efficacious, whilst potash produces little or no effect. Although the soil is well supplied with phosphoric acid, the repeated use of Chili saltpetre alone as a manure is found after a few years to necessitate the addition of artificial phosphates. The special purpose of the three years' experiments here described was to ascertain the best mode of application of the artificial manure, and the influence, if any, of the mode of application on the elaboration of sugar.

Experiments were made on small plots in 1881 and 1882 with the manure distributed in three different ways—(1) broadcasted and raked in; (2) broadcasted and buried with the hoe; (3) broadcasted and ploughed in. In 1881, the manure consisted of a mixture of sodium nitrate, potassium chloride, and superphosphate; in 1882, the mixture contained sodium nitrate, dried blood, ammonium sulphate, potassium chloride, bone superphosphate, and precipitated phosphate. The results of both years' experiments on the small scale were largely in favour of the deeper mode of burying the manure, and preparations were accordingly made for testing the question on a larger scale in 1883. In order to determine the natural variation in produce of the different plots of the experimental field, ten plots were marked out in 1882, and cropped without manure under precisely similar conditions. The weight of roots obtained on each plot varied from 59,375 to 62,157 kilos. per hectare, mean 60,571; the leaves from 45,162 to 58,005 kilos. per hectare, mean 50,750. The percentage of sugar in the roots varied from 9·13 to 10·07, mean 9·53. Having thus tested the homogeneity of the plots, they were in 1883 again sown with sugar-beet, and manured with a mixture of 500 kilos. (per hectare) of sodium nitrate and 650 kilos. superphosphate. The manure was broadcasted on the plots two days before the seed was sown, and was buried to the various depths required by the harrow or the plough. One pair of plots was left without manure, and to another pair the manure was applied by being drilled in with the seed. The season was much less moist than the two previous ones, and the temperature of the last three months of vegetation was high. The roots were lifted on October 10, and were weighed, and the percentage of sugar subsequently determined in them; the leaves were also weighed. The following table gives a summary of the principal results:—

No.	Mode of manuring.	Roots per hectare.	Leaves per hectare.	Per cent. of sugar.	Sp gr. of juice.
1	Unmanured	47,827	25,685	11·26	1·0610
10	„	50,792	23,753	11·67	1·0610
2	Harrowed in	59,142	32,320	11·45	1·0601
9	„	57,592	30,929	11·47	1·0605

The increase of crop produced by the manure is thus 18·73 per cent. (of the unmanured crop) when the manure is simply harrowed in, 33·29 per cent. when buried to a depth of 0·12 metre, 41·14 per cent. when buried to a depth of 0·22 metre, and 24·30 per cent. when buried between the rows. These results are in the same order as those of the two previous years, and lead the author to the following conclusions:—Artificial manure composed of superphosphate and Chili saltpetre, with or without sulphate of ammonia or organic nitrogen, applied in spring on a loamy soil for the growth of sugar-beet, should be buried by deep cultivation. Burying by the harrow or by superficial cultivation is insufficient to extract from the manure its maximum effect, the absorbent power of the loam being too powerful to allow the nutritive ingredients to descend, even in rainy seasons, to the deep layers of the soil whence the roots of the beet draw their nourishment.

Differences in the mode of applying the manure are without sensible influence on the elaboration of sugar.

Drilling in the manure with the seed delays the appearance of the plant by several days, and may seriously compromise the crop in a spring without rain and with drying winds. Under favourable climatic conditions the plant may regain the lost growth, but will not give the same crop as when the manure is buried by deep cultivation, and the plants have consequently suffered no delay in appearing above ground.
J. M. H. M.

Manuring of Vineyards. By A. Stutzer (*Bied. Centr.*, 1884, 413).—Experiments on manuring of vines carried out by the author have proved as successful in 1883 as in previous years, and equally in favour of artificial manures. Of 100 average vines, the yield was—

Manured with stable manure	79·4 kilos.
„ artificial manure	96·9 „

The artificial manure employed contained 6 per cent. soluble phosphoric acid, 2½—3 per cent. ammoniacal nitrogen, and 6 per cent. potash; it costs about 1½ pfenning per vine. J. F.

Manuring of Hops. By E. POTT (*Bied. Centr.*, 1884, 412—413).—Hops are considered to require heavy manuring; as a rule, stable manure and the cleaning of cesspits are applied to them. The author, after inspection of the systems pursued in various parts of Germany celebrated for hops, thinks the very high manuring with those organic matters wrong. They increase the yield at the expense of the quality. He thinks they should be used as a well-made and matured compost. Artificial manures should yield good results, 3—6 kilos. bone-meal per square metre with 1½—2 kilos. Chili saltpetre in soils poor in phosphates, 6—15 kilos. potassium chloride, with or without Chili saltpetre, in soils poor in potash. J. F.

Analytical Chemistry.

A Simple Method of Estimating Halogens in the Side-chains of Aromatic Compounds.—By K. E. SCHULZE (*Ber.*, 17, 1675—1676).—A weighed quantity of benzyl chloride (or a compound of similar constitution) is introduced into a flask with an excess of a hot saturated alcoholic solution of silver nitrate, an inverted condenser adapted, and the mixture boiled for five minutes. The precipitated silver chloride is then filtered off through a weighed platinum crucible, the bottom of which is perforated and covered with a layer of asbestos, the filtration being assisted by a suction-pump. The silver chloride is washed with alcohol, then with hot water acidulated with nitric acid, and finally again with alcohol; the crucible is lastly ignited and weighed. This method has the advantage of quickness, and is a means of distinguishing between a halogen in a side-chain, and a halogen directly united to an aromatic nucleus. Bromomethylnaphthalene may, for instance, be boiled for several hours with alcoholic silver nitrate without yielding silver bromide. A. K. M.

Determination of Nitrogen by Combustion with Calcium Hydroxide. By S. W. JOHNSON (*Amer. Chem. J.*, 6, 60—63).—It has been shown that soda-lime may be replaced by a mixture of sodium carbonate and calcium hydroxide, and it is found that under proper conditions calcium hydroxide alone may be used. Quicklime is slaked, dried, and powdered. Using 0·5 gram of substance containing up to 8 per cent. of nitrogen, a tube of 14 inches is long enough; substances richer in nitrogen require longer tubes. The mixture of substance and slaked lime must not quite half fill the tube, the long anterior layer of slaked lime must be brought to a full red heat before heating the mixture, and must be so kept throughout the combustion; the combustion may be rapid; the tube is cooled below a red heat before aspirating; cochineal is to be preferred to litmus as indicator in titrating the standard hydrochloric acid used to absorb the ammonia. In the analysis of strychnine, a very small quantity of substance and a long tube must be taken. A number of test analyses are given proving the accuracy of the method.

H. B.

Estimation of Ammoniacal Nitrogen in Soils. By A. GUYARD (*Bull. Soc. Chim.*, **41**, 337—339.)—It is proposed to estimate the total ammoniacal nitrogen of soils in the following way, by which not only are the ammoniacal salts separately estimated, but also the nitrogenous organic matter which is readily convertible into ammonia. The soil is boiled successively with water and (1) 10 per cent. of calcium carbonate prepared by precipitation, which evolves ammonia only from ammoniacal salts; (2) 5 per cent. of magnesium oxycarbonate; (3) 2 per cent. magnesium oxide (calcined magnesia); (4) 2 per cent. of calcium oxide (quicklime); (5) 0·5 to 1 per cent. of caustic soda or potash; these reagents decompose successively different kinds of nitrogenous organic matter. Lastly, the nitrogen is estimated by combustion with soda-lime. W. R. D.

Estimation of Iodine in Human Urine. By E. HARNACK (*Zeit. Physiol. Chem.*, 8, 158—164).—This is a criticism on Zeller's paper. The author concludes from his own determinations that no reliance can be placed on the results obtained by the two direct methods, viz., by precipitation as palladium or silver iodide; he has, however, obtained concordant results with either of the following processes:—1st, evaporating the urine to dryness with excess of soda and igniting, and then precipitating the iodine as palladium iodide in the extract of this residue; 2nd, by igniting the precipitate formed by direct precipitation with dry powdered soda, and then reprecipitating the iodine as before, after acidifying with hydrochloric acid.

To account for the high results obtained by direct precipitation with palladium chloride solution, the author supposes the formation of some double compound insoluble in water (as palladium-iodine-creatinine). J. P. L.

Estimation of Iodine in Urine. By E. BAUMANN (*Zeit. Physiol. Chem.*, 8, 282—290).—Baumann defends Zeller's results and disputes Harnack's statement that no reliance can be placed on the two direct methods; he also points out that Harnack's high results obtained with palladium chloride solution are most probably due to an admixture of organic compounds consequent on the use of hydrochloric acid, and not to the formation of a double compound.

The whole paper is devoted to a defence, and the conclusions are directly opposed to those of Harnack. J. P. L.

Estimation of Chlorides in Dog's Urine. By v. MERING (*Zeit. Physiol. Chem.*, 8, 229—234).—Salkowski's modification of Volhard's volumetric method of estimating the chlorides in dog's urine is liable to give too high results in consequence of the presence of compounds containing sulphur (thiosulphuric or thiocyanic acid). To avoid this error, the author precipitates the urine with an excess of silver nitrate and nitric acid, and then either fuses this precipitate with soda and saltpetre, or warms it with zinc-dust and acetic acid, and estimates the chlorides, in the first case, in the watery extract of the fusion, in the second case in the filtrate after reduction.

The chlorates can also readily be determined by taking another portion of urine and reducing with zinc-dust and acetic acid before precipitation, the difference between the two weights gives the chloride derived from the chlorate. J. P. L.

Volhard's Volumetric Estimation of the Chlorides in Urine. By M. GRUBER (*Zeits. f. Biol.*, 19, 569—570).—If nitric acid be used to decompose the sulphur-containing bodies which occur in dog's urine, the end-reaction is much masked by the deep colour. The best course is to treat the urine with a little zinc and sulphuric acid before titrating. (See also preceding Abstract.) J. P. L.

Estimation of Phosphoric Acid in Superphosphates. By E. AUBIN (*Compt. rend.*, 98, 1591—1594).—The insoluble phosphate in superphosphates is usually estimated by extraction with ammonium citrate solution, either at once, or, if magnesium is present, after previous treatment with water. Treatment with water is effected by triturating the phosphate and digesting with a known volume of water, or by exhausting it repeatedly with successive small quantities of water, but the results obtained by the two methods do not agree. In most cases, the first method gives results which are too high, the error being due to the presence of free acid (phosphoric and sulphuric) which attacks the phosphate during trituration, this effect being greatest with samples which form a paste when triturated, and also to the incomplete extraction of the magnesium phosphate. Joulie's method of treating at once with ammonium citrate solution even in presence of magnesium, also gives results which are too high.

Whenever phosphoric acid is precipitated as ammonium magnesium phosphate in presence of ammonium citrate, account must be taken of the solubility of the precipitate in solutions of this salt. The solubility increases with the concentration of the solution, and by always using the same bulk of liquid, containing the same proportion of ammonium salts, a correction may be introduced. C. H. B.

Reverted Phosphoric Acid. By T. S. GLADDING (*Chem. News*, 50, 16—18; 27—28).—Experiments with natural phosphates and artificial soils have been described (this vol., p. 1075). The natural soils used were light loams, one from the truck gardens of Long Island, New York, one from the cotton plantations of North Carolina, and one from the tobacco fields of Connecticut, taken from plots upon which fertilisers had been spread, and large crops had been grown. The soils were ground to pass a 20-mesh sieve, and 100 grams were taken for each experiment. A solution of an ammoniated superphosphate was prepared, of which 50 c.c. contained 0·284 gram phosphoric acid, and this quantity was added to each portion of soil, the wet pasty mass being exposed in thin layers to the atmosphere for five days. The portions were then divided into four equal parts for digestion with ammonium citrate solution at 40° and 65°, and with water to determine the amount of phosphoric acid not reverted. Experiment I with Long Island garden soil showed that ammonium citrate solution at 65° dissolved all the phosphoric acid added to the soil, whilst at 40° it failed to dissolve 27·81 per cent. of the acid actually reverted by the soil. Experiment II with North Carolina soil gave the same result. In experiment III with Connecticut soil, the result was as in experiment I, with 29·23 per cent. undissolved at 40°. During two days, the mixture of soil and phosphate was very wet, and represented very wet lands; later it passed through all the stages of drought, but at no time contained less moisture than was observed in the fields during the summer season. Tests made with other portions of these mixtures showed that all the phosphoric acid was dissolved at both temperatures, if kept constantly saturated with water, owing to the ready solubility of all gelatinous precipitates at low temperatures. Whether phosphoric acid exists in the soil in combination with lime only, or also with iron and alumina, has heretofore never been proved by any direct laboratory experiment, because no method of separation was known for these three phosphates in the presence of each other in the soil. The fact that a strongly alkaline ammonium citrate solution rapidly attacks insoluble iron and aluminium phosphates, but dissolves even less of insoluble calcium phosphate than when neutral, constitutes a test for distinguishing these phosphates.

The author cites numerous investigators who have dealt with the question of phosphates in soils; he criticises results obtained by Albert and Volbrecht (Abstr., 1880, 571) from which these authors, with Millot and Joulie (*Ann. Agronomiques*, December, 1880), conclude that the amount of phosphoric acid not dissolved by ammonium citrate solution at 40° had become insoluble calcium phosphate. Had they digested at 65° the discrepancies would have disappeared. It is impossible to conclude otherwise than that a portion of the phosphoric acid was in combination as reverted iron and aluminium phosphates. The physical conditions of iron and aluminium oxides in the soils do not seem to affect the principal result of these comparisons of temperature at which ammonium citrate solution is used. Few deposits of mineral phosphates exist free from iron and alumina. It is evident that superphosphates made from such minerals are undervalued when the reverted phosphoric acid is estimated at 40°, because the oxides dissolved by the sulphuric acid subsequently combine in the superphosphate with their equivalent of phosphoric acid, and the reverted iron and aluminium phosphates thus formed are *not all dissolved at the temperature of* 40°, whereas a slight increase in temperature dissolves them entirely without unduly attacking the *insoluble* mineral. Experiments by Millot, Heyden, Stochmann, and Liebig on the rapidity with which the reversion of phosphates takes place are quoted, and the author concludes that it is evident, from the marked and positive results of these experiments, that the only equitable method of valuing the reverted phosphoric acid of a superphosphate must be based on those facts; that the true method of valuation is that which dissolves reverted phosphates of the same degree of solubility as those which are formed when a soluble superphosphate is mixed with the soil. The author gives the following method of analysis of superphosphates:—

Preparation of Sample.—Pass the sample through a 12-mesh sieve. *Moisture.*—Dry 5 to 10 grams at 100°. *Total Phosphoric Acid.*—Dissolve 2 grams in 200 c.c. flask with 50 c.c. nitric acid, with addition of a little hydrochloric acid if necessary, boil gently for fifteen minutes, cool, and fill to mark, filter, take 50 c.c., add 25 c.c. concentrated ammonia, and then nitric acid to acidity. To the hot liquid add molybdic solution, and allow it to remain for an hour at 65°, filter, wash with ammonium nitrate solution, dissolve on the filter with hot ammonia solution, and wash. Run in magnesia mixture from a burette at the rate of one drop a second, stirring constantly. Allow it to stand several hours, filter, and weigh. *Soluble Phosphoric Acid.*—Rub up 2 grams in a mortar with a soft rubber-tipped pestle, digest in 25 c.c. cold water, decant, add another 25 c.c. water to the residue, digest several minutes, and repeat this five or six times; pass all through a filter, fill up to the mark, and take out 50 c.c. and treat as above. *Insoluble Phosphoric Acid.*—Wash the residue on the filter into a 200 c.c. flask with 100 c.c. citrate solution, cork, and digest at 65° for 30 minutes. Filter the warm solution quickly, and wash with *cold water*. Return the filter and contents to the same flask, add 50 c c. nitric acid, boil for 15 minutes, and estimate the phosphoric acid as in the total. *Reverted Phosphoric Acid.*—The sum of the soluble and the insoluble phosphoric acid subtracted from the total will give the reverted. J. T.

Electrolytic Estimations. By J. WIELAND (*Ber.*, **17**, 1611—1612). —The author has examined the various methods of electrolytic estimations with the view to test their accuracy. Classen's method for the estimation of iron in oxalic acid solution (Abstr., 1881, 1081) gives good results. The method applied to manganese (*loc. cit.*) is less to be recommended, whilst Riche's method, in which a sulphuric acid solution is employed (*Compt. rend.*, **85**, 226), gives satisfactory results. Classen's method of separating iron and manganese (Abstr., 1881, 1081; 1882, 896) has been tested with currents of different strengths, but the manganese precipitate always contained a considerable proportion of iron, and his method of separating iron and aluminium is likewise unsatisfactory, some aluminium being thrown down with the iron. Parodi and Mascazini's method of separating lead from an alkaline solution (*Gazzetta*, **8**, 6, 255) is not to be recommended owing to the ready oxidation of the lead, whilst the estimation of small quantities of this metal may be effected by Riche's method, according to which a nitric acid solution is used (*Ann. Chim. Phys.* [5], **13**, 508). Cadmium may be thrown down in a compact form by a current (0·05 ampère) from a thermopile, the negative electrode being a platinum dish of about 150 c.c. capacity; also by stronger currents from a potassium cyanide solution (*Ber.*, **12**, 759), and from a weak sulphuric acid solution (*Amer. Chem. J.*, **2**, 41). To estimate bismuth, it must be precipitated by a feeble current (0·01—0·05 ampère) from an oxalic or nitric acid solution. A. K. M.

Estimation of Calcium in Presence of Aluminium, Iron, Magnesium, and Phosphates. By A. GUYARD (*Bull. Soc. Chim*, 41, 339—340).—Calcium oxalate is appreciably soluble in acetic acid or in alkaline acetates, the amount dissolved being proportional to the quantity of these substances that are present. In order to precipitate calcium from such a solution, it is necessary to add sufficient ammonium oxalate to convert the acetates into oxalates, and even then the precipitation is not complete. It is, therefore, better to modify the usual process for estimating calcium in presence of aluminium, iron, &c., by adding sufficient ammonium citrate to keep these substances in solution, and then to precipitate with ammonium oxalate, when the calcium is entirely removed. In presence of magnesium, the operation should be conducted at 70—80°, at which temperature the ammonium magnesium phosphate is soluble. Where silica is present, it sometimes happens that it is also precipitated, carrying with it traces of iron and aluminium, in which case it is necessary to purify the calcium oxalate. When the calcium oxalate has been separated, magnesium or phosphoric acid may be determined in the filtrate and by the usual methods. W. R. D.

New Method of Estimating Carbon in Steel. By ZABOUDSKY (*Bull. Soc. Chim.*, 41, 428—433).—The combined carbon in cast iron, steel, &c., is most accurately estimated by means of a mixture of copper sulphate and sodium chloride. Instead of adopting the usual method of using aqueous solutions of these salts, the author recommends the following plan as quicker and easier. A dry mixture is prepared by evaporating solutions of these two salts to dryness. The finely powdered metal is intimately mixed with about 20 grams of this in a mortar, which should be surrounded by water, and sufficient water added to the mixture to form a pasty mass. After triturating for about half an hour the contents of the mortar are transferred to a beaker, the mortar being washed out with a solution of ferric chloride (25 per cent.). After the addition of some hydrochloric acid the liquid is heated for about three-quarters of an hour, and the precipitate filtered off, dried at 125—130°, and weighed. The results agree very well with those obtained by the older method. The residue, however, is not pure carbon, but a hydrate of that element, and if it is calculated as pure carbon the result is an error of about 35 per cent. on the total quantity. The author has, therefore, determined the coefficients which express the quantity of pure carbon in the residue. These were deduced from a number of experiments with different specimens of cast iron, steel, &c. The results of these analyses, which are tabulated in the paper, lead to the following coefficients:—

Pure specular cast iron containing no manganese	0·720
Ferromanganese	0·700
Ferromanganese (specular).........................	0·685
White cast iron..	0·710
Pure grey cast iron (Bessemer)	
Grey cast iron slightly impure, combined carbon low....	0·655

Cannon and gun steel (about 0·5 per cent. of carbon)....	0·660
Hard steel	0·675
Swedish iron	0·690

The author states that the copper mixture method is more accurate than either the iodine or colorimetric methods of Eggertz. The quantity of pure carbon contained in the iodo-carbon residue of the first process is often much less than the reputed amount (60 per cent.). In the case of Swedish iron, the author found in two different residues 50·9 per cent. and 48·6 per cent. of pure carbon. The second method requires much practice, and does not give comparable results with metals of different origin. W. R. D.

Estimation of Chromium. By H BAUBIGNY (*Bull. Soc. Chim.*, **41**, 291—301).—The usual process for estimating chromium by precipitation as trioxide is inaccurate, owing to the facility with which this compound combines with metallic oxides, which are consequently precipitated with it. The author strongly recommends Storer's process, in which the chromium is oxidised to chromic anhydride by means of nitric acid and potassium chlorate. Chromium is separated from iron or aluminium by first oxidising with nitric acid and potassium chlorate, and adding to the cold liquid a slight excess of hydrogen sodium carbonate, when the iron or aluminium is precipitated, and after washing with a dilute solution of the carbonate is dried, ignited, and weighed in the usual manner. Ammonia cannot be used as the precipitant, for by the action of the oxides of chlorine on it compounds are formed that reduce the chromic anhydride, and the trioxide is precipitated. The chromium is estimated in the filtrate by acidifying with sulphuric acid, adding ammonia, and saturating the liquid with hydrogen sulphide. After boiling, the chromium hydroxide is collected and washed. To completely free it from alkalis it is dissolved in hydrochloric acid, and reprecipitated in the cold with ammonia. Any iron that may have escaped precipitation can be recognised in the precipitate by oxidising it with nitric acid and potassium chlorate, evaporating to dryness at 100°, and after dissolving the residue in a few drops of water, precipitating the iron with ammonia. In presence of alkalis, the same process may be followed, but the chromium oxide should be tested for alkalis by strongly heating, when a chromate is formed and can be recognised in the usual way. When the quality of alkali is large, a loss may occur from the volatilization of chromic anhydride, accompanied by reduction and deposition of chromium trioxide in a crystalline form. The author has noticed that this occurs when a dichromate is heated for some hours at a red heat. In cases where chromium occurs alone, it is estimated by precipitating as lead chromate with lead acetate. Precipitation as mercurous chromate is not accurate in presence of ammoniacal salts, particularly the nitrate, as the chromic anhydride is more or less reduced. W. R. D.

Estimation of Arsenic. By C. HOLTHOF (*Zeitschr. Anal. Chem.*, 1884, 378—390).—The gravimetric estimation of arsenic when it is present as arsenic acid, and especially when it is weighed, as customary, as ammonium magnesium arsenate presents so many difficulties, and requires so much attention, that the author examined a method first proposed by Mohr, but afterwards abandoned by him, and which consists in the reduction by SO_2 and titration of the arsenious acid produced by standard iodine. Very careful experiments established that on evaporating arsenic acid with hydrochloric acid to dryness, no trace of arsenic is volatilised, and that on subsequent addition of abundance of sulphurous acid solution the arsenic acid is completely reduced.

The author operates as follows: in case of precipitates containing As_2S_3 and sulphur, he oxidises with HNO_3 or HCl and $KClO_3$, evaporates to dryness, adds 300 c.c. of strong sulphurous solution, heats on the water-bath for about two hours, expels the acid by subsequent boiling down to about one half, and after cooling neutralises with acid sodium carbonate, and titrates with iodine. The reagents used must be quite pure, and atmospheric dust must be carefully excluded. The results are quite accurate. O. H.

Analysis of Type Metal. By F. Weil (*Zeitschr. Anal. Chem.*, 1884, 348—349).—2 grams of the alloy are heated in a flask with nitric acid, the excess of the acid is removed, hydrochloric acid is added, and the mixture is boiled until iodised starch-paper is no longer affected. The solution is made up with tartaric acid solution to 200 c.c. In 10 c.c. of this, the antimony is titrated with stannous chloride (Weil's method, "Fresenius' Quantitative Analysis," 6 ed., p. 542).

2 grams of the metal are oxidised with nitric acid, and the mixture of SbO_4 and SnO_2 weighed together, the tin being obtained by subtracting the amount of antimony previously found. The lead is estimated in the filtrate in the usual manner.

The object of the method is to avoid the troublesome separation of antimony and tin. O. H.

Estimation of Molybdenum and Tungsten. By O. v. d. Pfordten (*Chem. News*, **50**, 18—19).—1. *Gravimetric methods.*—The author finds that the reduction to metal can be effected in a crucible, with a perforated cover, by means of a good gas-blast. He uses a platinum crucible and passes in a current of hydrogen through an earthen tube. In the analysis of ammonium molybdate, he heats the sample in the crucible at 170° for some hours in an air-bath, thus avoiding spirting. If the temperature is raised higher, say to 200°, there is a slight loss by sublimation. The crucible is then heated gently in a slow current of hydrogen to superficial reduction. In order to guard against possible loss by sublimation, the aperture of the gas delivery pipe is wrapped in a sheet of platinum, running to a point below and fitting into the aperture of the lid, with which it is weighed. After the heat has been gradually raised, the complete reduction is effected in the highest heat of a good gas-blast in a strong current of hydrogen. This method is applicable for all neutral solutions containing molybdic acid, if combined with precipitation by mercurous nitrate as proposed by H. Rose. The cold concentrated solution, exactly neutralised and freed from carbonic acid, is mixed with excess of the nitrate, and filtered after a few hours. Particles which adhere to the beaker are dissolved off with hot nitric acid and evaporated in a platinum crucible. The main precipitate, when dry, is separated from the paper and placed in the crucible. The portions adhering to the paper may be rinsed into the crucible with hot nitric acid; or the filter is carefully folded up and ignited, so that the particles may be reduced by the carbonaceous matter before molybdic acid can sublime away. The reduction to metal is then effected as above. For the analysis of acid solutions containing molybdic acid, the reduction of molybdenum trisulphide to the bisulphide is recommended as described by Liechti and Kempe. It requires more time than the reduction to metal, and the conclusion of the reduction is not so distinctly marked. The bisulphide obtained must not be too strongly ignited in the hydrogen current.

The gravimetric determination of tungsten is much less difficult. The method of Berzelius—precipitation with mercurous nitrate—is convenient and gives good results. Scheele's method—evaporation of the solution with hydrochloric acid, exactly as for silica—is also good.

2. *Volumetric methods.*—The solution of the salt is mixed, for molybdenum, with 50—60 c.c., and for tungsten with 70—80 c.c. of hydrochloric acid of 27 per cent. There are then added for molybdenum, 8—10 grams, and for tungsten 14—15 grams zinc in the form of rods, and in as large pieces as possible. The solution may contain 0·3 gram molybdic oxide, or 0·1 gram of tungstic oxide; in the latter case, the solution is previously heated on the water-bath, and the hydrochloric acid and zinc are then added; the deposition of tungstic oxide in a solid state is thus avoided. Towards the end of the reduction, a little heat may sometimes be applied to the molybdenum solution with advantage. When the molybdenum solution has become yellow, and that of tungsten red, the flask is cooled—in the case of tungsten with especial care. The remainder of the procedure is different. The molybdenum solution is poured into a porcelain capsule containing 40 c.c. dilute sulphuric acid, and 20 c.c. of manganous sulphate solution free from ferrous salt, and containing 200 grams per litre. An equal volume of water is added, and a dilute solution of standard permanganate is run in. The results are accurate:

$$1 \text{ c.c. } KMnO_4 = 0{\cdot}0007521850 = 0\ 00151311 MoO_3.$$

The reduced tungsten solution is rinsed quickly into a capsule in which there is an excess of permanganate, 70—100 c.c. dilute sulphuric acid, 40 c.c. manganous sulphate solution, but otherwise no water. Not until the flask has been rinsed out is the liquid diluted to 1 litre. In presence of such large quantities of hydrochloric acid the manganous sulphate exerts its power of transferring oxygen only in concentrated solutions. Quick working is essential. An excess of ferrous sulphate is now run in, and the solution is finally titrated with permanganate. J. T.

Analysis of Potable Water. By W. BACHMEYER (*Zeitschr. Anal. Chem.*, 1884, 353—359).—The author shows that in Kubel-Tiemann's method of measuring the amount of "oxygen absorbed," the length of boiling, and the quantity and concentration of the acid employed, have a material influence on the result. O. H.

Determination of the Flashing Point of Petroleum. By J. T. STODDARD (*Amer. Chem. J.*, **6**, 18—23).—Beilstein (*Zeitschr. Anal. Chem.*, **22**, 309) has come to conclusions differing from those of Stoddard (Abstr., 1883, 383, 517). The method employed is a modification of Liebermann's (Abstr., 1882, 1326).

It is shown that the flashing point does not depend as stated by Beilstein upon the length and diameter of the oil-cylinder employed, so much as upon the dimensions of the vapour space above the surface of the oil. The quantity of oil to be used is 50 c.c., the cylinder, 2·5—4 cm. in width, must then have a vapour space of 6—4 cm., and the continuous air current should be strong enough to maintain a foam of at least 1 cm. By this method, the lowest flashing point which can be accurately determined is obtained; an approximate and a final test are made. H. B.

Analytical Estimation of the Three Xylenes in Coal-tar. By A. REUTER (*Ber.*, **17**, 2028—2029).—The author disputes the accuracy of the method proposed by Levinstein (this vol., p. 898), as it has been shown by several writers that pure metaxylene cannot be obtained by treating the mixture of xylenes with dilute nitric acid, whilst stronger nitric acid such as is recommended by Levinstein attacks metaxylene, although more slowly than its isomerides. The author has converted 1 kilo. of pure metaxylene by a few successive treatments with nitric acid (2 vol. acid of 1·4 with 3 vol. water) into a crystalline mass consisting of metatoluic acid, together with a small quantity of an aldehyde. Isophthalic acid was not formed. Paraxylene is attacked by ordinary sulphuric acid, although with considerably more difficulty than its isomerides. A. J. G.

Detection and Estimation of Small Quantities of Carbon Bisulphide in Air, Gases, Thiocarbonates, &c. By GASTINE (*Compt. rend.*, **98**, 1588—1590).—The gas or vapour to be tested is carefully dried, and then passed through a concentrated solution of recently fused potassium hydroxide in absolute alcohol. The presence of even traces of water seriously diminishes the delicacy of the reaction. The alcoholic solution is afterwards neutralised with acetic acid, diluted with water, and tested for xanthic acid by adding copper sulphate.

In order to determine the distribution of carbon bisulphide introduced into the soil (*Compt. rend.*, 1877), 250 c.c. of the air in the soil is drawn by means of an aspirator through sulphuric acid, and then through bulbs containing the alcoholic potash. For quantitative determinations, a larger quantity of air must be used, and the xanthic acid formed is estimated by means of the reaction $2C_3H_6OS_2 + I_2 = 2C_3H_5OS_2 + 2HI$. The alkaline solution is slightly acidified with acetic acid, mixed with excess of sodium hydrogen carbonate, and titrated in the usual way with a solution of iodine containing 1·68 grams per litre, 1 c.c. of which is equivalent to 1 mgrm. of carbon bisulphide.

To apply this method to thiocarbonates, about 1 gram of the substance, together with about 10 c.c. of water, is introduced into a small flask and decomposed by a solution of zinc or copper sulphate, the flask being heated on a water-bath, and the evolved carbon bisulphide passed first through sulphuric acid and then into alcoholic potash. In the case of gaseous mixtures of carbon bisulphide, nitrogen, hydrogen sulphide, carbonic anhydride, carbonic oxide, and water-vapour, the gas is passed through a strong aqueous solution of potash, then into sulphuric acid, and finally into alcoholic potash. The thiocarbonate formed in the first flask is decomposed by treatment with copper or zinc sulphate as above, and the xanthic acid obtained is added to that formed in the third flask, and the whole titrated with iodine. C. H. B.

Wine Analysis. By J. Nessler and M. Barth (*Zeitschr. Anal. Chem.*, 1884, 318—323).—For the quantitative estimation of magenta in wine, the following modification of Falière's method is recommended: 100 c.c. of the wine are mixed with 5 c.c. strong ammonia, and well shaken with 30 c.c. ether. 20 c.c. of the ether are drawn off and evaporated in a little basin containing a thread of white wool 5 cm. long. Other threads are then dyed with known quantities of magenta, and from the comparison of tints the amount of the added colouring matter in the wine is inferred. As little as 2 mgrms. per 100 litres may thus be determined. The standard woollen threads, fused into glass tubes, and kept in the dark, do not alter in tint when kept.

The authors determine the amount of tannin as follows: 12 c.c. of wine are mixed with 30 c.c. alcohol; pectinous and albuminous substances are precipitated. Of the filtrate, 35 c.c., corresponding with 10 c.c. of wine, are evaporated to about 6—7 c.c., transferred to a conical test-tube tapering from 16 mm. to 8 mm., and divided into $\frac{1}{10}$ c.c. Sodium acetate and ferric chloride are added, and after 24 hours' standing the precipitate is measured, 1 c.c. corresponding with 0·033 per cent. tannin. O. H.

Estimation of the Dry Extract of Wine. By E. H. Amagat (*Compt. rend.*, 99, 195—197).—The wine is boiled until its volume is reduced to one-half, in order to expel alcohol, and is then brought back to its original volume by addition of water, and its sp. gr. determined. The amount of dry extract in the wine is very nearly, although not exactly, proportional to the difference between its sp. gr. and unity. This method gives strictly comparable results.

C. H. B.

Estimation of Dry Substance in Wine and Must. By R. Ulbricht (*Landw. Versuchs-Stat.*, 30, 425—427).—The saccharimetric tables of Balling, Steinheil, and Schultze-Ostermann agree fairly with each other, and are correct as tested by the author, whose experiments were carried out on samples free from water, and at a uniform temperature of 15°; the subjoined table shows the close agreement of the results. The author thinks the table could be used to ascertain the amount of dry extract in wines and must from their sp. gr. Wines poor in sugar and containing relatively high proportions of glycerol cannot be so readily estimated, but glycerol in aqueous solutions can readily be valued in this way.

In order to eliminate the probable error in pyknometric estimation of dry substance, the author adds 0·39126 per cent. for every 1 per cent. of glycerol present in the wine; he is engaged on experiments to eliminate similar errors due to acetic acid.

Method for the Determination of the Molecular Weight and Atomicity of the Higher Fatty Alcohols. By C. HELL (*Annalen*, **223**, 269—283).—By heating primary fatty alcohols with soda-lime, hydrogen is evolved according to the equation $R.CH_2.OH + NaOH = R.COONa + 2H_2$. The author endeavoured to found a method of determining the molecular weight of the higher alcohols on the measurement of the hydrogen so evolved, but finds that only about 90 per cent. of the hydrogen indicated by the above equation is given off. The cause of this deficiency could not be ascertained. The method can, however, be used in discriminating alcohols from aldehydes, in ascertaining whether an alcohol is primary, and whether monohydric, dihydric, &c. A. J. G.

Alkaline Bismuth Solution as a Test for Glucose in Urine. By E. NYLANDER (*Zeit. Physiol. Chem.*, **8**, 175—185).—As the determination of glucose in urine with Fehling's solution is liable to error, owing to the presence of other reducing bodies, uric acid, creatinine, &c.; the author has made a series of experiments with the view of ascertaining the conditions under which the above reagent is most sensitive and accurate. He prepares the solution in the same manner as Almén, except that he substitutes for the strong potash a solution of soda containing different percentages of Na_2O, 3, 6, 7, 12, and 17 per cent. (2 grams of bismuth subnitrate, 4 grams Rochelle salt, and 100 c.c. of soda solution); the undissolved bismuth salt is filtered off. The general results shortly stated are as follows: A solution containing 8 per cent. Na_2O, added in the proportion of 1 part of reagent to 10 of urine, is the most sensitive and gives the best results, 0·025 per cent. of glucose being easily detected. A larger percentage of soda or addition of the reagent is to be avoided. The albumin, in cases of albuminous urine, should first be removed, as if present in quantity it vitiates the result to some extent. The author has made no experiments to determine whether lactose can be estimated in the urine.

J. P. L.

Volatility of Glycerol at 100°. By J. NESSLER and M. BARTH (*Zeitschr. Anal. Chem.*, 1884, 323—332).—Dry pure glycerol is volatile to a considerable extent at 100°, the amount of loss varying with the mode of heating, the shape and material of the vessel, and the surface exposed. Thus 1 gram heated in a water-oven in a platinum basin 80 mm. diameter lost during the first two hours 46 mgrms., during the second two hours 29 mgrms., in the three succeeding hours 21 mgrms. The loss on 0·5 gram similarly heated was the same. On the open water-bath, the loss per hour varied from 29 to 39 mgrms. When the vessel holding the glycerol is of glass the loss is less, other circumstances being equal.

When aqueous or alcoholic solutions of glycerol are evaporated, the loss varies both with the strength of the solution and the volume of the water to be volatilised. It is in all cases very considerable.

O. H.

Valuation of Calcium Tartrate. By L. WEIGERT (*Zeitschr. Anal. Chem.*, 1884, 357—365).—5 grams of the finely-powdered substance are heated with 30 c.c. of a 10 per cent. potassium carbonate solution for two hours, the solution is filtered, concentrated to 5 c.c., and mixed with an equal amount of strong acetic acid and 100 c.c. of 90 per cent. alcohol. After a few hours' standing, the hydrogen potassium tartrate is separated, washed with alcohol, and titrated with standard alkali.

If calcium carbonate is present at the same time and this has to be estimated, ordinary volumetric methods cannot be employed, and the carbonic acid has to be determined directly by Scheibler's apparatus or some similar method.

O. H.

Estimation of the Volatile Fatty Acids in Butter Analysis. By C. E. SCHMITT (*Ann. Agronomiques*, 10, 262—268).—Having in a previous paper recommended Angell and Hehner's process for the estimation of the volatile fatty acids in samples of butter, the author now enumerates some objections to its use, and recommends as more convenient and delicate Reichert's process, carried out with certain modifications, as follows:—

2·50 grams of butter-fat are taken for the analysis. The butter must be purified by drying it, and decanting the melted fat through a filter, as the presence of salt in the purified fat will cause the results to be too high. The butter is saponified with an alcoholic potash solution, as in Hehner's process, and the saponified solution, which should measure 70—80 c.c., is introduced with some pieces of pumice into the flask of Boussingault's distilling apparatus for the estimation of ammonia. 10 c.c. of medicinal phosphoric acid (sp. gr. 1·45) are added, and the liquid is distilled until the beaker in which the distillate is received is filled up to a mark at 60 c.c. The distillate is then directly titrated with standard sodium hydroxide of normal strength. Four samples of pure Flemish butter required 13 0, 13·50, 14·0, and 14·3 c.c. of soda. Two other samples of pure butter each required 13·5 c.c. soda, but when analysed by Hehner and Angell's process, one gave 89·15 per cent. of insoluble fatty acid, and the other 88·57 per cent. A sample of goat's milk butter tested by Reichert's process required 13·58 c.c [soda, and a sample of ewe's milk butter 13·65 c.c. A mixture of 4 parts oleomargarine with 1 part of genuine butter required 2·7 c.c. The author mentions that in some cases *butyric acid* is purposely added to oleomargarine in concocting artificial butter. J. M. H. M.

Estimation of the Fat in Skim Milk. By W. FLEISCHMANN and others (*Bied. Centr.*, 1884, 336—338).—The estimations made of fat in milk by evaporating with sand or by the aräometric process are very closely concordant, but when the milk analysed has been skimmed there is a large discrepancy between the two methods, the evaporation process being the lowest; if twice the usual amount of sand is used, the results are better, but the difference is even then 0·125 per cent. of the whole; consequently Fleischmann employs plaster of Paris: 10 grams of milk are evaporated down with 35 of plaster of Paris, and then extracted with ether for three hours; the error is thus reduced to 0 05 per cent. In consequence of these results, all early analyses of skim milk must be used with caution. Schrodt and Hansen publish a similar account of their experience with skim milk; and, in addition, Schrodt states that more dry matter is found by employing sand than when the plaster is used, viz., 0·198—0·246 per cent. E. W. P.

General Method of Examining Fats. By HÜBL (*Dingl. polyt. J.*, **253**, 281—295).—As the chemical composition of the various fats is very similar, an attempt is rarely made to ascertain their constitution, the examination of the substances which as "natural constituents" accompany fats being considered of more value in judging of their quality. The term "natural constituents" is applied to colouring matters, resins, nitrogenous substances, &c. Owing to the fact that the estimation of these substances is limited in its application, and that the qualitative composition of the various fats is very similar, those methods only are useful which are based on quantitative determinations, whether of chemical or physical nature. Such methods, which the author calls "quantitative reactions," afford valuable indications of the purity of fats, as they are intimately connected with their chemical constitution. Qualitative tests are of value in doubtful cases, and serve to control the conclusions drawn from the results of the "quantitative reactions." After referring to the ordinary methods employed for the examination of fats, the author gives a detailed account of his process called the "iodine-addition method." This method is based on the following considerations:—Almost all fats contain members of three groups of fatty acids, viz., acids of the acetic acid series (stearic and palmitic acids), acids of the acrylic acid series (oleic and erucic acids), and acids of the tetroleic acid series (linoleic acid). Chemically, these groups of fatty acids show characteristic differences in their behaviour towards haloïds. Whilst the first group remains unaltered under ordinary conditions, the second group takes up two haloid atoms very readily, and the third group four atoms. Accordingly, members of the first group are recognised as saturated fatty acids; whilst those belonging to the second and third groups are regarded as unsaturated fatty acids. If, therefore, the addition of a haloid to a fat can be effected under circumstances which exclude the formation of substitution-products, and the quantity of haloid added can be determined with certainty, a constant for each fat is obtained, the magnitude of which corresponds with the character and quantity of the unsaturated acids present. Theoretically the following amounts of iodine are absorbed by unsaturated acids in fats:—

Fatty acids.	Formula.	Grams iodine taken up by 100 grams fatty acids.
Hypogoeic acid......	$C_{16}H_{30}O_2$	100·00
Oleic acid	$C_{18}H_{34}O_2$	90·07
Erucic acid	$C_{22}H_{42}O_2$	75·15
Ricinoleic acid	$C_{18}H_{34}O_2$	85·24
Linoleic acid	$C_{16}H_{28}O_2$	201·59

The action of iodine on fats being too slow, an alcoholic solution of iodine in the presence of mercuric chloride was used. This mixture was found to act on unsaturated fatty acids at the ordinary temperature, chlorine and iodine addition-products being formed, whilst the saturated acids remained unaffected. This mixture acts on free fatty acids in a similar manner. The amount of iodine which a fat is capable of absorbing was determined by treating a weighed quantity of the fat with a measured quantity of a standard alcoholic solution of iodomercuric chloride, and estimating the excess of iodine by titration with a solution of sodium thiosulphate. The percentage of iodine taken up by the fat is called the "iodine number." The subjoined table (p. 1437) illustrates the results obtained by treating a number of fats in the above-described manner. In most cases, the fatty acids were separated simultaneously, and their melting and solidifying points determined.

It will be seen that the drying oils give the highest iodine numbers, the non-drying vegetable oils are the next in order, then come the liquid and lardaceous animal fats, and finally the solid fats. The iodine number does not, however, indicate the drying properties of an oil, although with it the extent to which the oil thickens or dries up increases, and the capability to form elaïdin diminishes. D. B.

Reaction for Pyridine Bases. By A. W. HOFMANN (*Ber.*, **17**, 1908—1909).—The author some time ago (Abstr., 1881, 921) described a peculiar reaction which takes place when the methiodide of a pyridine is heated with a caustic alkali. A very characteristic odour, probably due to a methylated pyridine, is produced. The author proposes to use this as a test for pyridine bases. A drop or two of the base and the same quantity of methyl iodide are warmed together in a test-tube, then mixed with powdered potash, just moistened with water, and the whole heated, when the characteristic odour is produced if a pyridine-derivative be present. The smallest trace of a pyridine base may be detected in this way. The odour is something like that of a mixture of mustard oil and isonitrile, and also somewhat resembles that given by quinoline bases when similarly treated. It is most characteristic, and when once smelt will never be again mistaken. L. T. T.

Estimation of Amides in Vegetable Extracts. By E. SCHULZE (*Landw. Versuchs-Stat.*, **30**, 459—467).—In continuation of previous experiments, the author examines the different processes; in the present series, he employs sulphuric instead of hydrochloric acid. 2 grams of crystalline asparigine were treated with 5 c.c. of pure concentrated sulphuric acid (= 8·79 grams H_2SO_4) and about 100 c.c. of water, connected with an upright condenser and boiled for certain periods; on cooling, the fluid was nearly neutralised with soda, leaving but a trace of free acid, made up to 200 c.c. (in two of the experiments soda was not added, but the boiling was continued longer), 40 c.c. were then distilled with magnesia, and the ammonia estimated by a standard solution. The quantity of ammonia obtained by two hours' boiling was so near the theoretical amount that the author believes the whole of the asparagine to have been decomposed. On reducing the quantity of acid, the results were not so accurate, and the boiling had to be prolonged. Experiments made according to Schlösing's method show that when solutions are nearly neutralised with soda, prior to the addition of milk of lime, the ammonia comes off very slowly, not being finished even in 72 hours. J. F.

Indigo Assaying. By C. T. LEE (*Chem. News*, **50**, 49).—For several years, the author has used a method by sublimation, which has been uniformly satisfactory. Indigo-blue sublimes readily, and, by a careful regulation of temperature, can be separated from the other components of indigo, indigo-brown, indigo-red, mucilaginous matter, &c. Platinum trays 7 cm. long, 2 cm. wide, and 3 4 mm. deep, are used. About 0·25 gram of finely-powdered indigo, which has been dried at 100°, is taken. It is spread uniformly and the tray very carefully heated on an iron plate, covering with a flat iron arch when volatilisation commences. The time required is from 30 minutes to two hours. The heat must not be so high as to cause the formation of yellow vapours. The results are constant within ¼ per cent.

J. T.

Action of Air on Solutions of Tannin and the Estimation of Tannin. By A. GUYARD (*Bull. Soc. Chim.*, **41**, 336—337).—The author finds that air which has been purified by passing through a series of tubes containing potash solution, cotton-wool, soda-lime, and calcium chloride, has no action on either concentrated or dilute solutions of pure tannin. The usual decomposition which is noticed when solutions of tannin are exposed to the air, and which results in the formation of gallic acid is, therefore, probably due to atmospheric particles or ferments, which act without the co-operation of oxygen. It is otherwise with an alkaline solution of tannin, which is rapidly attacked by purified air, the tannin undergoing a process of combustion, provided an excess of air is allowed to pass through it. For this reason Terreil's process for the estimation of tannin is only valid in presence of a limited supply of air. The best reagent for separating tannin from gallic acid is a solution of lead acetate acidulated with acetic acid; as it precipitates the tannin only, the lead compound may be collected and decomposed with dilute sulphuric acid, and the filtered liquid titrated with potassium permanganate. The gallic acid may also be estimated in the filtrate from the lead compound by potassium permanganate. W. R. D.

Tannin. By F. MUSSET (*Dingl. polyt. J.*, **253**, 341—343).—The author found two acids in oak-bark which are precipitated by gelatin and oxidised by potassium permanganate, hence the determination in the case of a mixture of both acids is attended with inaccuracies, owing to the difference in the "permanganate values" of these acids. It is therefore proposed to treat the extract of oak-bark with ethyl acetate, and repeat this operation until the clear ethereal solution ceases to give a blue coloration with ferric acetate. The ethyl acetate is said to contain the tannin of oak-bark, whilst the aqueous solution contains the tannic acid of "oak-red." As this method is too lengthy, the author recommends titration with iodine, the mode of procedure being described in detail in the original paper.

German barks contain 7—8 per cent. oak-bark tannin and 6—10 per cent. oak-red tannin. As the latter may be used with advantage for tanning purposes, the valuation of oak-bark according to the percentage of oak-bark tannin, no longer suffices, and it becomes necessary to consider also the quantity of oak-red tannin in the assay of barks. D. B.

Estimation of Extract of Malt. By K. KRUIS (*Bied. Centr.*, 1884, 428).—The author finds different methods of estimation to yield different results; he recommends Stolba's process with slight variations, viz., to digest 100 grams malt in 400 c.c. water for one hour at the ordinary temperature, then heat to 60°, at which keep it for three hours, cool, dilute to 1 litre, and filter, take the sp. gr., calculate by Balling or Schulze's tables the percentage of extract, and multiply by 10. J. F.

Testing Sulphured Hops. (*Bied. Centr.*, 1884, 369.)—The hops are to be washed, the wash water treated with zinc and hydrochloric acid in a flask, and the evolved gas to be tested for sulphuretted hydrogen. It sometimes happens that unsulphured hops yield sulphuretted hydrogen when treated as above. When bleached and unbleached hops are mixed, at least 10 grams must be used in the analysis—the washing does not remove all the sulphur.

To detect sulphurous anhydride in beer and wine, the distillate of their liquors must be treated with iodine, and the resulting sulphuric acid precipitated by barium chloride. E. W. P.

Estimation of the Total Nitrogen in Urine. By PATRI and LEHMANN (*Zeit. Phys. Chem.*, 8, 200—213).—The authors have extended the process Kjeldahl described in the *Zeitschr. Anal. Chem.*, 1883, for the estimation of nitrogen in food-stuffs and organic compounds generally, to the determination of the total nitrogen in urine, fæces, &c. The general mode of procedure is as follows:—A measured or weighed quantity of the sample is boiled in a flask with fuming sulphuric acid until a colourless solution is produced; this is usually complete after two hours. The solution is then oxidised by adding gradually small quantities of powdered potassium permanganate until the solution is of a deep green. After cooling, it is diluted with water, and an excess of alkali is added. The distillation of the ammonia is at once commenced, the distillate being passed into acid, and the ammonia afterwards estimated by any of the usual methods. In order to avoid the violent bumping that usually accompanies the concentration of the alkaline liquid, a current of steam is passed through the flask. By this means the last traces of ammonia can be easily obtained without any fear of bumping. The figures obtained by this process agree very closely with those given by Dumas, or Will and Varrentrapp's method. J. P. L.

Technical Chemistry.

A Filter yielding Physiologically Pure Water. By C. CHAMBERLAND (*Compt. rend.*, 99, 247—248).—The water is filtered under pressure through biscuit porcelain, and is thus obtained entirely free from microbes and germs, although originally very impure. After being used, the filter can be cleaned by brushing and heating to a moderately high temperature in order to destroy the arrested organic matter. C. H. B.

Antiseptic Action of Nickelous Chloride. By H. SCHULZ (*Bied. Centr.*, 1884, 360).—A solution of 1 gram nickelous chloride per litre preserves fibrin. Solutions of 0·5—5 per cent. strength were employed on *Aspergillus glaucus* sown in bread; these were prevented from growing. The action is referred to the great affinity of this salt for ammonia. E. W. P.

Borax as an Internal Disinfectant. By E. DE CYON (*Compt. rend.*, 99, 147—148).—The author some time ago confirmed Dumas' observations as to the antiseptic properties of borax, and showed that this salt can be introduced into the human body in quantities amounting to 15 grams per diem, without producing any functional disturbance. He now proposes the internal administration of borax (with food, in quantities of about 6 grams per diem) as a preventative against cholera and other epidemics due to microbes. The borax will not only exert a direct action on the microbes in the alimentary canal, but will also be absorbed into the blood and attack the bacilli which have penetrated into it. A solution of borax or boric acid may also be used for washing. During the violent cholera epidemic in Italy in 1864–65, the workmen in the seven boric acid factories at Lardarello escaped the epidemic, whilst a village 3 kiloms. distant lost a third of its population. C. H. B.

Recovery of Ammonia from the Gases of Coke-ovens. By C. WINKLER (*Dingl. polyt. J.*, 253, 374—376).—The author doubts the possibility of success in endeavouring to recover ammonia from coke-oven gases by the methods hitherto adopted, in which the recovery of ammonia is added to the ordinary coking process, without attempting to effect an alteration in the same. He suggests that trials should be made with an experimental oven of the ordinary form, and the latter heated by means of a special generating furnace, instead of utilising the hot gases evolved during the process of carbonisation. It would thus be possible to determine the amount of heat required for coking purposes and the conditions under which the best and densest coke is produced and the largest yield is obtained. The properties of the volatile products of distillation could be studied simultaneously, the yield of tar and ammonia established, and experiments be made to ascertain the most suitable arrangement for cooling the gases. It would be interesting also to determine the evaporative power of the hot gases, their fuel value after cooling, and how far it would be practicable to utilise them for heating the coke ovens. Finally, it would be useful to study the question of increasing the yield of ammonia by the addition of alkaline or chlorinating substances to coal.

It has been demonstrated that it is impossible to convert the total nitrogen contained in coal into ammonia by the process of destructive distillation. In carbonising coal containing 1·73 per cent. nitrogen, Foster found 14·51 per cent. of the total nitrogen as ammonia, 1·56 as cyanogen, 35·26 in the gas, and 48·66 in the coke.

Winkler has investigated the manufacture of coke at the Deuben Works, and obtained the following results:—

Composition of the coal carbonised—

C.	H.	O.	N.	S.	Ash.	H_2O.
58·44	3·75	5·99	1·08	1·92	10 05	18·77

Yield obtained from 50 hectolitres or 4061·5 kilos. coal—

15·0 hectolitres, or	719·5 kilos.	good coke.
33·0 „	1359·5 „	cinder.
2·3 „	144·0 „	ash.
50·3 hectolitres, or	2223·0 kilos.	

The average composition of the coal, when calculated according to these proportions, gave—

C.	H.	O.	N.	S.	Ash.	H_2O.
72·88	0·48	2·31	0·56	2·56	18·36	2·85

Hence 100 parts of the above coal yielded—

53·2 parts coke and 46·8 parts volatile products.

Containing—		Equal to
C....	39·91 parts	68·3 p. c.
H ...	0·26 ,,	6·9 ,,

	46·80 parts.	

It was not possible to determine the amount of nitrogen contained in the volatile products in the form of ammonia.

As the annual consumption of coal for carbonising purposes amounts to 18,000,000 tons, it is estimated that 58,600 tons of ammonia could be produced from this quantity, *i.e.*, as much nitrogen as is imported in the form of sodium nitrate from South America.

D. B.

Production of Ammonium Sulphate and Hydrochloric Acid. (*Dingl. polyt. J.*, **253**, 350.)—On treating ammonium chloride with sulphuric acid, partial decomposition only is effected, an acid residue remaining which contains ammonium chloride. To remedy this, Mond (Ger. Pat., 28,063, November, 1883) adds sufficient sulphuric acid to form hydrogen ammonium sulphate, and neutralises the latter by ammonia or a salt of ammonium. D. B.

Recovery of Hydrogen Sulphide from Alkali Waste. By H. v. Miller and C. Opl (*Dingl. polyt. J.*, **253**, 350).—It is proposed to treat the residues from soda works with carbonic anhydride or hydrogen sulphide, so as to form a solution of calcium hydrosulphide. This is introduced into iron vessels fitted with stirrers, and heated either by a furnace or with high pressure steam. When the boiling point is reached, decomposition takes place, calcium hydroxide (?) being precipitated and hydrogen sulphide disengaged. Half of the latter is used for obtaining sulphuric acid or sulphur, and the remaining half is employed in the preparation of a further supply of calcium hydrosulphide. The following equations explain the reactions which take place:—

$$CaS + H_2S = CaH_2S_2 \text{ and } CaH_2S_2 + 2H_2O = CaH_2O_2 + H_2S.$$

D. B.

Notes on the Soda Industry. By Scheurer-Kestner (*Bull. Soc. Chim.*, **41**, 335—336).—Reidemeister has obtained from the crude soda solution of Leblanc's process a double sodium calcium carbonate containing only half as much water of crystallisation as gay-lussite. The compound is found in crystals associated with those of gay-lussite, from which they differ in form. These crystals have the formula $2(CaCO_3,Na_2CO_3) + 5H_2O$. Some of them were found blackened with ferrous sulphide; others dull and opaque from contamination with silicates of the alkaline earths. W. R. D.

Analysis of an English Bottle-glass. By. L. GOTTSTEIN (*Dingl. polyt. J.*, **253**, 338).—The author states that although English bottle manufacturers work without the addition of alkalis, the resulting glass resists the action of acid solutions as energetically as alkali glass. At the Stockton Bottle Works the following mixture is used:—Sand 36 parts, clay 18, lime 24, marl 12, and river mud 10. The subjoined analysis indicates that the glass prepared with this mixture has absorbed a small amount of alkali from one of these constituents:—

	SiO_2.	Fe_2O_3.	Al_2O_3.	CaO.	MgO.	K_2O.	Na_2O.
I.	60·91	3·16	3·39	22·61	6·07	1·10	2·51
II.	61·20	3·29	3·47	22·76	5 73	1·06	2·39

The composition of the glass is remarkable, inasmuch as it is poor in alkalis, but rich in lime and magnesia. D. B.

Decomposition of Cements by Water. By H. LE CHATELIER (*Bull. Soc. Chim.*, **41**, 377—379).—When cements are treated with water, not only is the free lime dissolved as is usually assumed, but decomposition of certain metallic compounds containing calcium oxide takes place, which results in the formation of calcium hydroxide. In order to determine the quantity of free lime in cements, they are treated with water in successive quantities so long as the liquid is saturated with lime (1·3 gram in a litre). Under these conditions no decomposition of any calcium compound occurs. The most unstable of these latter compounds is calcium ferrite, which begins to decompose when the liquid contains less than 0·62 gram of CaO in a litre. Those cements which contain much free lime "set" but slowly, whilst those which contain little "set" rapidly. In continuing the progressive action of water on cements, it is found that the decomposition of such compounds corresponds with a fixed content of lime, which does not decrease with further additions of water. By titrating the quantity of calcium oxide contained in these solutions, and comparing the results with those obtained from synthetical compounds, the author was able to prove the existence in the cements of the following compounds:—

Grams of CaO in 1 litre.
1·3 = $CaOH_2O$
1·6 = $Fe_2O_3,4CaO,12H_2O$
0·2 = $Al_2O_3,4CaO,12H_2O$
0·05 = $SiO_2,CaO,3H_2O$.

W. R. D.

Decomposition of White Iron by Heat. By L. FOURQUIGNON (*Compt. rend.*, **99**, 237—238).—White charcoal-iron was heated to redness for several days in a vacuum, all traces of air having been displaced by hydrogen. It did not melt nor soften, but became distinctly malleable, and its surface was covered with a dull greyish efflorescence which left a mark on paper. The fracture was sometimes of a uniform black, like that of a lead pencil, sometimes dotted over with regularly disseminated black points of amorphous graphite. The composition of the iron was as follows:—

	I.		II.	
	Original.	Heated 172 hours.	Original	Heated 196 hours.
Combined carbon..	2·959	0·895	2·824	1·159
Graphite.........	0·0	2·061	0·0	1·676
	2·959	2·956	2·824	2·835

When white iron is heated, it is decomposed into graphite and a carbide less rich in carbon. C. H. B.

Imitation of Patina. By E. DONATH (*Dingl. polyt. J.*, **253**, 376—380).—The formation of the so-called "patina" on bronze statues has been the subject of much investigation of late years, in consequence of the fact that most of those of recent origin have become covered with a dense greyish-black film, which gives them an unpleasing appearance. Weber attributes the formation of patina to the composition of the alloy, and recommends the use of tin, suggesting also that the quantity of zinc used should be limited as much as possible. Brühl states that the production of the dark-coloured film is due to the large number of coal fires and furnaces in operation at the present time. His conclusion that this film is free from sulphur is not confirmed by Weber.

Referring to the processes for producing patina by artificial means, the author, after much investigation, found that the treatment of statues with acids (acetic, oxalic, hydrofluosilicic acids, &c.) or ammonia, ammonium carbonate, &c., is attended with practical difficulties. Some time ago Brühl had occasion to make a series of experiments on a bronze statue erected at Aix-la-Chapelle. To restore the statue to its original colour a mixture of 20 parts of acetic acid and 100 parts of fat oil from bones was used. The author in his trials employed oleic acid treated with a small amount of cupric oleate, which is said to prevent the oleic acid from altering. Bone-oil being composed largely of olein, the use of commercial oleic acid suggested itself to the author, inasmuch as the formation of the copper-soap, which is said to be the cause of the green film observed by Brühl, cannot take place until the decomposition of the fat into glycerol and free fatty acid has been effected; moreover, the oxidising action of oleic acid on metals in the presence of oxygen is more powerful. On adding acetic acid to the mixture, it is gradually decolorised, cupric oxide being deposited. It is, therefore, necessary to heat the same gently, and thoroughly agitate it before use. The objects to be treated are washed repeatedly with a concentrated solution of ammonium carbonate, which produces a bluish-green film. They are then painted with the mixture of oleic and acetic acid. D. B.

Toughening Gold (and Silver) in the Melting Crucible. By J. C. Booth (*Chem. News*, **50**, 37—38).—Some brittle coinage gold was toughened as follows:—5400 oz. were melted in a crucible with one or two ounces of soda-ash and anhydrous fused borax. The contents of the crucible appeared as a quiet mass of metal covered with a rather viscid slag, disposed to swell and puff. A few crystals of potassium nitrate, say one or two ounces, were then dropped successively into the centre of the metallic surface, and as they melted their spreading out over the whole surface was aided by the concentric motion of the bottom of a small crucible. The moment the visible oxidising action began to slacken, the fluxed matter was skimmed off by means of a small black lead dipping crucible, as rapidly as was consistent with the care necessary to avoid taking up metal. In this particular case, 1 part of foreign matter was sufficient to impart brittleness to 75,000 parts of good standard gold (900 gold + 100 copper, &c.). By a slight oxidising process, the matter causing brittleness was removed at a trifling cost, without appreciable loss of gold; the standard of the gold was not perceptibly changed by the operation. When the bullion appears to be baser, the only change made in the toughening consists in using a larger amount of soda and borax, and a still larger proportion of nitre. In this case, some of the graphite of the crucible is cut away at the level of the metal, and as the larger bulk of fluxing matter increases the time of skimming, some of the oxidised foreign matter, in the presence of a large amount of metal, and surrounded by graphite, tends to revert to the metallic state. To obviate this, after going through the stronger oxidising process, the oxidation is suddenly fixed by the rapid addition to the floating slag of sand, lime, or bone-ash, which thickens the slag so as to allow more deliberate skimming. The impurities from 75,000 ounces were concentrated into a single button of about 8 ounces. J. T.

Chemistry of Wine. By R. Kayser (*Zeitschr. Anal. Chem.*, 1884, 297—317).—A large number (109) of analyses of wines from the Palatinate, Wurtemberg, the Moselle, Franconia, Italy, Dalmatia, France, and Spain, are given, including estimations of alcohol, extract, ash, acidity, sugar, tartaric, phosphoric and sulphuric acids, lime, magnesia, potash, and glycerol. O. H.

Malt Extract by Different Waters. By E. A. Moritz and A. Hartley (*Bied. Centr.*, 1884, 404—406).—Two natural waters and six samples of distilled water, each treated with a special salt, were used to extract albuminoids from a sample of malt. The malt was of good quality, and the process was conducted in miniature mash-tins, exactly as in commercial way. The extract was filtered from the draff, diluted to 1 litre, 50 c.c. dried at 100° and ignited with soda-lime. The fresh malt contained N, 2·01 per cent. = albuminoïds 12·68.

The results differ in many respects from empirical assertions, and show that the mineral constituents have a considerable influence on the solubility of albuminoïd substances in malt; but even those differences do not, in the author's opinion, account for the variety in the finished products, the mineral salts, he thinks, must exert a direct influence on the fermentation.

J. F.

Nitrogenous Combinations in Barley, Malt, and Beer Wort. By H. Bungener and L. Fries (*Bied. Centr.*, 1884, 406—409).—A series of experiments was undertaken to ascertain the influence of the origin of the barley process of malting and mode of brewing on the quality and quantity of the different nitrogenous substances, and the part played by them in fermentation. In these experiments, the nitrogen called albuminoïd was the difference between total nitrogen and peptones; these were estimated by precipitation with lead hydroxide, and the amides by precipitation of the resulting filtrate with tannic acid. The first series of experiments was with barley of 1882, from Alsace and Champagne, and pale malt made from it at 65°. Solutions were prepared by steeping the ground barley and malt severally for 18 hours in cold water, with the addition of a little thymol solution, and for the worts at 15 per cent., three-quarters of an hour at 20—70°, and half hour at 70°. The results are, in per cent.:—

	Alsatian.			Champagne.		
	Barley.	Malt.		Barley.	Malt.	
Dry substance, nitrogen.....	1·69	1·58		1·84	1·73	
Nitrogen dissolved..........	*a.*	*b.*	*c.*	*a.*	*b.*	*c.*
Total......................	21·0	40·6	36·7	20·6	36·2	36·4
As albuminoïds............	9·5	14·5	10·3	21·1	14·4	10·6
Peptones	2·4	3·8	5·0	2·2	2·4	3·5
Amides	19·1	22·3	21·4	6·3	19·4	22·3

The other series of experiments yielded similar results.

J. F.

Hydrogen Peroxide as Beer Preservative. By WEINGÄRTNER (*Bied. Centr.*, 1884, 428).—The experiments recorded yielded negative results; after 14 days, the flasks of beer treated with hydrogen peroxide were clouded, whilst Pasteurised samples remained perfectly clear. The taste of beer had changed to a flavour of rum; microscopic examination showed much albumin and living yeast cells.

In a second notice, it is stated that nine flasks of beer to which had been added 3, 5, 6, 7, 8, 9, 10 c.c. hydrogen peroxide were carried by the ship "Fulda" to Bremerhaven and back, the voyage lasting a month; they were daily inspected as to colour and transparency, three days after commencement of the voyage, two flasks which were not so treated but kept as control became muddy; the nine remaining clear and bright until returned to New York; four days afterwards they were opened in the laboratory, but during those four days it had become excessively hot and the beer became clouded, the taste and aroma remaining good.

J. F.

Separation of Sugar from Molasses. By P. DEGENER and others (*Bied. Centr.*, 1884, 343).—Degener gives the results of numerous analyses of molasses-lime prepared by different processes. Jünemann separates the sugar by gradual addition of milk of lime to boiling dilute molasses and then filtering; 98 per cent. of the sugar present is thus precipitated as lime saccharate, it may then be washed and decomposed by carbonic anhydride. An improvement in the osmotic process is mentioned by G. Stude as employed in France where the organic potash salts are converted into chlorides by the addition of 1—1·3 kilo. ammonium chloride to every 100 kilos. molasses.

E. W. P.

Quality of the Flour obtained by various Methods of Grinding. By A. GIRARD (*Compt. rend.*, 99, 380—383).—The flour from the same grain has practically the same chemical composition by whatever method it has been ground, but the extent to which it is contaminated by the nitrogenous *débris* of the envelope of the grains, and by germs, depends on the method of grinding. If the wheat has been ground between metal cylinders, the flour is practically free from these impurities, and yields white bread of excellent quality; if the flour is obtained by progressive grinding between metallic runners, or if the grain has been previously cut and granulated, the flour contains a small proportion of the impurities and the bread is less white; whilst if the wheat has been ground under stones by any method, the proportion of the nitrogenous *débris* and germs is relatively high and the bread is distinctly discoloured.

C. H. B.

Comparison of Separators. By FJORD (*Bied. Centr.*, 1804, 339—341).—Three forms of separator were compared, as to their power of separating the cream, and under the various conditions Laval's always left most cream unremoved. The author prefers to use two small machines in preference to one large one.

E. W. P.

Butter Making and the Souring of Cream. By Köhnke and others (*Bied. Centr.*, 1884, 334—336).—The pleasant aromatic taste of good butter is due to the action of lactic acid on some of the constituents of the milk. Butter for keeping should be prepared from cream only slightly acid, nor should the cream be kept longer than 18 hours at 20° so as to avoid precipitation of caseïn. According to De la Marvonnais, after the butter has "come" and is in the state of small granules, it should be washed in the churn after removal of the butter-milk; washing it thus removes the caseïn which is precipitated by the souring of the cream, and is not separated by "working" alone. Calberla by a patent process washes butter in a centrifugal machine; this renders the butter firmer and improves its taste and colour. E. W. P.

Loss of Weight during the Ripening of Cheese. By B. Martiny and W. Fleischmann (*Bied. Centr.*, 1884, 341).—Skim milk cheeses will loose by ripening at least 15 per cent. of their weight. Fleischmann publishes a table showing the loss incurred during the ripening of various kinds of cheese; the diminution varies from 12—30 per cent. E. W. P.

Application of Electrolysis in Preparing Indigo-vats. By F. Goppelsroeder (*Dingl. polyt. J.*, **253**, 245—252, and 381—385).—In furtherance of his former researches on the use of electrolysis in preparing indigo-vats (this vol., p. 942), and in consequence of a publication by Wartha, the author has conducted a series of experiments with indigo-paste and indigo-vats of different concentrations, such as are employed in dye works, the object being to study one or two points in dispute between Wartha and the author. Although the former does not dispute the formation of indigo-vats by electrochemical means, the author deemed it expedient to make a number of experiments with samples of indigo of different origin, and mixed with caustic alkalis or caustic lime, employing various apparatus, working with cold or hot solutions, and exposing them to the current for a longer or shorter period. To prepare the indigo-vat, indigo was mixed with a solution of caustic alkalis or lime, heated gently and the current passed in. In former trials, it was found that the hydrogenation of indigo-blue to indigo-white could be effected in the cold, although the quantity of indigo-white thus obtained had not been determined. Recent experiments confirm Wartha's results, who found that the vat produced at the ordinary temperature acts very slowly, the hydrogenation of the indigotin being very imperfect; hence it is necessary to work with hot solutions. At the boiling point, the conversion is effected with great ease; the current should not, however, be allowed to act on the indigo-vat for too long a period, otherwise the indigo-white formed at first is altered, and finally decomposed. The author gives a detailed account of his experiments, accompanied by diagrams showing a series of electrolytic apparatus of simple construction.

In prosecuting these researches, the author discovered a new fact. He found that by producing the indigo-vat direct on the fibre and exposing the latter to the action of the atmosphere, the indigo-white could be converted into indigotin. For this purpose, finely divided indigo was mixed with caustic alkalis and the fabric saturated with the mixture; it was then placed on a plate of metal and covered with another plate, the two plates forming the electrodes. The current was now passed through, and in the course of a short time the indigotin was completely converted into indigo-white. The advantage gained by the use of this method is the possibility of producing new colours on certain parts of the fabric, and printing reserves for white or other colours on the material before it is subjected to the electrolytic treatment. D. B.

New Mode of Treating Caseïn. By A. Dollfus (*Dingl. polyt. J.*, **253**, 351).—The author proposes to treat caseïn with nitric acid, nitrocaseïn being formed, which may be used very advantageously for the fixation of colours. Nitrocaseïn, when dyed on cotton, yields a yellow-drab colour, which resists the action of chlorine and extreme soaping. D. B.

Artificial Blue Colours. By W. Rospendowski (*Chem. News*, **50**, 84—87).—In order to ascertain if the dye is homogeneous or a mixture of several colouring matters, the author recommends that a little of the powder should be sprinkled on cold water, when coloured veins will descend from each particle (if the dye is soluble in water), and these will be of the same or different colours, according as the dye is homogeneous or a mixture.

He then proceeds to give the reactions of the ordinary commercial blue dyes, when treated with sulphuric acid, soda, ammonia, stannous chloride, and zinc powder. The reactions are given for 18 dyes—Extract of indigo; Nicholson Blue BBB; Soluble blue BB; Induline BBB; Blue SS; Marine Blue BB; Solid Blue; Solid Black Blue; Blue-Black B; Neutral Blue; Vat Indigotin; Indigotin for wool; Topping Blue (*Bleu remontage*); Gallocyanin and Solid Violet; Acid Myrtle; Liquid Green B; Solid green B, 2B, and 3B; Liquid Greens, No. 1 and No. 2; all these greens are mixtures of malachite green and Paris violet. C. E. G.

Canarine. (*Dingl. polyt. J.*, **253**, 130—131, comp. this vol., p. 796.)—This yellow dye, placed in the market by Durand and Huguenin, of Basle, is the yellow precipitate produced by the action of chlorine or bromine on thiocyanic acid.

Prochoroff and O. Miller prepare it as follows: to 1 kilo. potassium thiocyanate in 1 litre water add 20 c.c. hydrochloric acid, and then 1 kilo. bromine gradually, keeping the mixture cool. The yellow precipitate of crude canarine is dissolved in potash and mixed with alcohol, when a potassium compound is thrown down, which yields pure canarine when decomposed with hydrochloric acid. When dried at 100°, it is a reddish-brown glistening powder, insoluble in water, alcohol, and ether, soluble in concentrated sulphuric acid and in potash solution.

H. Schmid considers canarine to be identical with persulphocyanogen, $C_3NH_3S_3$. O. Miller disputes this, asserting that canarine dissolves in concentrated sulphuric acid with evolution of sulphurous anhydride, which is not the case with persulphocyanogen.

To apply canarine, Prochoroff and O. Miller dissolve 1 part in 1 part caustic potash and 20 parts warm water, and add to the brown solution 7 to 10 per cent. of soap, afterwards allowing to cool. Water containing lime or magnesia should be avoided, as these bases throw down the dye. Neither can caustic soda be used, as the sodium compound is insoluble in the cold. The dye is decomposed if it is heated too long with potash. Köchlin boils 100 grams canarine in 1 litre water with 100 grams borax. Hot solutions of canarine in soda can also be employed. The procedure is then similar to that of alizarin dyeing. By thickening the borax solution, printing, and steaming, a pure yellow is obtained. Canarine colours are distinguished for their resistance to light and soap. J. T.

Auramine. (*Dingl. polyt. J.*, **253**, 86—87.)—This interesting novelty is the first artificial yellow dye which can be fixed on the vegetable fibre with tannic acid like aniline dyes. According to C. Köchlin, a steam colour is prepared of auramine 1 part, tartaric acid 1 part, and tannin 6 parts. If this colour be printed on ordinary textures instead of on those prepared with tin, it becomes perfectly fixed, after steaming, by the usual treatment with tartar emetic. The dye then resists soap. Auramine also becomes fixed on wool, giving colours of great purity. The colours bear light very well, but are sensibly affected by chlorine.

Owing to its property of being fixed by tannin, it can be mixed with other tannin dyes, as, for example, in the production of very yellow shades of malachite green, &c. Auramine can be fixed, under certain conditions, with metallic mordants such as alumina.

Poirrier produces a dye, *jaune solide*, remarkable for purity; it is an azo-dye, which can be fixed by chromium acetate. Like Persian berries, it can be mixed with coerulin, logwood, &c., to produce olive and other tints, also with aniline dyes. Alone, the dye gives orange-yellow shades of considerable resistance to light and soap.

Flavaniline, a third new yellow dye for silk and wool. According to C. Köchlin, in printing it is best fixed with its weight of tartaric acid and magnesium acetate. If cotton goods printed with manganese brown be dyed with flavaniline, a bright brown is produced, as is the case with naphthylamine, only where the brown has been discharged with tin salt a yellow appears. J. T.

New Coal-tar Dyes and their Preparation. (*Dingl. polyt. J.*, **252**, 519—523.) According to the Farbenfabriken, formerly F. Bayer and Co., a third body has been found in the two monosulphonic acids of β-naphthol, which appears to be a sulphonic acid of β-naphthol, and, like Schaeffer's acid, combines more readily with diazo-compounds than the α-monosulphonic acid previously described.

A new yellow colouring matter, called "echurin," is obtained, according to the Leeds Manufacturing Company, by mixing 5 parts picric acid with 3 parts flavin, adding 12 parts nitric acid of 36° B., heating on a water-bath, and evaporating to dryness.

Majert obtains quinoline-derivatives from the nitro- and amido-derivatives of anthraquinone in the same way as from nitrobenzene or aniline. These bodies form yellow colouring matters, whose alcoholic solutions impart a yellow colour to wool and silk, which is very permanent. By converting the dyes into sulphonic acids, they are obtained in a soluble form. D. B.

Separation of Azo-colouring Matters of Mixed Naphtholsulphonic Acids. (*Dingl. polyt. J.*, **252**, 440.) Dahl and Co., instead of separating naphtholsulphonic acids and preparing azo-dyes from the pure acids, isolate certain azo-compounds by the different solubility of their alumina, lime, baryta, and strontia derivatives. This is specially applicable to azo-dyes prepared from a mixture of the α- and β-monosulphonic acid of β-naphthol with diazo-naphthalenemonosulphonic acid and diazo-azobenzenemonosulphonic acid, or in the case of dyes obtained from a mixture of the di- and tri-sulphonic acids of β-naphthol with diazo-naphthalenemonosulphonic acid, diazoazobenzene, and diazo-azobenzenemonosulphonic acid. D. B.

Preparation of Red and Violet Dyes. (*Dingl. polyt. J.*, **252**, 343.)—When α-naphthol is introduced into cold fuming sulphuric acid, a new α-naphtholsulphonic acid is produced, in addition to that described by Schaeffer. A new acid is obtained also when the diazo-compound of Piria's naphthionic acid prepared by sulphonating naphthylamine is decomposed by boiling it with acidulated water. Whilst by the action of diazo-compounds on Schaeffer's acid, orange and brown dye-stuffs are produced, the monosulphonic acids which are obtained from α-naphthol in the cold, and from Piria's naphthionic acid, yield ponceau to cherry-red dyes (Verein chemischer Fabriken, Mannheim).

By the action of phosgene on dimethylaniline and diethylaniline, the corresponding acid chlorides and ketone bases are formed, and as bye-products, violet colouring matters. According to the Baden Aniline and Soda Works, the formation of these dyes becomes the primary reaction when the action of phosgene on the tertiary bases is assisted by some energetic condensation agent, such as aluminium chloride. It is thus possible to obtain from dimethylaniline and diethylaniline violet dyes of the triphenylmethane group; also similar colouring matters, by extending this reaction to a large series of tertiary aromatic monamines. D. B.

Manufacture of Lignose (Wood Cellulose). (*Dingl. polyt. J.*, **252**, 323—328.)—In order to remove the difficulty attending the "sulphite boiling" process, viz., the evolution of sulphurous anhydride and the contamination of the surrounding atmosphere with this gas, Graham proposes the use of the monosulphites of potassium, sodium, magnesium, &c. For this purpose a solution of the monosulphite or a suitable combination of any of them is introduced into the boiler, and when the gases contained in the wood and the boiler have been driven off by heat, sulphurous acid in the gaseous or liquid state is injected. Instead of the introduction of sulphurous acid alone, it may be injected in combination with potassium, sodium, or magnesium. An excess of acid should be employed, but not sufficient to form in the boiler a solution of acid sulphites.

In bleaching the fibres from vegetable substances, Graham has patented a process which consists in bringing sodium or potassium nitrate in solution into contact with the fibrous substances, being treated either at the same time as or subsequent to their treatment with the ordinary chlorine bleaching agents.

Pictet and Brélaz show that the high temperature (120—140°) used in the process for preparing lignose converts all gummy and resinous substances into tars, which interfere with the subsequent bleaching operations. They therefore recommend the use of an aqueous solution of sulphurous acid, which is said to dissolve the incrustating substances of the wood at a low temperature, so that a larger yield of cellulose is obtained, and the bleaching is facilitated.

For the preparation of cellulose from wood, straw, &c., 100 kilos. wood are brought into a wrought-iron boiler, and treated with an aqueous solution of sodium sulphide (10° B.) containing 30 kilos. pure sodium sulphide. The mixture is then heated for 6—10 hours, at a pressure of from 5—10 atmospheres.

Blitz boils wood for 3—4 hours in a closed vessel, at a pressure of 4 atmospheres, with a solution containing 6 kilos. sodium sulphide, 3 kilos. caustic soda, and 1 gram ammonium vanadate. D. B.

Explosives. (*Dingl. polyt. J.*, **253**, 70—77.)—Recently, much has been said about panclastite, an explosive patented by E. Turpin, but not to be confounded with a compound of the same name previously described (*Dingl. polyt. J.*, **252**, 153). Turpin's procedure rests on the application of nitrous acid, with which the liquid hydrocarbons (petroleum, toluene, xylene, naphthalene) nitrogen-compounds of the tar-derivatives (nitrobenzene, nitroxylene, aniline nitrate, nitraniline), and various fats (suet, butter, linseed oil) gives mixtures of explosive substances. The fatty bodies are first nitrated by means of nitrous acid, and warmed on the water-bath to expel nitrous fumes. These nitrated fatty bodies, or the other non-nitrated compounds, are mixed with 1—2 parts of nitrous acid, in order to produce the explosive; this product is absorbed by porous substances, as in the case of nitroglycerol, and made up into air-tight cartridges of metal or glass. When ignited, panclastite burns quietly, and only detonates under a percussive impulse. The addition of carbon bisulphide makes the compound more easily explosive, whilst increase in the nitrous acid increases the explosive power. Panclastite, however, appears to be too unstable and uncertain for practical work. J. T.

INDEX OF SUBJECTS.

ABSTRACTS. 1884.

A.

Absorbents in stables, Stassfurt salts as, 491.
Absorption of an iodine-compound by aluminium, 655.
Absorption-spectrum of blood in the violet and ultra-violet, 381.
Accumulators, variation of electromotive force in, 881.
Acediamine, 1289.
Acetaldehyde, action of baryta on, 989.
—— action of orthonitrobenzaldehyde on, 58.
—— formation of crotonaldehyde and β-hydroxybutaldehyde from, 420.
Acetamide, formation of, from acetic acid and ammonia, 1295.
Acetamidine hydrochloride and platinochloride, 723.
Acetamidocumic acid, 303.
Acetanilide, formation of, from acetic acid and aniline, 1295.
—— nitration of, 1012.
—— nitro-, reduction of, 665.
—— paramido-, and some new azo-derivatives, 1016.
Acetic acid, brom-, convenient method for preparing, 421.
—— —— decomposition of, by the silent discharge, 543.
—— —— estimation of, in wine, by distillation with steam, 641.
—— —— monochlor-, preparation and melting point of, 990.
—— chloride, action of zinc propyl on, 1280.
—— —— higher homologues of, 1125.
Acetoacrylic acid, 41.
—— —— β-trichlor-, and its bromine-derivative, 1122.
Acetochlorhydrose, action of dipotassium salicylate on, 439.
Acetohydrazobenzene, 1015.
Acetonaphthalides, α-, β-, and δ-nitro-, 751, 752.
Acetone, chlor- and brom-, action of, on ethyl acetoacetate, 746.
—— condensation of, with aromatic aldehydes, 1166.
—— cyanhydrin, imido-ethers from, 1292.
—— decomposition of, by the silent discharge, 543.
—— pentachlor-, and its isomeride, 580.
Acetonitrile, transformation of, in the organism, 1061.
—— trichlor-, a polymeride of, 35.
Acetonitrotoluide, 1007.
Acetophenone, amido-, and allied substances, 1343.
—— brom-, action of, on ethyl sodacetoacetate, 598.
—— —— action of, on hydroxylamine hydrochloride, 51.
—— bromide, action of, on ethyl acetoacetate, 746.
—— ω-dichlorometabromorthamido-, 1027.
—— orthamido-, derivatives of, 1021, 1026.
—— orthonitro-, bromo-, and chloro-derivatives of, 445.
Acetophenoneacetoacetic acid, 598.
—— —— derivatives of the ethereal salts of, 1177.
Acetophenone-acetone, 1177.
—— and its mono-isonitroso-derivative, 599.
Acetophenones, nitro-, three, and some of their derivatives, 445.
β-Acetopropionic acid, action of bromine on, 1297.
Acetorthamidotoluene, 1343.
Acetotriphenylmethylamine, 1033.
Acetoximes of the fatty series, 1115.
Acetoxypropylbenzoic acid, nitro-, 317.
Acetoxypyridine, 1370.
Aceturamide, 1308.
Aceturic acid and its salts, 1306.
Acetyl distearyl glycerol, 281.
Acetylcodeine, 614.

Acetyldihydroxytetrahydroquinoline, 78.

Acetylene, formation of, from iodoform, 418.

—— higher homologues of, 1108.

—— hydrocarbons, action of, on mercuric salts, 572.

Acetylglycocoll and its salts, 1306.

Acetylisatic acid, chemical constitution of, 78.

Acetylisatin, chemical constitution of, 78.

Acetylmethyltrimethylenecarboxylic acid, 1155.

Acetylorthamidoacetophenone, esobromo- and ω-dibromometabrom-, 1026.

Acetylorthamidobenzaldehyde, 1020.

Acetylpentamethylparaleucaniline, 607.

Acetylphenylparacoumaric acid, synthesis of, 176.

Acetylpyrroline and its derivatives, 289.

Acetylpyrroline-carboxylic acid, 290.

Acetylquinovite, 1191.

Acetylsulphanilic acid, salts of, 1024.

Acetyltrimethylene, 1155.

Acetyltrimethylenecarboxylic acid and its ethyl salt, 64.

Acid anhydrides, preparation of, 990, 991.

Acid, new, isomeric with crotonic acid, 295.

Acidamines, 725.

Acidoximes, 739.

Acids, complex, containing molybdenum, 161.

—— etherification of, 726.

Acorns, storage of, 100.

Acridine and some of its derivatives, 608.

—— formation of, 1182.

—— new method for producing, 748.

—— nitrite, 748.

—— picrate, 908.

—— the ammonium bases derived from, 1357.

Acridines, 1356.

Acridylbenzoic acid and its derivatives, 1183.

Acrylic acids, substituted, 663.

Actinometer, 202.

α- and β Æsculetic acids, 67.

Æsculetin, 67, 1347.

Agaricic acid, 354.

Air around Carlsberg, organisms in, 126.

—— boiling point of, under atmospheric pressure, 817.

—— charged with petroleum vapour, respiration of, 1057.

—— compressibility of, at 20 to 300° under 1 to 8 atmospheres' pressure, 146.

Air, critical temperature and pressure of; relation between its boiling point and the pressure, 1257.

—— estimation of carbonic anhydride in, 1076.

—— of Lille, sulphurous anhydride in, 710.

—— rarefied, compressibility of, 146.

—— —— effect of, on the animal organism, 470.

—— somewhat deficient in nitrogen, influence of, on animals, 344.

—— temperature, soil temperature in relation to, 357.

—— and moist phosphorus, behaviour of, towards carbonic oxide, 660, 711, 1092.

Alanine and ethyl oxalate: a correction, 995.

Albite, alteration of orthoclase into, 273.

—— from Mt. Blanc, analysis of, 402.

—— formation of, in the wet way, 163.

Albumin, 90.

—— decomposition products of, 849.

—— some reactions of, 910.

Albuminoids, 1388.

—— amount of, in feeding-stuffs, 631.

—— compounds of silver with, 343.

—— of the vitreous humour of the human eye, 198.

—— products of the bacterial fermentation of, 89, 188.

—— ultra-violet absorption-spectra of, 242.

Albumose, new forms of, 1389.

Alcohol, an, from birdlime, 1365.

—— estimation of small proportions of, in viscous liquids, 641.

—— evaporation of, from wooden vats, 526.

—— formation of, in the fermentation of bread, 532.

—— from melon-juice, 233.

—— halymetric estimation of, in beer, 641.

—— in the brain in cases of inebriation, 370.

—— liquid paraffin as a reagent for the presence of water in, 1073.

Alcoholates, heat of formation of, 546.

Alcoholic iodides, action of pyridine bases on, 612.

—— —— tertiary, some reactions of, 167.

Alcohols, dihydric, synthesis of, from mixtures of aldehydes, 832.

—— etherification of, 726.

—— normal, specific volumes and rate of expansion of, 1278.

Alcohols, of the ethyl series, direct conversion of, into amines, 984.
—— of the paraffin series, action of aluminium chloride on a mixture of, with ethyl chlorocarbonate, 1279.
—— polyhydric, a general reaction of, in presence of borax and paratungstates, 1284.
—— —— action of, on borax, 278.
—— and alcoholic liquors, purification of, 645.
Aldehyde-ammonia, explanation of the action of silver nitrate on, 722.
Aldehyde-collidine hexahydride, 1054.
Aldehyde-gum, 989.
Aldehydes, action of, on ketones, ketonic acids, and malonic acid, 445.
—— action of, on phenols, 597, 598.
—— action of phosphorous trichloride on, 833.
—— aromatic, condensation of, with phenols, 590.
—— —— Etard's reaction for the preparation of, 1161.
—— chlorinated, action of zinc-ethyl and zinc-methyl on, 1118.
—— conversion of hydrocarbons into, by the action of chromyl dichloride, 312.
—— phenylhydrazine, a reagent for, 1150.
—— phosphine-derivatives of, 1118.
—— reaction of ethyl acetoacetate with, 443.
Aldol, action of heat on, 579.
Aldoximes, action of acetic chloride and anhydride on, 1154.
Aldoximesalicylic acids, ortho- and para-, 42.
Alimentary canal of herbivora, gases of, 852.
—— principles, chief organic, in the animal body, substitute values of, 189.
—— substances, calorificient values of, 190.
Alisonite, artificial, 266.
Alkali polysulphides, constitution of, 1260.
Alkali-proof vessels, nickel, 1071.
Alkali-waste, recovery of hydrogen sulphide from, 1442.
Alkalimetry, use of boric acid and hæmatite in, 638.
Alkaline earths, heats of dissolution and hydration of, 250.
—— fluosilicates, thermochemistry of, 884.
—— solutions, freezing point of, 254.
—— estimation of, in lepidote from India, 27.
Alkalis, heats of solution and hydration of. 250.
Alkaloïd, liquid from *Lupinus luteus*, 1387.
Alkaloïds, action of zinc-ethyl on, 985.
—— of Angustura bark, 341.
—— of *Buxus sempervirens*, 188.
—— putrefactive, 1202.
—— vegetable, tests for, 120.
Alkines, aromatic, 1011.
—— some new, 1114.
Alkyl iodides, use of liquid paraffin in the preparation of, 1073.
Allanite from Alexander Co., N.C., 274.
Allantoïn, new synthesis of, 426.
Alloclasite, 266.
Alloy of platinum and tin, 822.
Alloys, change of volume of, at melting, 7.
—— metallic, 517.
Allyl cyanide, imido-ethers from, 1292.
—— dimethyl carbinol, crude, an alcohol in, 1283.
—— resorcinol methyl ether, 1331.
Allylacetophenone, 63.
Allylamine sulphate, 732.
Allylbenzoylacetic acid, 63.
Allylcarbamide, and derivatives of, 731.
Allylene, action of, on mercuric oxide and its salts, 719.
Allylphthalopseudocumidamide, 1319.
Almond oil, fatty, examination of, 120.
Altitude, effect of, on plant growth, 627.
Alum, estimation of, in wine, 1077.
Alumina, ferric oxide, and titanic oxide, separation of, 640.
Alumina-garnet containing manganese, 409.
Aluminium, absorption of an iodine-compound by, 655.
—— acetate, behaviour of, 39.
—— —— preparation of, 540.
—— atomic weight of, 395.
—— borides, 156.
—— chloride, action of, on a mixture of alcohols of the paraffin series with ethyl chlorocarbonate, 1279.
—— electrolytic deposition of, 934.
—— manufacture of, 230, 1230.
—— orthophosphate, crystallised, 1263.
—— oxalate, tribasic, 296.
—— salts, behaviour of, as mordants, 794.
—— soldering of, 961.
—— sulphate, hydrated, 820.
—— thiocyanate free from iron, 540.
—— and ferrous sulphate, native, from Mexico, 24.

Alums, differential dilatometer and its application in an investigation on the formation of, 887.
—— expansion of, 892.
Amalgam from the Friedrichssegen mine near Oberlahnstein, 563.
Amalgams of zinc and cadmium, position of, in electro-potential series, 382.
Amalic acid, decomposition of, by heat, 467.
Amides, action of alkalis on, 878.
—— behaviour of, in animal nutrition, 472.
—— estimation of, in vegetable extracts, 1438.
—— formation of, from ammonium salts, 836, 1294
Amidine hydrochlorides, action of heat on, 723.
Amidines, action of acetic anhydride on, 722.
—— action of benzoic chloride on, 1324.
—— action of hydroxylamine on, 739.
Amido-acids, action of thiocarbamides on, 907.
—— —— certain, optical behaviour of, 1306.
Amidobenzene, tetramethylated, 1320.
Amidobenzenemetasulphonamide, the action of nitrous acid on, 72.
Amido-fatty acids, general reaction for, 994.
Amido-groups, replacement of, in aromatic derivatives by chlorine, 1311.
Amidophenol, dibrom-, 594.
Amidoximes, 1325.
Amidulin, 575.
Amines, action of bromine in alkaline solutions on, 1114.
—— —— zinc-ethyl on, 985.
—— aromatic, action of dichloracetic acid on, 47.
—— —— conversion of, into the ethers of the corresponding phenols, 1314.
—— diagnosis of, 985.
—— molecular weight of, 257
—— organic, action of soda, lime, and magnesia on, 776.
—— primary, conversion of, into nitriles, 1288.
—— secondary, action of isothiocyanates, of isocyanates, of thiocyanates, and of cyanates on, 1320.
Ammonia, action of soda, lime, and magnesia on the salts of, 776.
—— detection and estimation of, in animal liquids, 1215.
—— electrolysis of solutions of, with carbon electrodes, 176.
—— estimation of, as nitrogen in manures, 638.
Ammonia, estimation of, in vegetable juices and extracts, 373,493.
—— recovery of, from the gases of coke ovens, 1441.
—— volumetric estimation of, 492.
Ammonia-gas, absorption of, by alcohols, 278.
Ammoniacal salts, electrolysis of solutions of, with carbon electrodes, 176.
Ammonio-silver chloride and iodide, crystallised, 890.
—— —— compounds, 1261.
—— —— nitrate, 261.
Ammonium albuminate, preparation of, 945.
—— carbonate, dissociation of, in presence of an excess of one of its elements, 388.
—— distearyl glycerol, 280.
—— ferrous sulphate as a reagent for nitric acid, 493.
—— fluoride as a blowpipe reagent, 927.
—— —— purification of, 492.
—— hydroxide, non-existence of, 1247.
—— iodide and iodate, preparation of, 153.
—— lactate, action of heat on, in presence of ammonia gas, 725.
—— salts, formulæ of certain organic, 729.
—— sulphate, production of, 1442.
—— superphosphate, crude, manuring with, 926.
—— thiocyanate, poisonous action of, on plant life, 768.
—— thiosulphate, use of, instead of sulphuretted hydrogen in qualitative analysis, 363.
Amphibole, relation between the optical properties and chemical composition of, 971.
Amphibole-granite, biotite-holding, from Syene, 413.
Amyl oxysulphide, action of chlorine on, 1127.
Amylaceous matters, estimation of moisture in, 927.
Amylene oxide, action of hydroxylamine on, 610.
Amylnaphthalene, preparation of, 1357.
Amylodextrin, 576.
Amylsulphonic acid, action of chlorine on, 1127.
Anana, presence of mannitol in, 629.
Anaquinolinecarboxylic acid and its salts, 1372.
Anderson's reaction for pyridine bases, 612
Andesine, new locality for, at Orijarvi, in Finland, 970.
Andesites, Cheviot, 413.
Angustura bark, alkaloïds of, 341.

Anhydrite, occurrence, association, and probable mode of formation of, 25.
Anhydrobenzodiamidobenzene, ethyl derivatives of, 741.
Anhydrodiacetylacetamidil, 723.
Anhydrodiacetylacetamidine, 723.
Anhydrodipyrogallopropionic acid and its derivatives, 319.
Anhydroformaldehydaniline, 988.
α-Anhydrosulphaminephthalic acid, potassium salt of, 320.
Anilacetone, isonitroso-, 1368.
Aniline, action of ethyl malonylchloride on, 729.
—— action of, on pyrotartaric acid, 1006.
—— action of the induction spark on, 1243.
—— colours, new, 1322.
—— derivatives, 1005.
—— nitration of, 1012.
—— nitro-, action of ethylene bromide on, 1142.
—— para- and ortho-toluidine, separation of, 46.
—— parabrom-, nitration of, 1013.
—— parabromonitro-, 1013.
—— titration of, 776.
—— and nitrobenzene, action of benzaldehyde and sulphuric acid on a mixture of, 442.
Aniline-black, dyeing with, 942.
Aniline-dyestuffs, fixation of, by means of metallic sulphides, 539.
Aniluvitonic acid and its derivatives, 320.
Animal body, elimination of nitrogen in the free state from, 1391.
—— —— influence of cold and warm baths on the temperature of, 621.
—— —— substitute values of the chief organic alimentary principles in, 189.
—— liquids, detection and estimation of ammonia in, 1215.
—— nutrition, behaviour of amides in, 472.
—— organism, inflammable gases in, 1395.
—— organs, fresh, supposed toxic action of aqueous solutions obtained from, 199.
"Animal quinine," 342.
Animals, diseases of, 914.
—— hydrocyanic acid from, 348.
—— observations on different diseases of, 95.
—— stony concretions in, 348.
—— which have died from contagious diseases, especially from Anthrax, destruction and utilisation of the bodies of, 106.
Anisaldoxime, 581.
Anisic acid, dibrom-, constitution of, 1172.
Anorthitic rock of St. Clement, Puy de Dôme, 411.
Anthophyllite, alteration of talc into, 272.
Anthracene and analogous compounds, chemical constitution of, 1186.
—— from tetrachlorophthalic acid, 1039.
Anthracene-carboxylic acid from methylanthraquinone and its derivatives, 329.
Anthranil, constitution of, 61.
Anthranilcarboxylic acid, 61.
Anthraquinoline, synthesis of, 759.
Anthraquinone, a new synthesis of, 1039.
—— and analogous compounds, chemical constitution of, 1186, 1187.
—— compounds, preparation of, 945.
—— monisonitroso-derivative of, 62.
—— nitro-, action of concentrated sulphuric acid on, 1187.
Anthraquinonecarboxylic acid and its derivatives, 1188.
Anthraquinones, chlorinated, 1039.
Anthraquinonesulphonic acid, α-nitro-, action of strong sulphuric acid on, and the constitution of the latter, 1189.
—— —— α-nitro-, and its derivatives, 1040.
Anthroxanaldehyde, 60.
Anthroxane, 61.
Anthroxanic acid, 60.
Antialbumid, 849.
"Antibacteride," preparation of, 782.
Anti-incrustators, secret, 1087.
Antimony chloride and oxychlorides, heat of formation of, 707, 1246.
—— fluoride, thermochemistry of, 884.
—— oxide, prismatic, transformation of, into the octahedral oxide, 894.
—— pentiodide, 19.
—— processes for recovering and refining, 516.
—— tartrates, 298.
—— tin and arsenic, qualitative separation of, 777.
Antipeptone, 849.
Antipyrine, and its nitro- and isonitroso-derivatives, 1378.
Antiseptic compound, an, preparation of, 782.
Antiseptics, different, action of, 1220.
—— properties of, 225.
Apatite from Horrsjöberg, Sweden, 269.
Apatites, chemical composition of, 162.
Apocolchiceïne, 1387.
Apparatus for collecting solid carbonic anhydride, 1253.
—— for estimating carbon in steel, 219.

Apparatus for obtaining sublimates, 364.
—— for preparing oxygen quickly, 1254.
—— for the estimation of carbonic anhydride, 1216.
—— for the rapid analysis of gases, 213, 214.
—— for the reduction of measured gas-volumes to normal condition, 775.
Apple-must, examination of, and of the cider obtained therefrom, 98.
Apples. cider, analysis of some, 203.
Aqueous vapour, atmospheric absorption by, 241.
Arabinose and lactose, non-identity of, 1287.
Arable land, dialysis of, 113.
Arbutin, 175, 432.
—— behaviour of, in the animal organism, 915.
Argentammonium compounds, organic, 721.
Arksutite, 265.
Aromatic acids as dye-forming substances, 1169.
—— bases, condensation-products of, with aldehydes, 1315.
—— substances, exhaustive chlorination of, 588.
Arsenic, detection of, 368.
—— distribution of, in a human body, 349.
—— estimation of, 115, 116, 1428.
—— —— Pearce's process, 115, 116.
—— in glass, 220.
—— localisation of, in a case of poisoning, 199.
—— phosphide, 155.
—— presence of, in wines free from artificial colouring matter, 526.
—— separation of, from saline solutions, 1083.
—— trihydride, temperature of solidification of, 816.
—— tin, and antimony, qualitative separation of, 777.
Arsenical pyrites, relations between the crystalline form and chemical composition of, 404.
—— —— from Hüttenberg, 1099.
Arsenomolybdic acid, 715.
Arsenotungstic acids, 965.
Arsenovanadic acid, 1266.
Artichokes a source of spirit, 526.
Asarite, 1042.
Asarone, 1042.
—— and the ethereal oil of *Asarum Europæum*, 1191.
Ash of leaves of plants grown in the earth under water-culture, 98.
Asparagine, chemistry of, 42.
—— detection of, in vegetable juices and extracts, 373.
Aspartic acid, preparation of, from asparagine, 42.
—— colloïd, amido-, 957.
Asphalt, Bentheim, geological and chemical investigation of, with reference to analogous occurrences in Italy, 522.
—— of Judea, 231.
Atmosphere, carbonic anhydride in, 659, 710.
—— contamination of, by products of respiration, 510.
—— method of correcting the weight of a body for the buoyancy of, when the volume is unknown, 13.
—— of dwellings, influence of artificial lighting on, 122.
—— superoxygenated, respiration in, 911.
Atmospheric absorption by aqueous vapour, 241.
—— dust, 225.
Atomic weights, determination of, by means of metallic sulphates, 256.
—— —— some, verification of, 813.
Atropine, influence of, on lactation, 1396.
Augite-andesites, European, 568.
Auramine, 1450.
Auric phosphoric chloride, 968.
Aurin, salts and ethers of, 1339.
—— tetranitro-, and its salts, 1339.
Aurous oxide, salts of, 17.
—— phosphorous chloride, 968.
Avalite. 1272.
Avenin from oats, 915.
Azidines, 743.
Azoacetanilide, 301.
Azobenzene, acetyldiamido-, and paradiamido-, 1016.
—— amido-, action of hydrochloric acid on, 1014.
—— —— derivatives of, 1148.
—— —— preparation of, 1014.
—— substitution-products of, 1145.
Azobenzeneazoparacresol, 901.
Azobenzenemonophenylthiocarbamide, 1149.
Azobenzeneparasulphonic acid, dinitro-, and parabrom-, and their salts, 1145, 1146.
Azobenzil, 313.
Azo-colours, 1036.
Azo-colouring matters of mixed naphtholsulphonic acids, separation of, 1451.
Azo-compounds, 1146.
—— —— amido-, action of hydrochloric acid on, 1014.
—— —— orthamido-, 742.
Azodimethyloxyquinizine, 1330.
Azodimethylquinol, and its dibromderivative, 1330.

Azo-dyes, preparation of, from β-naphtholtrisulphonic acids, 237.
—— —— red and brown, process for preparing, 238.
Azoethylmethyloxyquinizine, 1380.
Azomesitylene, 904.
Azonaphthol-dyes, constitution of, 609.
Azo-orthophenoxyacetic acid, and its salts, 1170.
Azoparacresol, 736.
Azoparatoluene, amido-, and its derivatives, 742.
Azophenols, behaviour of, towards various reagents, 1014.
Azoresorcinol, and derivatives of, 1333.
Azoresorufin, 1354.
—— and derivatives, 1333.
—— dimethyl ether, 1341.
Azoresorufyl hydrochloride, 1334.
Azotoluenedisulphonic acids, and their derivatives, 71.
Azoximes, 1325.
Azoxybenzotoluide, 666.
Azoxyorthophenoxyacetic acid, 1170.
Azulene, 82.
Azylines, 178, 179.
—— of tertiary diphenylamines, 179.
—— oxidation of, 179.

B.

Bacillus butylicus, products of fermentation with, 765.
Bacillus of cattle plague, 1398.
Bacteria, comparative poisonous action of metals on, 351.
—— influence of light on the development of, 475.
Barium alcoholate, heat of solution of, 4.
—— compounds, recovery of, 394.
—— glyoxal-hydrogen sulphite, heat of formation of, 989.
—— hydrogen phosphates, decomposition of, by water, 891.
—— manganite, crystallised, 1261.
—— oxychloride, 712.
—— permanganate, new method for preparing, 891.
—— sulphate, solubility of, in ac 813.
Bark of "Bois Piquant," 848.
"Barking" nets and sails to preserve them, 800.
Barley, American, analysis of, 1405.
—— Chili saltpetre for, 1419.
—— continuous cultivation of, at Woburn, 482.
—— malt, and peas, comparative feeding value of, 206.
Barley, manuring, 1419.
—— —— with nitrogen and phosphates, 925.
—— nitrogenous constituents of, 790, 1446.
—— Saxon, composition of, 630.
—— steeping of, 526.
—— and malt, and analyses of, 233.
Barytes, occurrence, association, and probable mode of formation of, 25.
Basalt from Naurod, near Wiesbaden, 414.
Basalt-glass of the Western Isles of Scotland, 570.
Basaltic rocks from the Faroe Islands, 415.
Bases formed by the addition of haloïd ethereal salts to quinoline, 1050.
—— of the pyridine and piperidine series, 759.
Basic sulphates, 151.
Bassia longifolia, seeds of, and the fat contained therein, 919.
Baths, cold and warm, action of, on the temperature of the animal body, 621.
Batrachians, poison of, 764.
Batteries, effect of temperature on the electromotive force and resistance of, 243.
—— liquid, conversion of, into dry piles, 1240.
Battery with carbon electrodes, 1240.
Bauxite, formation of, 406.
Bean of *Soja hispida*, notes on, 918.
Beer, absorption of carbonic anhydride by, 1233.
—— barrelled, Pasteurising, 789.
—— detection of sulphurous anhydride in, 1440.
—— halymetric estimation of alcohol in, 641.
—— Pasteurising, 527, 789.
—— ratio of glycerol to alcohol in, 641.
—— salicylic acid in, 778.
—— preservative, hydrogen peroxide as, 1447.
Beer-wort, nitrogenous combinations in, 1446.
Beer-yeast, fermentative strength of, in distillery mash, 939.
Beeswax, acids contained in, 1297.
—— —— analysis of, 779.
—— —— examination of, 506.
Beet, 356.
—— Chili saltpetre for, 637, 1418.
—— cultivation, 208, 921.
—— application of artificial manures in the cultivation of, 773.
—— composition of, 356.

Beet, distribution of sugar in, and the position in the beet of the mean amount of sugar, 766.
—— effect of drying, of frost, and of winter storage on the constitution of, 767.
—— estimation of sugar in, 642.
—— examination of, 1219.
—— experiments with, at Grignon, 1883, 1070.
—— formation and accumulation of saccharose in, 476.
—— influence of soil, size of seed, period of sowing, &c., on the quality and yield of, 103.
—— manuring, 103, 635, 773, 921, 1420.
—— percentage of sugar in, 133.
—— pulp, exhausted, effect of, on cows' milk, 347.
—— removal of juice from, 647.
—— researches on, 485.
—— sodium nitrate and ammonium sulphate as manures for, 491.
—— varieties, 865.
—— and other roots, cultivation of, 1211.
Beet-residues, exhausted, drying of, 1411.
Beet-seeds as cattle food, 631.
Beet-sugar, occurrence of a new acid in, 939.
—— —— preparation of strontianite for purifying, 939.
—— —— recovery of the ammonia in the alcohol used for the removal of molasses from, 939.
—— —— manufacture, composition of residues obtained in, 699.
—— —— manufacture, loss in, 791.
Beets, dry, effect of remoistening, 767.
—— valuation of, by their density, 118.
Belladonine, 761.
—— and derivatives of, 1055.
Benzal chloride, action of copper on, 1133.
Benzalacetone, 1166.
Benzalacetophenone, 1167.
Benzaldehyde, action of benzoic chloride on, in presence of zinc-dust, 1163.
—— action of, on the mononitro-derivatives of the paraffins, 313.
—— and paranitro-, indogenides of, 75.
—— dichloro-, 1028.
—— nitrated, action of potassium cyanide on, 1342.
—— orthamido-, and some of its derivatives, 1019.
—— orthonitro-, action of, on acetaldehyde, 58.
—— —— preparation of, 744.
Benzaldehyde, orthonitro-, amido- and dichloro-, 1028.
—— trichloro-, action of dimethylaniline on, 914.
—— cyanhydrin, action of hydroxylamine hydrochloride on, 734.
Benzaldehyde-green, acetamido-, 1316.
Benzaldiacetonamine, 1291.
Benzaldiacetonine, 1291.
Benzaldipiperyl, 1011.
Benzaldoxime, 1326.
Benzalfurfuralacetone, 1167.
Benzalmalonic acid, 444.
Benzamide, dibromo-, 601.
—— metamido-, derivatives of, 455.
—— —— reaction of, with aldehydes, 455.
—— hydrochloride, action of benzoic chloride on, 1324.
Benzanilide, parachlorometanitro-, 601.
Benzene, action of bromethylene on, in presence of aluminium chloride, 733.
—— —— chloraldehydes on, in presence of aluminium chloride, 837.
—— —— isobutyl chloride on, 1312.
—— —— methylene chloride on, 1312.
—— —— on vinyl bromide and on vinyl tribromide in presence of aluminium chloride, 753, 754.
—— —— the induction spark on, 1243.
—— as an insulator, 244.
—— constitution of, 41, 836, 1122.
—— derivatives, nitration of, 1011, 1310.
—— —— oxidation of, with potassium ferricyanide, 299.
—— hexachloride, new compound formed in the preparation of, 733.
—— —— vapour-density of the new isomeride of, 886.
—— nature of the hydrogen-atoms in, 314.
—— nitro-, and aniline, action of benzaldehyde and sulphuric acid on a mixture of, 442.
—— perbromo-, preparation of, 588.
—— perchloro-, 589.
—— triamido-, unsymmetrical, 1145.
—— and pyridine, relation between, 758.
Benzeneazoacetone, 1342.
Benzene-azo-α- and β-naphthol, 610.
Benzeneazoketone, 1342.
Benzeneazoparatoluene, 903.
Benzenemetasulphonamide, amido-, and the action of nitrous acid on, 72.
Benzenesulphonic acid, derivatives of, 1179.
Benzenylamidoxime, and its methyl-ether, 1325.
Benzenylazoximethenyl, 1326.

Benzenyldiphenylazidine, preparation of, 743.
Benzhydroxamic acid, structure of, 1324.
—— —— methyl ether of, 1325.
Benzidine, action of methyl iodide on, 747.
—— chromate, 1181.
—— derivatives of, 1015.
—— new reaction of, 1181.
Benzil, action of nitriles on, 313.
—— ammonia-derivatives of, 313.
—— derivatives of, 62.
—— hydrocyanide, saponification of, 329.
Benzilam, 313.
Benzilimide, 313.
Benzodiacetonalkamine, and the action of sulphuric acid on, 54.
Benzodiacetonamine, 54.
Benzoic acid, amido-, colloïd, action of phosphorus pentachloride on, 905.
—— —— chlorodinitro-, 602.
—— —— dimetabromorthonitro-, and its derivatives, 600.
—— —— iodo-, 1009.
—— —— metabromometanitro-, and its derivatives, 599.
—— —— metamido-, action of thiocarbimides on, 907.
—— —— orthochloro-, and its derivatives, 602.
—— —— parabromo- and parachloro-, and their derivatives, 600.
—— —— parabromometabromo-, and its derivatives, 601.
—— —— parabromometanitro-, and its derivatives, 600.
—— —— parametadibromorthonitro-, and its derivatives, 601.
—— —— prepared from gum benzoin, substances accompanying, 1168.
—— —— pure, from urine, 904.
—— —— test for catechol in, 1169.
Benzoic acids, substituted, 314, 599.
Benzoic isocymidide and its nitro-compound, 46, 47.
Benzonitrile, action of fuming sulphuric acid on, 1324.
—— action of hydroxylamine hydrochloride on, 734.
—— action of hydroxylamine on, 1325.
—— from formanilide, 734.
—— perbromo-, 588.
—— perchloro-, 589.
—— transformation of, in the organism, 1061.
Benzoparanitranilide, orthochloro-, 602.
Benzophenone, action of acetic chloride on, in presence of zinc-dust, 1167.
—— para-mononitro-, 310.
α- and β- Benzopinacoline, 1167.
Benzoquinone, action of hydroxylamine hydrochloride on, 735.
Benzoquinonedimethylanilenimide or phenol-blue, 595.
Benzotrichloride, action of copper on, 1133.
—— parachloro- 447.
Benzoxamidine, 739.
Benzoximido-ether, 739.
Benzoylacetic acid, and its derivatives, 63.
—— —— derivatives of, 838.
—— —— paranitro-, 1023.
Benzoylacetone, and isonitroso-, 1167.
—— and its orthonitro-derivative, 59, 60, 445.
α-Benzoylamidocinnamic acid, 1348.
α-Benzoylamidosalicylic acid and its salts, 308.
Benzoylanthranil, 61.
Benzolanthranilic acid, and its salts, 62.
Benzoylbenzenylamidoxime, 1326.
Benzoylbenzopseudocumide, 1319.
Benzoyldiamidohydrocinnamic acid, lactimide of, 1348.
Benzoyldi-β-naphthylamine, action of phosphorus pentachloride and pentoxide on, 1358.
Benzoylimidocinnamic acid, 604.
—— —— derivatives of, 1348.
Benzoyl-β-naphthylphenylamine and the action of phosphorus pentachloride and pentoxide on, 1358.
Benzoylnitrosophenol, 1003.
Benzoylorthonitranilide, reduction of, 1327.
Benzoylorthophenylenediamine, 1327.
Benzoylparamidodinitrophenol, and its salts, 308.
Benzoylphthalopseudocumide, 1319.
Benyoylpiperpropylalkeine, 1055.
Benzoylpseudocumidine, and its salts, 1319.
Benzoylpseudocuminol, 1319.
Benzoyl-trimethylenecarboxylic acid and its ethyl salt, 64.
Benzoyltrimethylenoxime, 1155.
Benzyl alcohol, paranitro-, preparation and condensation-products of, 310.
—— chloride, action of copper on, 1133.
—— chlorides and iodides, nitro-, 1004, 1005.
—— compounds, parabromo-, 665.
—— cyanide, derivatives of, 1134.
—— —— meta- and paramido-, 737, 738.
—— —— nitro-, and amido-, 1176.
—— ethers of the dihydroxybenzenes, 437.

Benzyl mercaptan, parabromo-, 665.
—— picrate, paranitro-, 1005.
—— sulphide and bisulphide, parabromo-, 665.
Benzyl-indigo, 1021.
Benzylarbutin, 432.
Benzyldinitroquinol, 437.
Benzylidenamidoazobenzene, 1149.
Benzylidineantipyrine, 1378.
Benzylidenephenylhydrazine, 1152.
—— derivatives of, 1323.
Benzylidenepiperylhydrazine, 468.
Benzylidenequinaldine, and its salts, 336.
Benzylnaphthalenes, two isomeric, 609.
Benzylnitroarbutin, 433.
Benzylnitroquinol, 433.
Benzylquinine hydrate, action of benzyl chloride on, 466.
Benzylquinol, 432, 437.
Benzylresorcinols, 438.
Benzylsulphonic acid, derivatives of, 69.
—— —— parabromo-, 665.
Berberine and its derivatives, 339, 340.
Beryl from Alexander Co., N.C., 274.
—— from Dakota, 23.
Beryllium, atomic weight of, 261.
—— crystalline form of, 1092.
—— chloride, vapour-density of, 820.
—— chloride and bromide, melting points of, 962.
Bessemer process, 517, 1083.
Bile, functions of, in taking up nourishment from the intestinal canal, 912.
Biliverdin, 197.
Biotite-holding amphibole-granite from Syene, 413.
Birdlime, an alcohol from, 1365.
Bismuth, atomic weight of, 558.
—— detection of, in lead, 640.
—— detection of, in presence of lead, by electrolysis, 368.
—— free from arsenic, preparation of, 558, 1092.
—— qualitative and quantitative separation of, from copper, 497.
—— salicylate, 905.
—— solution, alkaline, as a test for glucose in urine, 1433.
—— subnitrate, arsenic in, and preparation of pure, 1092.
—— —— test for, 116.
—— verification of the atomic weight of, 814.
Bismuthic acid, compounds of, 824.
Bitumen of Judea, 231.
Blende, pyroelectricity of, 3.
Blood, absorption spectrum of, in the violet and ultra-violet, 381.
—— action of potassium ferricyanide on, 1398.
Blood, behaviour of, with ozone, 95.
—— dried, manurial value of, 211.
Blood-stains, detection of, on washed clothes, 376.
Blue colours, artificial, examination of, 1449.
Boiler incrustation, barium and strontium in, 699.
Boilers, consumption of fuel for heating, 780.
Boiling point, definition of, 951.
—— —— dependence of, on pressure, 141, 950.
"Bois Piquant," bark of, 848.
Boldoa fragrans, a glucoside from, 845.
Boletus, alkaloïds in, 204.
Bone manure, weathering of, 360.
Bone-meal, manufacture of, 1419.
—— manuring with, 637.
—— nitrogen in, 359.
Bones, do they contain keratin? 1398.
Boracite, pyroelectric properties of 3, 655.
Borates, crystalline, production of, 711.
Borax, action of polyhydric alcohols on, 278.
—— as an internal disinfectant, 1440.
—— in California, 260.
—— physiological action of, 1061.
Bordeaux red, detection of, in wine, 370.
Borhegyer-water, composition of, 978.
Boric acid, action of, on the animal system, 782.
—— —— estimation of, in borosilicates, 871.
—— —— use of, in alkalimetry, 638.
—— —— use of, for preserving food, 782.
Boric anhydride, products of the reduction of, by aluminium, 156.
Borneol from camphor, 754.
—— —— method of preparing, 666.
Borocalcite from Chili, analysis of, 403.
Boron, line spectra of, 242.
—— carbide, 156.
Borotungstates, 559.
Botryogen, 269, 1103.
Bottle-glass, English, an, analysis of, 1443.
Bouty, Faraday's law and the law discovered by, 882.
Braken (*Pteris aquilina*) and its ash, analysis of, 207.
Bran, value of, for human food, 622.
—— oat and wheat, influence of, on the secretion of milk, 854.
Brass, dissociation of, 660.
—— polished, 521.
—— process for phosphorising, 936.

Brass, production of a gold-coloured or green surface on, 128.
Brazilin, contributions to the constitution of, 756.
—— derivatives of, 1043.
Brazinole, 756.
Bread, detection of ergot in, 377.
—— fermentation of, 132, 235.
—— formation of alcohol in the fermentation of, 532.
—— making, 132.
Brewing, system on which rice may be used in, 235.
—— use of maize in, 527.
Bricks, formation of sodium sulphate in, 127.
Brine-spring at Stoke Prior, Worcestershire, analysis of, 165.
Broad beans (*Vicia faba*), occurrence of vicin in, 1405.
Bröggerite, 1102.
Bromine as a disinfectant, 512.
—— detection of, in presence of chlorine and iodine, 492.
—— estimation of, in presence of large quantities of chlorides, 215.
—— chlorine, and iodine in presence of one another, estimation of, 694.
—— substitution, thermochemistry of, 883.
Bronze, process for phosphorising, 936.
Bronze-coloured surface on iron, new process for producing, 127.
Broom (*Genista pilosa*), analysis of its ash, 207.
Brucine as a test for tin, 498.
—— conversion of, into strychnine, 88.
Brucite from Cogne, Val d'Aosta, 162.
Butter, amount of fatty acids in, 1219.
—— analysis, 120, 778.
—— —— estimation of the volatile fatty acids in, 1434.
—— artificial and natural, comparative value of, as articles of food, 92, 622.
—— colourings, artificial, 236.
—— detection of salicylic acid in, 372.
—— goats', insoluble fatty acid in, 535.
—— manufacture, faults in, 135.
—— making, 135, 534, 1448.
—— method of testing, for foreign fats, 778.
—— notes on, 236.
—— preserved, 534.
"Butter beans," a new variety of fatty seeds, 1209.
Butyl butyrate, 167.
—— chloral, action of zinc-propyl and zinc-isobutyl on, 1117.
—— glycerol triacetin, 1284.
Butyl glycol and its derivatives, 169.
—— —— oxybutyrate, diacetyl-derivative of, 579.
Butylacridine and its derivatives, 1183.
Butylene and its derivatives, 166.
Butylpropylquinoline and its salts, 1376.
Butyltoluenes, two, occurring in rosin spirit, 300.
Butyric acid, α-β-diisonitroso-, and external anhydride of, 1120, 1121.
—— —— β-isonitroso-, 581.
—— ferment, occurrence of, 476.
Butyrimido-ether hydrochloride, chloro-, 1292.
Butyrolactonecarboxylic acid, 295.
Buxeine, 188.
Buxidine, 188.
Buxus sempervirens, alkaloïds of, 188.

C.

Cacao plant and the composition of its fruit, 202.
Cadmium amalgam, position of, in electropotential series, 382.
—— iodide, allotropic, 394.
—— oxide, heat of neutralisation of, 263.
Caffeïc acid in hemlock, 1353.
Caffeïne and its salts, 185.
—— chloro-, 466.
—— derivatives of, 466.
—— methhydroxide and its derivatives, 338.
Calcium chloroborate, 1262.
—— chloroferrite, 1262.
—— compounds, molecular, 892.
—— estimation of, in presence of aluminium, iron, magnesium, and phosphates, 1427.
—— hydroxide, solubility of, in water at different temperatures, 891.
—— oxychloride, silicates, and chlorosilicates, 1262.
—— oxysulphides, 1263.
—— phosphate, basic, as an addition to cattle fodder, 194.
—— phosphates, di- and tri-, preparation of, by precipitation, 1263.
—— separation of strontium from, 497, 1077.
—— silicophosphate, crystallised, produced in the dephosphorisation of iron, 157.
—— sulphate, solubility of, in acids, 813.
—— tartrate, valuation of, 1434.
Calcspar, fluorescence of, 649.

Calico-printing, gaseous chlorine as discharge in, 1234.
Calico-printing, novelties in, 379.
Callais or Callaina of Pliny, 26.
Calves, rearing, on skim-milk, 852.
Campholenic acid and its nitrile and amide, 1364.
Campholurethanes, isomeric, 755.
Camphor, 1364.
—— action of iodine on, 44.
—— contributions to our knowledge of, 43.
Camphoroxime, 1190.
—— derivatives of, 610.
Camphors, chloronitro-, isomeric, 1041.
Canarine, 797, 1499.
Canavalia incurva, 677.
Cancrinite, occurrence of, in the phonolites of Elfdalen, 276.
Cancrinite-aegirine-syenite, 276.
Cane-sugar, alteration of, in the human stomach, 91.
—— —— circular polarisation of, 1285.
—— —— examination of, 930.
—— —— fermentation of, in contact with arable soil, 351.
—— —— inversion of, by acids, 721.
—— —— velocity of inversion of, 1113.
Caoutchouc and its applications, 937.
Capillarity of liquids at their boiling points, constants of, 808.
α-Caproic acid, amidated acids of, 664.
Caprolactone from gluconic acid, 730.
—— normal, conversion of gluconic acid in, 993.
Capronamidine hydrochloride and platinochloride, 723.
Capronimido-ether and its hydrochloride, 723.
Caprylic acid, 461.
Carbamide, preparation of, 995.
Carbamidoazobenzene, 1149.
Carbanilide, action of sulphuric acid on, 1016.
Carbohydrates, formation of fats from, in animals, 912.
Carbodiisobutylphenylimide, 1010.
Carbodipropylphenylimide, 1009.
α-Carbopyrrolic acid, new methods for the formation of, from pyrroline, 1193.
Carbolic acid, commercial, estimation of phenol in, 503.
—— —— use of, in the disinfection of sewage, 697.
Carbon, absorption of chlorine by, and its combination with hydrogen, 1249.
Carbon-atoms, asymmetrical, influence of, on the ethanes derived from active amyl alcohol, 169.
Carbon bisulphide, detection and estimation of small quantities of, in air, gases, thiocarbonates, &c., 1431.
Carbon bisulphide, heats of combustion and formation of, 249.
—— —— hydrated, 260.
—— —— volumetric estimation of, in thiocarbonates, 1077.
Carbon-compounds, decomposition of, by the silent discharge, 542.
—— —— reaction of iodine with, at high temperatures, 1311.
Carbon, estimation of, in cast iron, 219.
—— in steel, apparatus for estimating, 219.
—— in steel, new method of estimating, 1427.
—— oxychlorides, heat of formation of, 250.
—— oxysulphide, reactions of, 728.
—— and oxygen, heat of combination of, 141.
Carbonic anhydride, antiseptic action of, 508.
—— —— apparatus for the estimation of, 1216.
—— —— compressibility of, 146.
—— —— compressibility of, at 20 to 300° under 1 to 8 atmospheres' pressure, 146.
—— —— condensation of, by glass, 146.
—— —— direct estimation of, in presence of sulphides, sulphites, and thiosulphates of the alkali-metals, 216.
—— —— estimation of, in air, 1076.
—— —— exhalation of, by frogs, 91.
—— —— in the atmosphere, 659, 710.
—— —— phenolphthalein as indicator in the estimation of, in mixtures of gases, 1072.
—— —— solid, 992.
—— —— solid, apparatus for collecting, 1253.
—— ethers, heats of combustion of, 547.
—— oxide, action of, on mixtures of sodium alcoholates and sodium salts of organic acids, 38.
—— —— boiling point of, under atmospheric pressure, 817.
—— —— conduct of moist phosphorus and air towards, 149, 660, 1092.
—— —— conversion of, into carbonic anhydride by nascent oxygen, 14, 15.
—— —— modification of Noack's method of preparing, 260.
Carbonyl iodide, 40.
—— sulphide, heats of combustion and formation of, 249.

Carbonyldihydroxydiphenyl, and its derivatives, 324.
Carbonyldiphenyl oxide, and its derivatives, 324.
Carbopyrotritartaric acid, 838.
Carbopyrrolic acid, and its salts, 1044.
—— —— dehydration of, 585.
Carbostyril, new method of preparing, 1183.
β-Carbostyrilcarboxylic acid, 1020.
Carbovaleraldine, oxidation of, 294.
Carboxylic acids from aromatic amines, 734.
Carboxytartronic acid, 41.
—— —— action of hydroxylamine on, 584.
Carnallite, a cheap substitute for kainite, 868.
Carnauba wax, chemical composition of, 1280.
"Carottine," 236.
Carrottin, 910.
Carroway oil, 1138.
Carvacrol, 331.
Carvene. 1138.
Carvol, 331.
—— derivatives of, 1138.
Carvolphenylhydrazine, 1138.
Carvoxime, 1138.
Casein, new mode of treating, 1449.
—— nitro-, use of, in dyeing, 1449.
Caseins of milk, 762.
Cassiterite from Dakota, 23.
Cast iron, estimation of carbon in, 219.
Cattle, stall-fed, experiments with, 472.
—— disease occasioned by town sewage, 95.
Cattle-food, horse-chestnuts as, 1411.
—— —— old sugar-beet seeds as, 631.
Cattle-foods, presence of mildew, &c., in, 1411.
Cattle-litter, moss and turf fibre as, 105.
Cattle plague and Pasteur's protective inoculation, 96, 473.
—— —— bacillus of, 1398.
Caustic potash, preparation of, 15.
—— soda, preparation of, 15.
Celestine, occurrence, association, and probable mode of formation of, 25.
Cell, a new, founded on the oxidation of carbon in the cold, 1239.
—— Skrivanoff's (pocket form), 881.
—— with copper oxide, 1.
Cell-sap, acidity of, 1209.
Cells, part played by vegetable acids in causing the turgescence of, 1064.
Cellulose, action of cuprammonium solutions of, on polarised light, 577, 833.
—— manufacture of, 232.
Cellulose, polarimetric investigation of various forms of, 1288.
—— researches by Witz on the oxidation of, 528.
Celluloses, 858.
Cement, adulteration of, 128.
—— and its adulteration, 1225.
Cements, decomposition of, by water, 1443.
—— hydraulic, influence of calcination and of carbonic anhydride on the setting of, 933.
Centrifugal separator, Nielsen and Petersen's, experiments with, 135.
Cereals, culture of, 482.
Cerite, and the extraction of cerium, lanthanum, and didymium therefrom, 557.
Cerium, extraction of, from cerite, 557.
Cerotic acid, formula of, 1297.
Cetene, preparation of, 571.
—— bromide, 1108.
Cetyl alcohol, 1280.
Cetylacetic acid, 1280.
Cetylmalonic acid, 1280.
Chaff, wheat-, digestibility of, and the changes which it undergoes by different methods of preparation, &c., 772.
Chalchuite, new locality of, 26.
Chalk mud, use of, in the production of crude soda, 644.
Champion spice, 473, 865.
Charcoal, behaviour of, towards gases, 1250.
Cheese, American, analyses of, 536.
—— blue, 942.
—— from skim-milk and foreign fat, 536, 942.
—— loss of weight during the ripening of, 1448.
—— Russian, analyses of, 700.
Cheleutite, from Schneeberg, 1099.
Chelidonic acid, action of hydroxylamine on, 993.
—— —— nitrogenous derivatives of, 1196.
Chemical affinities, determination of, 812.
—— —— in terms of electromotive force, 246.
—— compounds, colour of, mainly as a function of the atomic weights of the component elements, 1252.
—— constitution and physiological action, connection between, 348.
—— metamorphosis and transformation of forces, relation between during the germination of seeds, 1207.
—— nomenclature, 998.
—— reactions, influence of dilution on the rate of, 1090.

Chenopodium Quinoa, cultivation of, in Austria, 769.
Cherries, ripe, studies on, 766.
Chestnuts, common, fatty constituents of, 202.
Cheviot rock, analysis of, 413.
Chicken cholera, infection of eggs by, 1398.
Chicory, roasted, composition of, 648.
Chili saltpetre for sugar-beet and barley, 1418, 1419.
—— —— rubidium, cæsium, lithium, and boric acid in, 968.
China grass, preparation and dyeing of, 797.
Chinine, 1383.
Chiolite, 265.
Chloanthite from Schneeberg, 1099.
Chloral, preparation of, 1117.
—— allylate, action of acid chlorides on, 1117.
—— hydrate, contribution to the study of, 199.
Chloral-quinine, 186.
Chlorates, electrolysis of, 542.
Chlorhydrin, action of sodium on an ethereal solution of, 766.
"Chlorides of lime and lithia," 16, 820.
Chlorides, specific volume of some double, 956.
Chlorine, absorption of, by carbon, and its combination with hydrogen, 1249.
—— available, test for, in bleach works and similar establishments, 775.
—— displacement of, by bromine, and reactions accompanied by the absorption of heat, 955.
—— displacement of, by bromine in silver chloride, 1245.
—— estimation of, in presence of organic matter, 109.
—— gaseous, as discharge in calico-printing, 1234.
—— industry, future of, 225.
—— monoxide for lecture experiments, 552, 710.
—— processes, 227.
—— replacing, by other bleaching agents, 226.
—— temperature of solidification of, 816.
—— and hydrogen, action of light on a mixture of, 1237.
—— and iodine, separation of, in the dry way, 1073.
—— bromine and iodine, detection of, 492.
—— bromine and iodine in presence of one another, estimation of, 694.
Chlorine-atoms, ketonic, replacement of, by hydrogen, 1039.
Chlorite from the Bottino (Serravezza), 271.
Chloroform, estimation of, in the blood of an anæsthetised animal, 375.
—— chloroform, fate of, in the organism, 1062.
—— liquid paraffin as a reagent for the presence of water in, 1073.
Chloroform-vapour, preservative effect of, on organic substances, 932.
Chloropal, analyses of, 662.
Chlorophyll, 1366, 1367.
—— a compound of iron with a glucoside, 848.
—— a crystallisable colouring matter in, 910.
—— constitution of, 666.
Chocolate, 202.
Cholera, 349.
—— transmission of, by drinking water, 1081.
Chondropeptone, 1388.
Chromic acid, action of hydrogen peroxide on, 20.
—— —— preparation of, 1267.
—— anhydride, action of hydrochloric acid gas on, 1267.
—— —— purification of, 1267.
—— hydrogen selenite, preparation of, 397.
—— oxide, estimation of, by titration, 640.
—— sulphate, pure, 558.
Chromium acetate, behaviour of, 39.
—— determination of the atomic weight of, 834.
—— double chlorides of, 1266.
—— estimation of, 1428.
—— —— in presence of organic matter, 109.
—— group, colours of the oxides of, in acid solution, 559.
—— and potassium, double chloride of, 660.
Chromyl dichloride, 1267.
Chrysaniline, 748, 1034.
—— picrate, 908.
Chrysocolla from Arizona, 28.
Chrysophenol, 748.
Cicutine, a, 1047.
Cider, examination of an apple-must and of, obtained therefrom, 98.
—— apples, analyses of some, 203.
Cinchine, oxidation-products of, 1383.
Cinchocerotic acid, 332.
Cinchocerotin, 331.
Cinchona alkaloïds, 1382.
Cinchonamine, and its salts, 87.
Cinchonidine chloride, 1383.
—— ethylcyanide, 338.
Cinchonine, oxidation-products of, 1383.
Cinnamaldehyde anilide, salts of, 1345.

Cinnamaldehyde, cyanhydrin, 1292.
—— derivatives of, 1343, 1344.
—— orthonitro-, 59.
—— —— condensations with, 1345.
—— synthesis of 1345.
Cinnamic acid, α-amido-, 1349.
—— —— derivatives of, 603, 1172.
—— —— hydrazines of, 440.
—— —— new synthesis of, 446.
—— —— orthonitro-, derivatives of, 65, 747.
Cinnamone, 1166.
Cinnamylacraldehyde, orthonitro-, 1346.
Citric acid, occurrence of, in the seeds of Leguminosæ, 1304.
Clark's cell, electromotive force of, 246.
Clausius-Williamson's hypothesis, 701.
Clays, ferruginous, origin of, in limestone districts, 1272.
Clover, examination of, at different stages of growth, 100.
Coal, carbonised, composition of, 1441.
—— coking of, with conversion of its nitrogen into ammonia, 126.
—— estimation of the fuel value of, according to Scheurer-Kestner, 930.
—— distillation, new bye-product from, 525.
—— heat of combustion of, 122.
—— limed, use of, in gas making, 223.
—— methods for coking, 224.
—— and cannel coal, origin and distribution of phosphorus in, 1270.
Coal-gas as a source of heat, 697.
Coal-tar, analytical estimation of the three xylenes in, 1431.
—— —— pyridine bases from, 611.
—— —— dyes containing nitrogen, 587.
—— —— —— new, 237, 238, 536.
—— —— —— new, and their preparation, 1450.
—— —— oil, occurrence of diphenyl in, 1030.
—— —— xylenes, English and Scotch, 898.
Cobalt, extraction of, from its ores, 1233.
—— separation of, from nickel, 498.
Cobaltine from Schladming, 1099.
Cobaltous chloride, hydrates of, 967.
Coccinine, a hydrocarbon from, 84.
Cochineal dye-stuffs, 84.
Cocoa, 202.
—— Trinidad, decorticated by heat, and without heating, composition of, 203.
—— butter, 203.
—— —— composition of, 40.
Cocoa-nut meal for horses, 852.
Cod-liver oil, iodine in, 504.
Codeine, derivatives of, 614.
β-Codeïne methiodide, 615.
—— methochloride and its derivatives, 614.
Coffee, effect of, on the composition of the blood and on nutrition, 1392.
—— ground, preserving, 880.
Coke, gases occluded by, 377.
—— production of, from coal, 224.
Coke-ovens, recovery of ammonia from the gases of, 1441.
Colchiceine, 1387.
Colchicine, 1387.
—— crystallised, 1055.
β-Collidine hexhydride, 1048.
Colloid, nitrogenised, derived from amidobenzoic acid, 905.
Colloïds, 957.
—— coagulation of, 1250.
Colocynthin, 181.
Colophanthrenes, 83.
Colophony, destructive distillation of, 83.
Colouring matters. See Dyes.
Colorado beetle, vesicating substance in, 350.
Colour mordants for wood, 379.
—— of chemical compounds, mainly as a function of the atomic weights of the component elements, 1252.
Colours, incombustible, 379.
—— water and oil, used in dyeing and printing, action of sunlight, daylight, and electric arc light on, 700.
Columbates, methods of analysing, by means of hydrofluoric acid, 111.
Comanic acid, action of hydroxylamine and ethylamine on, 1302.
Combustion, demonstration of the increase in weight of bodies on, 258.
Comenic acid, action of ethylamine on, 1303.
—— —— action of hydroxylamine on, 1302.
—— —— amido-, action of phosphorus pentachloride on, 840.
Compost manure, 360.
Compression experiments, Spring's simple method of demonstrating, 958.
—— repeated, influence of, on the amount of sulphides formed by pressure, 959.
Condensation-products, use of dry oxalic acid in the formation of, 1019.
Conductors, hollow, in electrolytes, distribution of electricity on, 248.
Conilenamine-phthaleïn, 453.
Conilene-phthalamic acid, 453.
Conine, 1048.
—— and derivatives of, 1200.
—— synthesis of, 1201.

Conyrine, 1200.
Copaiba balsam, estimation of, 377.
Copper, atomic weight of, 256.
—— black, composition of, 515.
—— chlorides, action of, on metallic sulphides, 962.
—— commercial, sp. gr. of, 218.
—— commercially pure, examination of, 1084.
—— effect of, on the organism of ruminants, 474.
—— electrochemical equivalent of, 1089.
—— electrolytic extraction of, 934.
—— fluorine compounds of, 1264.
—— liquors, estimation of cuprous chloride in, 872.
—— oxide cell, 1, 541.
—— qualitative and quantitative separation of bismuth from, 497.
—— smelting, 515.
—— titration of, by means of potassium cyanide, 113.
Cork, composition of, 861.
Corn, the sum of mean temperatures in relation to the cultivation of maize and, 672.
Cornein, 1390.
Cornikrystallin, 1391.
Correlative growths in the vegetable kingdom, 626.
"Corrosiv," Kohn & Co.'s, 1088.
Corundum, remarkable occurrences of, 267.
—— gems in India, 23.
Cosalite from Colorado, 826.
Cotton, fixing indigo on, 136.
Cotton-cake as fodder for milch-cows, 1411.
—— —— influence of, on the secretion of milk, 669.
—— —— meal, influence of feeding with, on milk excretion, 623.
—— —— —— undecorticated, 100.
Cotton-yarn, dyeing with aniline-black in the cold, 942.
Coumalinic acid and its methyl salt, 1124.
Coumarins, new, 1346.
—— new mode of formation of, 1173.
—— substituted, 66.
Cows, milch, cotton-cake as fodder for, 1411.
—— —— fermenting maize for, 355.
—— —— sunflower-seed cake as fodder for, 483.
—— —— use of, for labour, 1396.
—— urine of, 1204.
Cow's milk, digestion of, and the substances which increase its digestibility, 192.
Cream, souring of, 1448.
Creatines, 613.
Creatinines, 613.
Cresol, nitro- and amido-, [1 : 2 : 6], 1317.
Cresols, amido-, 1145.
—— azo- and disazo-compounds of, 900.
Cresyl ethers of phosphoric acid, nitration of, 1337.
Cribriform vessels of *Cucurbita pepo*, contents of, 1067.
Critical temperatures, 252.
Crops, yield of, under steam cultivation, 359.
Croton-oil, purgative principle of, 947.
—— —— vesicating principle of, 909.
Crotonaldehyde, α-γ-dichloro-, compound formed by the addition of hydrochloric acid to, 1293.
—— hydration of, 420.
—— preparation and reactions of, 294.
Crotonylene glycol, 897.
Cryolite, 265.
—— from Colorado, 21.
Crystallisation, mixed, 958.
—— of substances at high pressures, 548, 549.
Crystals, dilatation of, on change of temperature, 1096.
—— of the regular system, elasticity of, 1096.
Cucurbita pepo, contents of the cribriform vessels of, 1067.
Culm conglomerate, containing variolite, at Hausdorf, in Silesia, 408.
Cultivation, continuous, without stable manure, employing artificial manures, 490.
—— Lupitz method of, 105.
Cumaldehyde, orthonitro-, 1352.
Cumene, 1356.
Cumenylacrylic acid, orthonitro-, and its salts, 1351.
Cuminalacetone, 1167.
Cuminaldoxime, 581.
Cumylazocumenol, 1147.
Cumylazoresorcinol, 736, 1147.
Cumylazoresorcinolazocumyl, 736.
Cumyldisazoresorcinol, 1147.
Cuprammonium compounds, manufacture of, and their technical application, 1232.
Cupric iodide, 962.
—— sulphide, action of, on potassium sulphide, 963.
Cuprous chloride, estimation of, in copper liquors, 972.
—— iodide, 962.
Currants, ripe, studies on, 766.
Currents produced by immersion and emersion, and by the movement of a metal in a liquid, 2.
Cusparine and its salts, 341.

Cutose, 859.
Cuttle fish, excretory product from the liver of, 94.
Cyamic acid, monochloro-, 840.
Cyanbenzin, 1292.
Cyanhydrins, action of phenylhydrazine on, 1152.
Cyanides, preparation of, from trimethylamine, 1276.
Cyanmethine, hydroxy-base of, ($C_6H_8N_2O$), 1292.
Cyanogen bisulphydrate, 1109.
—— compounds, some simple, constitution of, 1277.
—— iodide, action of, on certain metallic salts, 1277.
Cyanometatoluidine and its salts, 1142.
α- and β-Cyanonaphthalene, saponification of, 1362.
Cyanoparatoluidine and its salts, 1141.
Cyanorthotoluidine and its salts, 1142.
Cyanuric acid, ethereal salts of, 1278.
—— bromide, 588.
Cymene, action of chromyl chloride on, 1342.
—— boiling, action of chlorine on, 300.
—— from homocumic acid, 426.
Cymenesulphonamide, bromo-, 456.
β-Cymenesulphonamide, oxidation of, 456.
Cymenesulphonic acid, monobromo-, and its salts, 456.
Cymenesulphonic acids, 321.
Cymyl chloride, 300.
Cynene, 1363.
—— dihydrochloride, 1363.
Cysteïne, 1382.
Cystine, 1382.
—— action of water on, 1054.

D.

Dacite, 29.
Dairy farm, experimental, at Kiel, annual report of, 1390.
Daphnetin and its ethyl-derivatives, 1042.
—— diacetyl- and dibenzoyl-derivatives of, 1174.
—— synthesis of, 1173.
Dari seeds, analysis of, 630.
Date-sugar, 1234.
Daylight, action of, on water and oil colours used in dyeing and printing, 700.
Decane, and monochloro-, from American petroleum, 1107.
—— normal, 166.
Decay, properties of the volatile products of, 225.
Decylene, 1107.
Decylic alcohol, 1107.
Dehydracetic acid, action of hydroxylamine on, 1302.
—— —— derivatives of, 1121.
—— —— monobromo-, 1121.
Dehydracetophenylhydrazine, 1121.
Dehydracetoxime, 1121.
Dehydrobenzoylacetic acid and the action of sulphuric acid on, 839.
Densities of solutions of salts, 251.
Density of solids and liquids, determinations of, by means of the sp. gr. bottle, 213.
Deoxyamalic acid, 467.
Descloizite from Mexico, 24.
"Desincrustant Marseillais," 1088.
"Desincrustant Ragosine," 1088.
Desmine from the Viesch Glacier, analysis of, 402.
Desiccators, 491.
Deuteroalbumose, 1389.
Deweylite, analysis of, 663.
γ-Dextrin, 284.
Dextronic acids, 423.
Dextrose, action of alkalis on, 1112.
—— aldehydic nature of, 202.
—— behaviour of, with ammoniacal alkaline silver solution, 283.
—— examination of, 930.
—— solutions, decolorising, 930.
Diabase rich in apatite from Gräveneck, 275.
Diacetonamine, and derivatives of, 53.
Diacetonylphosphinous acid, 991.
Diacetonylphosphorous chloride, 991.
Diacetylchrysaniline, 1034.
Diacetylformamidine, 722.
Diacetyllupinine, 1387.
Diacetylmorphine, and its derivatives, 613.
Diacetylpentamethylpararosaniline, 607.
Diacetylquinol, and monochloro-, 430.
Dialysis, chloroform-water and ether in, 375.
Diamines, aromatic, action of thiocyanates on, 49.
—— aromatic, difference in chemical behaviour of, 49.
—— behaviour of, towards nitrous acid, 738.
Diammonio-silver acetate, 722.
—— —— nitrate, 261.
Diamonds, presence of, in an Indian pegmatite, 563.
—— combustion of, 1090.
Diamyl, 166.
Diamylsulphone, action of chlorine on, 1127.
Dianilide-phenolquinoneimide, monochloro-, 431.
Diantipyrine, 1379.

Diastase, action of acids, alkalis, and alcohol on, 530.
—— artificial production of, 1366.
—— formation of, under various conditions, 476.
Diazocaetamide, a, 988.
Diazoamidobenzene, 1014.
Diazoamido-derivatives of the paraffin series, 987.
Diazobenzene, amido-, 1148.
Diazobenzenesulphonic acid, behaviour of aldehyde, glucose, peptone, albuminous bodies, and acetone towards, 1322.
Diazobenzoic acid, paramido-, and its derivatives, 1148.
Diazo-derivatives, 1148.
—— —— action of alcohol on, 1322.
—— —— decomposition of, by means of alcohol, 1315.
—— —— of the paraffin series, 987.
Diazo-group, introduction of, into so-called aromatic para-compounds, 1013.
Diazoresorcinol, and its derivatives, 1333.
Diazoresorufin, and its derivatives, 1333.
Dibenzalacetone, 1166.
Dibenzenylazoxime, 1326.
Dibenzoresorcinol, mono- and tri-nitro-, 174.
Dibenzoylacetic acid, 64.
Dibenzoylbenzidine, 1015.
Dibenzoylmesitylene, 904.
Dibenzoylmethane, 64.
Dibenzoylsuccinic acid, mono- and dilactone of, 839.
Dibenzylbenzene, dinitro-, 310.
Dibenzylcatechol, 438.
Dibenzylhydroxylamine, 51.
Dibenzylnitroquinol, 438.
Dibenzylquinol, 437.
Dibenzylresorcinol, 438.
Dicalcium phosphate, preparation of, 892.
Dicaprylamine, 985.
Dichroite, artificial production of, 565.
—— from Asama-Yama, 407.
—— twin crystals of, from the Laacher See, 407.
Dichromates, action of a red heat on, 559.
—— process for preparing, 783.
Dicuminalacetone, 1167.
Dicyandiamide, 613.
Dicyanotriparatolylguanidine, and its salts, 1141.
Dicyminylthiocarbamide, 47.
Dicynene, 1363.
Didymium, diffusion of, 262.
—— estimation of, 111.
—— extraction of, from cerite, 557.
Didymium, molybdate, normal, 821.
—— valency of, 821.
Diethoxycoumarilic acid, 69.
Diethoxyhydroxycaffeine, 466.
Diethyl alizarin ether, 1187.
—— cinnamylethylacetate, 444.
—— methylene ether, 171.
—— quinonehydrodicarboxylate, and its formula, 834, 835.
—— succinosuccinate, formula of, 835.
Diethylacetophenone, 63.
Diethylæsculetin, 67.
—— monobromo-, 69.
Diethylamidocinnamic acid, 440.
Diethylamidosulphonic chloride, 286.
Diethylanilinazyline, action of methyl iodide on, 178.
Diethylaniline, dinitro-, 179.
—— methiodide. 1006.
Diethylbenzene, oxidation of, 587.
Diethylbenzoic acid, 63.
Diethylbromophenylamine, 1006.
Diethyldaphnetilic acid, 1042.
Diethyldimethylparaphenylenediamine, 179.
Diethylformamidine hydrochloride, unsymmetrical, 724.
Diethylglycerolphosphoric acids, two isomeric, 283.
Diethylindigo, 76.
Diethylphenylacetamidine, and its hydrochloride, 1135.
Diethylsafranine, 539.
Diffusion, extracting by, 539.
—— residues as cattle food, 921.
Diformylbenzidine, 1015.
Difurfuralacetone, 1167.
Digallic acid, 1178.
Digestion, experiments on, 912.
—— of meat and milk, time required for, 470.
Digitaleïn, estimation and separation of, from digitalin and digitin, 507.
Digitalin, estimation and separation of, from digitaleïn and digitin, 507.
Digitin, estimation and separation of, from digitalin and digitaleïn, 507
Dihydroanthracenecarboxylic acid, 330.
Dihydrocinchonine, a, 1384, 1385.
Dihydrocollidine, 1047.
Dihidrofurfurane, 897.
Dihydroxyamidoanthraquinonesulphonic acid, 1189.
Dihydroxyanthraquinone, a new, 1188.
Dihydroxybenzenes, benzylic ethers of, 437.
β-γ-Dihydroxycarbostyril, 79.
Dihydroxychloralphosphine, 1119.
Dihydroxydimethylpurin, 997.
Dihydroxydiphenylcarbinol, orthopara-, 311.
Dihydroxydiquinoline, 1372.

Dihydroxymethylcoumarin, 67.
Dihydroxynaphthalene, amido-, hydrochloride of, 1186.
Dihydroxypropyldicarboxyldiphenylcarbamide, 1023.
Dihydroxypyridine, and its salts, 1369.
Dihydroxypyridinecarboxylic acid, 1302.
Dihydroxyquinone, diimido-derivative of? 58.
Dihydroxytoluene [1 : 2 : 6], 1317.
Diisobutylphenylcarbamide, 1010.
Diisobutylphenylguanidine, 1010, 1011.
Diisobutylphenylthiocarbamide, 1010.
Di-isopropyl glycol, 37.
Diketones, action of hydroxylamine on, 62.
—— hydrocyanides of, and their saponification, 329.
Dilatometer, differential, and its application in an investigation on the formation of alums, 887.
Dilution, influence of, on the rate of chemical reactions, 1090.
Dimetaisocyminylcarbamide, 47.
Dimethoxypropionic acid, 68.
Dimethylacridinium hydroxide, 1356.
Dimethylamidoazobenzene, 1149.
Dimethylamidobenzene, 1320.
Dimethylamidobenzeneazotoluene, and its sulphonic acid, 1150.
Dimethylamidosulphonic chloride and its derivatives, 285.
Dimethylaniline, action of, on ethylene bromide, 1317.
—— nitration of, 1013.
—— paranitro-, 1013.
Dimethylanthracene hydride, synthesis of, from benzene and ethylidene chloride, 753.
Dimethyldiethylparaphenylenediamine, diiodomethylate of, 178.
Dimethyldiethylsulphonamide, 286.
Dimethyldiphenylmalonamide, 729.
Dimethyldiquinizinhydrobenzene, 1381.
Dimethylethylbenzene, 44.
Dimethylethylphenylammonium iodide, 1005.
Dimethylgentisic aldehyde, 1166.
Dimethylhomocatechol, 186.
Dimethylmalonamide, 728.
—— dibromo-, 1124.
Dimethyl-β-methylumbellic acid, 1331.
Dimethylnaphthalene, 328.
Dimethylnaphthol dihydride, 327.
Di-methyloxyquinizine, 1153, 1378, 1379, 1380, 1382.
Dimethylparatoluidine, action of, on ethylene bromide, 1317.
Dimethylphenylacetamidine, symmetrical and unsymmetrical, 1135.
Dimethylphenylene-green, 539.
Dimethylphenylene-safranine, 539.
Dimethylphenylsulphonamide, 285.
Dimethylpiperidine, bromo-derivatives of, 1385.
Dimethylpropylphenylamine, 1006.
Dimethylpyrroline, 1368.
Dimethylpyrrolinecarboxylic acid, 1368.
Dimethylquinaldine, 1053.
Dimethylquinol, derivatives of, 1329.
Dimethylquinoline and its derivatives, 1197.
Dimethylquinolthiocarbamide, 1330.
Dimethylquinoltrimethylammonium iodide, 1329.
Dimethylquinophenol, 1197.
Dimethyl-β-resorcylic acid, 67, 1331.
Dimethyl-triphenylmethylamine, and its iodine-compound, 1033, 1034.
α- and β-Dimethylumbellic acid, 68.
α-β-Dimethylumbelliferone, 67.
Dimethyluric acids, 1308.
Dinaphthyl, α-α-, α-β-, and iso-, 1185.
β-Dinaphthylamine, nitro-derivatives of, 752.
Dinaphthylsulphone, 1362.
Dioctoic acid, 462.
Dioctyl, 166.
Dioctylamine, 984.
Dioximidophthalaconecarboxylic acid, and its ethyl salt, 1177.
Dioxyisoamylamine, 1190.
Dioxyretistene, 1040, 1041.
—— action of barium hydroxide, and of acetic anhydride on, 1041.
Diparahydroxybenzoylparahydroxybenzoic acid, 447.
Diparatolyloxamide, 1141.
Diparatolylparaphenylenediamine, 593.
Diparatolylthiocarbamide, orthonitro- and dinitro-, 307, 308.
Diphenic acid, paramononitro-, 320.
Diphenyl, dibromodiamido-, and its azoimido-compound, 903.
—— dichlorodiamido-, 903.
—— occurrence of, in coal-tar oil, 1030.
—— perchloro-, 589.
Diphenylacetoxime, and some of its derivatives, 1155.
Diphenylamine diphenylphthalamate, 451.
—— ethylphenylphthalamate, 452.
—— sulphoxides, dinitro-, 1156.
Diphenylamine-phthaleïn, 451.
Diphenylene ketone oxide, formula of, 1182.
Diphenyleneacetoxime, 1182.
Diphenylene-diethylidine, synthesis of, from benzene and ethylidene chloride, 753.
Diphenylenetoluoquinoxaline, 1053.
Diphenylethane, synthesis of, from benzene and ethylidene chloride, 753.

Diphenylethane, synthesis of, from ethylidene chloride, 1356.
β-Diphenylglyoxime, 62.
Diphenylhydrazinepyroracemic acid, synthesis of, 1181.
Diphenylmetaphenylenediamine, and its derivatives, 591.
Diphenylmethane, dinitro-, 310.
—— para-mononitro-, and monamido-, 310.
Diphenylorthoxylylenediamine, 1313.
Diphenylparaphenylenediamine and its derivatives, 592.
Diphenylparaxylylmethane and its products of oxidation, 321.
Diphenylphenylacetamidine, 1135.
Diphenyl-phosphoric acid, dinitro-, 1337.
Diphenylphthalamic acid, and its salts, 451.
Diphenylpropionic acid, and its derivatives, 55.
Diphenyltartaric acid, and the hydrobromide of the amide of, 62.
Diphenylthiocarbamide, action of ethoxallyl chloride on, 1159.
—— compounds of, with metallic salts, 1018.
Diphenyltoluoquinoxaline, 1053.
Diphthalyl-diparabenzidine, 1015.
Dipiperylthiosemicarbazide, 468.
Dipropionylmorphine, 613.
Dipropylpropylidenic oxide, 1283.
Dipropylphenylcarbamide, 1008.
Dipropylphenylguanidine, 1008.
Dipropylphenylthiocarbamide, 1008.
Dipyrogallopropionic acid, and its derivatives, 318.
Diquinizine-blue, 1379.
Diquinizinhydrobenzene, action of nitrous acid on, 1381.
Diquinoline, formation of, by aid of heat, 1372.
—— from benzidine, and its derivatives, 1371.
—— peculiar method of formation of, and derivatives of, 1372.
—— preparation of, 84.
Diquinolinedisulphonic acid, and its salts, 1371.
Diresorcinol, and its derivatives, 1139.
Diresorcinoldicarboxylic acid, and its salts, 1336.
Diresorcinolphthaleïn, and its derivatives, 1139.
—— insoluble, 1140.
Diseases of animals, 623, 914.
Disodium glycollate, 548.
Dispersion, crossed, of several rhombic substances, 381.
Dissociation, 549.
α-Distearin, preparation of, 280.
α-Distearylglycerolphosphoric acid, and its salts, 281.
α-Distearylglycerolphosphoric chloride, 281.
Distillation, different methods of, compared, 1248.
Distillers' waste, influence of, on milk secretion, 194.
Disulphur dichloride, constitution of, 1255.
Dithienyl, 1132.
Dithienyldibromethylene, 1001.
Diethienyldichlorethylene, 1001.
Dithienylmethane, 586, 1001.
Dithienyltribromethane, 1001.
Dithienyltrichlorethane and hexabromo-, 1001.
Dithiodilactylic acids, 1299.
Dithiomolybdates, 161.
Ditolyl, 903.
Dixylylbenzene, 427.
Dodecyl palmitate, 572.
Dodecylene dibromide, 1108.
—— preparation of, 571.
Dodecylidene, 1108.
Dog, nutrition of, 344.
Dopplerite, 265, 923.
Double salts formed by fusion, 704.
—— —— of tin, 1265.
—— silicate of zinc and aluminium, hydrated, 1105.
—— sulphates, hydrous, natural, 1103.
—— sulphide of potassium and copper and of potassium and mercury, 963, 964.
Dragon's blood, so-called, 462.
Drainage water, chemical changes in, 633.
Drinking water, zinc in, 697.
Drosera rotundifolia, experiments with, 917.
Dulcitol, reaction of, in presence of borax and paratungstates, 1284.
Duplothiacetone and its derivatives, 580.
Dye-forming substances, aromatic acids as, 1169.
Dyeing, substitute for tartar emetic in, 796.
Dyes, blue, from pyrroline, 740.
—— from the action of diazoacetanilide on β-naphtholdisulphonic acid, 1016.
—— red, of the phanerogams, relation of, to the migration of starch, 1402.
—— 1169.
—— aniline, fixation of, by means of metallic sulphides, 539.
—— blue, from rosaniline, 1048.
—— —— preparation of, 798, 943.
—— brown, from chrysoïdine and diazo-compounds, 537.

Dyes, cochineal, 84.
—— extraction of, by a solution of borax, 83.
—— formed by the oxidation of glycocine, 987.
—— formed by the simultaneous oxidation of paradiamines and monamines, 740.
—— formed by the union of phenols with aromatic aldehydes, 837.
—— from amidoazoparatoluene, 743.
—— from nitroanthraquinone, 1188.
—— from thiophene, 586.
—— indophenol-like, and indophenols, 593.
—— Liebermann's, amidophenolsulphonic acids and their relationship to, 1354.
—— methylene blue and allied, 1156.
—— new coal-tar, 536.
—— of the so-called bile of invertebrates, and of the bile of vertebrates, and some unusual urine pigments, &c., 194.
—— from phenol, 1340.
—— preparation of, from anthraquinonesulphonic acid, 945.
—— preparation of, from quinoline and pyridine bases, 944.
—— process for preparing, from pyridine and quinoline bases, 798.
—— pyrroline, 1045.
—— red and violet, preparation of, 1451.
—— safranine, 538.
—— yellow, 1449, 1450.
Dysalbumose, 1389.

E.

Earthenware enamels, 1229.
Earth-nut cake, fungus spores in, 356.
—— —— meal, feeding horses with, 100.
Echurin, 1450.
Edible fungi, poisonous properties of, 204.
Edmonsonite, 417.
Eggs, infection of, by chicken-cholera, 1398.
Elaeolite-syenite from Jivaara, 413.
Elaphomyces granulatus, constituents of, 480.
Electric accumulator, a high pressure, 246.
—— arc light, action of, on water- and oil-colours used in dyeing and printing, 700.
—— conductivity of very dilute saline solutions, 881, 882.
Electric layers of two liquids which are in contact, difference of potential of, 383.
—— light, galvanic batteries for, 1240.
Electricity, a new method of generating, 652.
—— application of, in chemical industry, 785, 933.
—— distribution of, on hollow conductors in electrolytes, 248.
—— influence of the chemical nature and pressure of gases on the generation of, by an induction machine, 701.
—— measurement of the quantity of, produced by a Zamboni's pile, 138.
—— production of, by condensation of aqueous vapour, 138.
—— —— by evaporation, and electrical neutrality of vapour arising from electrified surfaces of liquids, 243.
Electrification, conditions affecting area of, 247.
Electrodynamometer, mercurial, 949.
Electrolysis, 541, 1136.
—— application of, in preparing indigo-vats, 942, 1448.
—— determination of the limits of, 2.
—— work done during, 247.
Electrolytic estimations, 1426.
Electrometer, an, 243.
Electromotive force in terms of chemical energy, 650.
—— —— measurement of, 246.
—— —— variation of, in accumulators, 881.
Electrosyntheses, 1136.
Enamels for earthenware, 1229.
Energy, radiation, and temperature, relation between, 249.
Ensilage, and analyses of, 1409.
Enterochlorophyll, 195.
Ergot, chemical properties of the violet colouring matter in, and its detection in flour and bread, 376.
Erica vulgaris, analysis of, and of its ash, 207.
Eruptive rocks, basic, of Mâconnais and Beaujolais, 414.
—— —— of Elba, the more recent, 567.
Erythrane, the first anhydride of erythrol, 897.
Erythrogranulose, 576.
Erythrohydroxyanthraquinone - sulphonic acid and its anhydride, 1189.
Erythrol, reduction of, by formic acid, 897.
—— $C_4H_6O_2$, second anhydride of, and its derivatives, 979.
Essential oils, action of iodine pentabromide on, 370.

Essential oils, coloured, 82.
—— —— extraction of, 378.
Etching ink, manufacture of, 880.
Ethane, bromine substitution-products of, 32.
—— bromotrichlor-, 978.
—— chlorobromiod-, and its decomposition, 830.
—— dichloromoniodo-, 719.
—— haloid derivatives of, 571.
—— nitro-derivatives of, 717.
Ethanes, brom-, chlorinated, properties of, 979.
—— derived from active amyl alcohol, influence of asymmetrical carbon-atoms on, 169.
Ethanesulphonic acid, monochlor-, salts of, 1126.
Ethenylphenylazidine hydrochloride, 1323.
Ether, action of sulphuric anhydride on, 1126.
—— liquid paraffin as a reagent for the presence of water in, 1073.
—— production of, by the action of *Aspergillus glaucus* on lemon-juice, 855.
Ether-vapour, preservative effect of, on organic substances, 932.
Ethereal oil of *Asarum Europæum*, 1191.
—— salts, preparation of, by double decomposition, 1110.
—— —— saturated and unsaturated, specific volume of, 8.
Etherification, influence of isomerism on, 726.
—— of alcohols and acids, 726.
Ethoxycinchonic acid and its salts, 84.
β-Ethoxypyridine, 1370.
Ethoxypyridine, dichlor-, 1369.
Ethoxythioxyl chloride, decomposition of, on distillation, 1256.
Ethoxytoluenesulphonic acid, 454.
Ethyl acetate, formation of, from acetic acid and ethyl alcohol, 1295.
—— acetisamylidineacetate, 443.
—— acetisobutylideneacetate, 443.
—— acetoacetate, action of carbamide on, 583.
—— —— action of chlor- and brom-acetone, acetophenone bromide, and phenylbromacetic acid on, 746.
—— —— action of ethylene bromide on, 64.
—— —— action of hydroxylamine on, 581.
—— —— constitution of, 836.
—— —— derivatives of, 834.
—— —— formula of, 835.
—— —— reaction of, with aldehydes, 443.
Ethyl acetobenzylideneacetate, 443.
Ethyl α-acetocrotonate, 443.
Ethyl acetofurfuralacetate, 443.
—— acetophenoneacetoacetate, 598.
—— —— action of reducing agents and of hydrochloric acid on, 746.
—— acetotrichlorethylideneacetate, 443.
—— aceturate, and its conversion into ethyl acetylglycollate, 1307.
—— acetylenetetracarboxylate, 297.
—— acetylglycollate, preparation of, 1307.
—— acetylmethyltrimethylenecarboxylate, 1155.
—— alcohol, combined action of potassium dichromate and chlorine on, 660.
—— —— decomposition of, by the silent discharge, 543.
—— benzalmalonate, and its carboxylic acid, 444.
—— benzoylacetate, 63.
—— —— action of ethylene bromide on, 64.
—— α-bromisovalerate, action of, on sodium malonic ether, 423.
—— carbamate, decomposition of, 731.
—— cinnamylethylacetate, 444.
—— collidinedicarboxylate, decomposition of the ammonium salt by potash, 1046.
—— —— methiodide and methydroxide of, 1045.
—— diazoacetate, and its derivatives, 987.
—— dibenzoylsuccinate, and the action of sulphuric acid on it, 838.
—— dibromosuccinate, action of, on ethyl malonate, 1300.
—— dicarbontetracarboxylate, 297.
—— diethylprotocatechuate, 846.
—— dihydroxypropyldicarboxyldiphenylallophanate, 1023.
—— α-β-diisonitrosobutyrate, 1121.
—— dimethylpyrrolinedicarboxylate, 1368.
—— dinitrophenylacetoacetate, 178.
—— diphenylizindiacetosuccinate, 1382.
—— diphenylizinsuccinosuccinate, 1381.
—— ether, temperature of solidification of, 817.
—— ethylacetoacetate, bromine-derivatives of, 835.
—— ethylacetocyanacetate, 727.
—— ethylenephenoloxybenzoates, 435.
—— ethylidenemalonate, 422.
—— furfuryl carbinol, 1304.
—— glycollate, 992.
—— hippurate, synthesis of, 1348.
—— β-imidobutyrate, action of nitrous acid on, 1368.
—— imidodiethyldioxamide, 907.
—— isocrotyl ether, 1276.

Ethyl isonitrosoacetoacetate, reduction of, 1368.
—— isonitrosodiethylacetate, 581.
—— isonitrosomethylethylacetate, 581.
—— isonitrosotriethylacetate, 581.
—— isosaccharate, 725.
—— malonanilidate, 1023.
—— malonate, action of α-β-dibromopropionic acid on, 991.
—— —— action of ethyl dibromosuccinate on, 1300.
—— —— action of ethylene bromide on, 832.
—— mandelate, 65.
—— mercaptan, action of diazobenzenesulphonic acid and of diazobenzene chloride on, 1328.
—— metabenzammalonate, 906.
—— metabenzamoxalate, 906.
—— metamidobenzamoxalate, 906.
—— methylacetocyanacetate, 727.
—— methyloxyqunizinacetate, 1380.
—— moniodoacetate, monochlor-, 421
—— monobromacetate, monochlor-, 421.
—— monochloracetate, monochlor-, 421.
—— mononitro-β-naphthol, and the action of ammonia on it, 1036.
—— nitrosobenzoylacetate, 64.
—— nitrosophenolcarboxylate, 1003.
—— œnanthaldoxime, 581.
—— orthethoxyphenylglycinate, 1144.
—— orthoxyldimalonate, 908.
—— oxalate and alanine: a correction, 995.
—— paratolueneacetoacetate, 1342.
—— paratolylhydrazine acetoacetate, 1154.
—— phenylacetosuccinate, and its derivatives, 746.
—— phenylcarbonate, 1005.
—— phenylizinacetosuccinate, 1380.
—— phenylizindiacetosuccinate, 1381.
—— phenylizinquinizinhydrobenzenecarboxylate, 1381.
—— phenylizinsuccinosuccinate, 1380.
—— phenylsulphonacetates, properties of, 319.
—— phosphate, a new, 1282.
—— propylcarbonate, 1279.
—— pyrogallocarboxylate, 1335.
—— quinovate, 1191.
—— sodacetoacetate, action of bromacetophenone on, 598.
—— sulphides, 1282.
—— tartronate, 1124.
—— telluride, preparation of, 663.
—— tetrahydronaphthalenetetracarboxylate, 908.
—— thioisophthalate, 1158.
—— trichlorethylidene-malonate, 423.
—— triethylgallate, 1335.
—— triethylpyrogallocarboxylate, 1335.
Ethyl trimethylenetetracarboxylate, 1300.
—— trimethylenetricarboxylate, 991.
—— uvitonate, 758.
Ethylacetanilide, nitration of, 1013.
—— paranitro-, 1013.
Ethylacetylene, action of, on mercuric chloride, 720.
Ethylæsculetin, 67.
Ethylamido-α-butyrocyamidine, 613.
Ethylamido-α-caproic acid, and its derivatives, 664.
Ethylamido-cinnamic acid, and nitroso-ortho-, 440.
Ethylamidohydrocarbostyril, 412.
Ethylaniline, action of phthalic anhydride on, 448.
—— ethylphenylphthalamate, 450.
Ethylanilphthaleïn, 450.
Ethylbenzene, dichlor-, 1020.
Ethylbenzenes, amido-, derivatives of, 1142.
Ethylbenzhydroxamic acid, structure of, 1324, 1325.
Ethylbenzoylacetic acid, 63.
Ethylcumazonic acid, 304.
Ethyldaphnetins, 1042.
Ethyldiphenylaminazyline, 180.
Ethyldiphenylcarbamide, 1321.
Ethyldiphenylthiocarbamide, 1321.
Ethylene, boiling points of, under low pressures, 1257.
—— bromide, action of dimethylparatoluidine and dimethylaniline on, 1317.
—— bromide, tetranitro-, 33.
—— bromine substitution-products of, 32.
—— chloriod-, unsymmetrical, 719, 830, 831.
—— bromiod-, unsymmetrical, 830, 831.
—— α-dibrom-, formula of, 418.
—— dichlor-, unsymmetrical, 719.
—— ethers of the nitrophenols and hydroxybenzoic acids, 433.
—— glycol, action of carbon oxychloride on, 419.
—— monobrom-, action of iodine monochloride on, 830.
—— monochlor-, action of iodine chloride on, 719.
—— nitro- and amido-phenyl ethers, 433.
—— nitro-derivatives of, 33.
—— table of the formulæ and boiling points of the known symmetrical and unsymmetrical di-haloïd derivatives of, 831.
Ethylenedimethyltolylamine, and its salts, 1318.
Ethylenediphenyldimethylammonium bromide, and its salts, 1318.

Ethylenediphenylenediamine, and its salts, 1142.
Ethyleneditoluylene-diamine and -nitramine, 1142.
Ethyleneditolyldimethylammonium bromide, and its salts, 1317.
Ethylenemalonamide, 729.
Ethylenemalonic and vinylmalonic acids, identity of, 992.
Ethylenemethyltolylamine - dimethyltolylammonium iodide, 1318
Ethylenephenol-oxybenzoic acids and some of their derivatives, 435.
Ethylfurfuraldoxime, 585.
Ethylglycocine nitrite, 987.
—— hydrochloride, action of nitrous acid on, 42.
Ethylhydrocarbazostyril, 442.
Ethylhydroparacoumaric acid, dinitro-, 1350.
Ethylidene bromide, brom-, action of sodium ethoxide on, 418.
—— chloride, behaviour of, with ethylamine and amylamine, 1275.
Ethylidene-diacetic acid, 422.
Ethylidenedimalonic acid, ethyl salt of, 422.
Ethylimidodiethyldioxamide, 995.
Ethylindole, synthesis of, 1181.
Ethylindolecarboxylic acid, synthesis of, 1181.
Ethylmalonic acid, preparation of the potassium salt of, 1123.
Ethylmethylquinoline and its salts, 1376.
β-Ethylnaphthalene, 1035.
Ethylortho-xylyldichlorodimalonic acid, synthesis of, 908.
Ethylphenetoïl, 1002.
Ethylphenol, and its derivatives, 1002.
Ethylphenolphthaleïn, 1002.
Ethylphenylcarbamide, unsymmetrical, 1321.
Ethylphenylphthalamic acid, and its salts, 449.
Ethylphenylpropylalkine, 1011.
Ethylphenylthiobiuret, 1141.
Ethylphenylthiocarbamide, unsymmetrical, 1321.
γ-Ethylpiperidine, 760.
—— synthesis of, 1054.
Ethylpseudoisatin, 74.
—— synthesis of, 1181.
—— β-indogenide of, 76.
Ethylpseudoisatin-α-ethyloxime, 74.
Ethylpseudoisatin-β-oxime, 75.
γ-Ethylpyridine, 910.
Ethylquinazolcarboxylic acid, and its brominated derivatives, 442.
Ethylquinazole, 442.
Ethylsuccinosuccinic acid, and its salts, 835.
Ethylteraconic acid, salts of, 459.
Ethyltetrahydroquinoline, Wischnegradsky's, 1051.
Ethyltoluidine-phthaleïn, 450.
Ethyltolylthiobiuret, 1141.
Euxanthone, formula of, 1182.
—— group, 1182.
Evaporation experiment, 510.
—— of liquids, relation between molecular weight and velocity of, 551, 950.
—— studies on, 627.
Evigtokite from Greenland, 22.
Experimental plots at Grignon in 1882, report on, 204.
—— —— —— in 1883, report on, 1068.
Explosive gaseous mixtures, combustion of, 549.
—— —— —— influence of the density of, on the pressures which they develop, 805.
—— —— —— relative rapidity of combustion of, 804.
—— —— —— combustion of, in various states of dilution, 1247.
"Explosive gelatin," spontaneous decomposition of, 947.
Explosive mixture of chlorine and hydrogen, action of light on: a lecture experiment, 552.
Explosives, 540, 1452.
—— and their application, 239.
Extract of Senega, liquid, 540.

F.

Fabrics, bleaching, 1234.
Faraday's law, and the law discovered by Bouty, 882.
Farm, Silesian, without cattle, 636.
Fat, absorption of, in the intestines of animals, 912.
—— estimation of, in skim milk, 1435.
—— formation of, from carbohydrates in animals, 912.
—— —— in the animal organism, 345.
—— neutral, formation of, from fatty acid in the animal system, 852.
—— pathological formation of, 1392.
—— percentage of, in the milk of cows of different breeds, 94.
—— volumetric method for the estimation of, in milk, 372.
Fats, amount of, in feeding-stuffs, 631.
—— examination of, 504.
—— examination of, by the "iodine-addition method," 1436.
—— general method of examining, 1435.
—— natural, constitution of, 35.

Fats, some, behaviour of, with glacial acetic acid, 1078.
—— vegetable, occurrence of the higher fatty acids in the free state in, 96
Fatty acid, formation of neutral fat from, in the animal system, 852.
—— acids, amido-, general reaction for, 994.
—— —— amount of, in butter, 1219.
—— —— constitution of, 1125.
—— —— normal, specific volumes and rate of expansion of, 1278.
—— alcohols, higher, method for the determination of the molecular weight and atomicity of, 1433.
Feeding-stuffs, amount of fat and albuminoïds in 631.
—— —— analyses of, 630.
Fehling's solution, action of light on, 1238.
—— —— influence of the quantity of the constituents of, on the rate of separation of cuprous oxide, by invert sugar. 574.
—— —— rate of reduction of, by sugars, 1112.
Felspar, 716.
—— from Pantelleria, 1104.
Fermentation, alcoholic, influence of salicylic acid on, 764.
—— butyric, excited by garden-soil, 1063.
—— experiments with gluten instead of diastase in the mash, 789.
—— schizomycetic, 1062.
Ferments, diastatic, formation of, in the cells of the higher plants, 1402.
—— reduction of nitrates by, 350.
—— starch-transforming, formation of, in the cells of highly organised plants, 917.
—— —— —— development of, in the cells of the higher plants, 1063.
Ferric chloride, use of, in sugar factories, 939.
—— ethylate, 573.
—— hydroxide, colloïdal, 573.
—— —— colloïdal derivatives of, 966.
—— oxide, alumina, and titanic oxide, separation of, 640.
—— —— salts, behaviour of, as mordants, 796.
Ferrocyanides, preparation of, from trimethylamine, 1276.
Ferrous chloride, vapour-density of, 965.
—— and aluminium sulphate, native, from Mexico, 24.
Fibrin, formation of, 912.
Filter yielding physiologically pure water, 1440.
Filtering funnel, hot, a new form of, 364.
Fish, guanine in, 623.
—— oils, certain, iodine in, 505.
Flames, electric properties of, 651, 1238.
Flavaniline, 1450.
Flax, bleaching, 793.
Flour, alteration of, 532.
—— alteration of, by age, 236.
—— analysis of, 374, 1080.
—— detection of ergot in, 376.
—— estimation of gluten in, 122.
—— obtained by various methods of grinding, quality of, 1447.
Flower petals, absorption of water by, 1403.
Flowers, constituents of, 862.
—— withering of, 918.
Fluellite, 266.
Fluobenzene, 426.
Fluobenzoic acids, transformation of, in the animal organism, 440.
Fluohippuric acids, 446.
Fluoresceïns from maleic acid, 1340.
Fluorene, para-amido-, 329.
—— paramido- and paranitro-, 754.
Fluorides, heat of formation of, 545.
Fluorine compounds, natural, 265.
—— —— of copper, 1264.
—— —— thermochemical researches on, 1245.
Fluorspar, corrosion faces of, 403.
—— a peculiar kernel structure in, 403.
Fluosilicates, alkaline, thermochemistry of, 884.
—— investigation of, 1246.
Fluotoluene, 426.
Fodder, cattle, basic phosphate of lime as an addition to, 194.
—— valuation of, 100.
—— woody fibre and white mustard as, 864.
—— plant, new, 100.
Folia uvæ ursi, behaviour of, in the animal organism, 915.
Food, estimation of starch and glucose in, 930.
—— preserved, presence of tin in, 800.
—— use of boric acid for preserving, 782.
Forces, relation between chemical metamorphosis and transformation of, during the germination of seeds, 1207.
Forests as a protection against hailstorms, 632.
Formaldehyde, 293.
—— derivatives of, 988.
Formanhydroisodiamidotoluene and its brominated derivative, 1143.
Formins, 897.
Four-year rotation experiments, 635.
Foyaite from the Serra de Monchïque, analysis of, 970.

Fractionating apparatus, a new, 364.
Franklinite ores from New Jersey, analysis of, 27.
Freezing of solvents, general law of, 254, 952.
—— point of alkaline solutions, 254.
—— —— of solutions of salts of the alkali-metals, 701.
—— —— of bivalent metals, 808.
Freiberg gneiss, 829.
Fresh-water animals, influence of the salts of sea-water on, and the causes of the death of fresh-water animals in sea-water, and marine animals in fresh water, 620.
Friction, influence of galvanic polarisation on, 139.
—— and galvanic conduction, relations between coefficients of, 139.
Frog, common, chemical composition of the egg and its envelopes in, 198.
Frogs, exhalation of carbonic acid by, 91.
Frost, irrigation as preventive of injury from, 357.
Fruit, stone, ratio of flesh to stone in, 477.
Fruits, constituents of, 862.
Fuel, consumption of, for heating boilers, 780.
—— mineral, composition of, 521.
Fulminates, conversion of, into hydroxylamine, 277.
Fumaric and maleic acids, isomerism of, 1301.
Fumarimide, mono- and dichloro-, 293.
Fungi, edible, poisonous properties of, 204.
—— respiration and transpiration of, 628.
Funnel for protecting liquids from dust, during evaporation on the water-bath, 552.
Furfuraldehyde and its occurrence in pyroligneous acid, 1304.
—— constitution of, 1304.
—— derivatives, 585.
—— group, action of hydroxylamine on compounds of, 585.
Furfuraldoxime and its hydrochloride, 585.
Furfurbutylene, action of nitrous acid on, 1129.
—— oxide, 1129.

G.

Gadolinite from Ytterby, 717.
Gahnite, 268.
Galactose, action of cupric hydroxide on, 1111.
Galipeïne and its salts, 341.
Gallic acid, acetylisation of, 1178.
—— —— test for, 119.
Gallisin, conversion of, into grape-sugar, 982.
—— the unfermentable part of commercial glucose, and its derivatives, 981.
Gallium, separation of, 17, 158.
—— —— from boric acid, 822.
Galvanic batteries for the electric light, 1240.
—— conduction, relations between coefficients of friction and, 139.
—— couples, a probable cause of the difference between the observed electromotive force of, and that calculated from thermochemical data, 802.
—— polarisation, influence of, on friction, 139.
—— temperature coefficient, 140.
Galvanometer, mercury, 881, 949.
Gannister from Sheffield, analyses of, 518.
Ganomalite, and analysis of, 972.
Garnet, artificial production of, 565.
—— decomposition-products of, 565.
—— white, from Wakefield, Canada, 828.
Gas-batteries and the silent discharge, compounds obtained by means of, 1242.
Gas-engines, illuminating gas and, 508.
Gas-liquor, examination of, 928.
—— —— purification of, 1221.
—— —— and gas purification residues, working up, 1221.
Gas-making, use of limed coal in, 223.
Gas-volumes, measured, apparatus for the reduction of, to normal condition, 775.
Gaseous explosive mixtures, 709.
—— mixtures, explosive, combustion of, 549.
Gases, apparatus for the rapid analysis of, 213, 214.
—— behaviour of vegetable tissues, starch, and charcoal towards, 1250.
—— compressibility of, 145.
—— compressibility and liquefaction of, 5.
—— contained in vegetable tissues, nature of, 670.
—— diffusion of, through a porous septum, 1251.
—— dissolved in watery liquids, estimation of the quantities of, 364.
—— elementary, expansion of, 889.
—— —— variations in the specific heats of, at high temperatures, 804.
—— inflammable, in the animal organism, 1305.

Gases, influence of the chemical nature and pressure of, on the generation of electricity by an induction machine, 701.
—— occluded by coke, 377.
—— of the alimentary canal of herbivora, 852.
—— solids and liquids and, a new relation between, 256.
Gearksutite, 265.
—— from Colorado, 22.
Gedrite, occurrence of, as an essential constituent of certain rocks, 274.
Gehlenite, artificial production of, 564.
Geierite from Breitenbrunn, 1100.
Gelatin, 619.
—— peptone, 344.
—— valuation of, 647.
Genista pilosa, analysis of, and of its ash, 207.
Germs, existence of, in the air at great heights, 225.
Geyser waters and deposits, analyses of, 30.
Gibbsite from Brazil, 23.
Glacialin, 378.
Glacialin-salt, 378.
Glanders, bacilli of, 914.
Glass, alkaline reaction of, as a source of error in analysis, 775.
—— arsenic in, 220.
—— solid, electrolysis of, 1241.
Glaucophane schists of the island of Groix, 412.
Globulin, from proteïd matters by the action of pancreatic ferment, 1056.
Gluconic acid, 730.
—— —— conversion of, into normal caprolactone, 993.
—— acids from different sources, and their calcium and barium salts, 423.
Glucoproteïn hydroxide, 90.
Glucosamine hydrochloride, 724.
Glucose, birotation of, 1112.
—— commercial, gallisin, the unfermentable part of, 981.
—— estimation of, 370.
—— estimation of, in food, 930.
—— in urine, alkaline bismuth solution as a test for, 1433.
Glucoses, action of sodium-amalgam on, 574.
Glucoside from *Boldoa fragrans*. 845.
—— group, synthetical researches on, 439.
Glucovanillin, 1343.
Glutamic acid, and its rotary power, 1308.
Glutamine, detection of, in vegetable juices and extracts, 373.
Gluten, estimation of, in flour, 122.
Gluten, fermentation experiments with, instead of diastase in the mash, 789.
Glyceric acid, optically active, 296.
Glycerol, action of arsenious anhydride on, 896.
—— electrolysis of, with electrodes of carbon and platinum, 170.
—— estimation of, in aqueous solution by means of its refractive power, 877.
—— fermentation of, with the bacteria from ammonium tartrate, 170.
—— mesitylene-, 57.
—— purification of, 938.
—— test for, 118.
—— trioleate and triricinoleate, action of sulphuric acid on, 238.
—— volatility of, at 100°, 1434.
Glycerol-borin, 279.
Glycerolphosphoric acid, occurrence of, in urine, 1058.
Glyceryl phosphate, normal, 282.
—— sulphate hydroxyoleate, and its salts, 238.
—— —— trihydroxyoleate and its salts, 239.
Glycerythrol, 766.
Glycidic acid, homologues of, 1301.
Glycocine, new method of preparing, 583.
Glycogen in plants, 354.
—— new method for preparing and estimating, 1287.
Glycol, action of ammonium chloride on, at high temperatures, 1284.
—— an aromatic, from β-naphthol, and its derivatives, 180.
—— carbonate, 419.
Glycollic acid, boiling points of the ethereal salts of, 897.
—— —— disodium salt of, 548.
—— —— preparation of, and its calcium salt, 583.
—— —— preparation of, from glycerol, 295.
—— —— transformation of glyoxal into, 898.
—— oxides, distinct types of, 730.
Glycollide, preparation and heat of hydration of, 547.
Glyoxal derivatives, preparation of, from trichlorlactic acid, 1298.
—— transformation of, into glycollic acid, 898.
Glyoxalines, oxidation of, by means of hydroxyl, 986.
Glyoxalisoamyline and its derivatives, 985.
Gneiss, Freiberg, 829.
Gold chlorides, compounds of, with phosphorus chlorides, 968.
—— colorimetric estimation of, 17, 115.

Gold, extraction of, from ores by means of sodium thiosulphate, 1084.
—— new reactions of, 115.
—— toughening, in the melting crucible, 1445.
Gold-coloured surface on brass, production of, 128.
Grain, chemical changes induced by the sprouting of, 200.
—— report on experiments on manuring, 1213.
Granite district of the Black Forest, 1273.
Grape-sugar, preparation of, from starch, 721.
—— testing, 778.
Grapes, from infected vines, analyses of, 1406.
Grass, China, preparation and dyeing of, 797.
Green surface on brass, production of, 128.
Growth of plants, effect of artificial influences on the, 624.
Guanine, bromo-, 467.
—— in fish, 623.
Guano, coexistence of ammonium carbonate and potassium sulphate in, 359.
—— from Aves Island, examination of, 489.
—— of Cape Vert, analysis of, 359.
—— recently discovered in Australia, 107.
Gun-cotton, compressed, experiments with, 918.
Gunpowder, flashing test for, 927.
Gypsum for manure, 637.
—— formation of, 406.

H.

Hæmatin, use of, in alkalimetry, 638.
Hæmatite from the Hargita-Gebirge, 405.
Hæmatoxylin, derivatives of, 1043.
Hæmochromogen, 196.
Hæmoglobin, compound of, with carbonic oxide, 343.
—— poisons and drugs which act on, especially those which convert it into meta-hæmoglobin, 764.
Hagemannite, 265.
Hailstorms, forests as a protection against, 632.
Halogens, density of, at high temperatures, 804.
—— in the side-chains of aromatic compounds, a simple method of estimating, 1422.
Haloid salts, compounds of, with oxysalts of the same metal, 1261.
—— —— melting points of, in relation to the contraction occurring during their formation from their elements, 709.
—— —— solubilities of, 960.
—— —— thermochemistry of, 656.
Hay, changes which take place in the conversion of, into silage, 772.
Hay, heated, composition of, 864.
Haydenite, 1271.
Heat, action of, on the animal system, 1393.
—— displacement of chlorine by bromine, and reactions accompanied by the absorption of, 955.
—— influence of, on plants, 1206.
—— liberated by the compression of solid bodies, 919.
—— of combination of carbon and oxygen, 141.
—— of dissolution of alkalis and alkaline earths, 250.
—— —— and hydration of the alkaline earths and the alkalis, 250.
—— —— of sodium alcoholates, 142.
—— of formation of alcoholates, 546.
—— —— of antimony chloride and oxychlorides, 707.
—— —— of fluorides, 545.
—— —— of lead oxychlorides and oxybromides, 384.
—— —— of the oxides of the alkali-metals, 1247.
—— —— of mercuric acetate and oxalate, 706.
—— —— of mercuric oxybromides, 707.
—— —— of sodium alcoholates, 142.
—— —— of sodium fluorides, 546.
—— —— of the oxychlorides of carbon, phosphorus and sulphur, 250.
—— of hydration of salts, 803.
—— radiation from the earth, 486.
Heather (*Erica vulgaris*), and its ash, analysis of, 207.
Heats of combustion and formation of carbon bisulphide and carbonyl sulphide, 240.
—— —— of ketones and carbonic ethers, 547.
Helianthin, 1149.
Helichrysin, 847.
Hemialbumose, 849, 1388.
—— in urine, 854.
Hemipeptone, 849.
Hemlock-red, and its derivatives, 1025.
Hemp tissues, bleaching, 793.
Heptic acid, 41.
Herderite, 827, 1102.
Herring offal as manure, 866.

Heteroalbumose, 1389.
Heulandite, action of heat on, 828.
Hexadecylene, preparation of, 571.
Hexadecylidene, 1108.
Hexamethylenamine, 287, 988.
Hexamethylparaleucaniline, new synthesis of, 749.
Hexamethylquercetin, and its diacetyl-derivative, 847.
Hexethylquercetin, 846.
Hexhydroanthracenecarboxylic acid, 330.
Hexylamylquinoline, 1376.
Hexylene-derivatives, 33.
High farming, effect of, on the amount of nutritious matter in straw, 772.
Hipparaffin, 838.
Hippuric acid, source of, in the urine, 1057.
—— —— synthesis of, 1347.
—— ethers, synthesis of, 1347.
Homologous compounds, specific volume of, 11.
Homoquinine, and its salts, 1384.
Homo-umbelliferone, 1346.
Hop extract, process for preparing, 800.
—— mildew, nature of, and means of counteracting it, 629.
Hops, behaviour of tannin in, towards the albuminoïds in malt, 527.
—— manuring of, 1422.
—— sulphured, testing, 1439.
—— the bitter principle of, 1366.
Hornblende-diabase from Graveneck, 275.
Horse, digestive fluid and digestive power of, 92.
—— digestive powers of, 472.
Horse-chestnuts as cattle-food, 1411.
Horses, feeding, with earth-nut meal, 100.
—— maize as food for, 355.
Hübnerite, from Colorado, 827.
—— from the Pyrenees, 406.
—— Nevada, optical properties of, 407.
Human excreta, utilisation of, 1418.
Humites, green, from Monte Somma, 272.
Hydrazine compounds of phenol and anisoïl, 440.
Hydrazinecinnamic acid, 441.
Hydrazinehydrocinnamic anhydride, 441.
Hydrazine-quinizine derivatives, action of ethyl acetoacetate on, 1153.
Hydrazines of cinnamic acid, 440.
—— of pyroracemic acid, 52.
Hydrazobenzene, action of bibasic organic acids on, 1015.
—— derivatives of, 1015.
Hydrazo-compounds, molecular changes of, 902.
Hydrazo-orthophenoxyacetic acid, and its salts, 1171.
Hydrazophenetoïl, 1147.
Hydrindonaphthene, derivatives of, 752.
Hydrindonaphthenemono- and di-carboxylic acid, 753.
Hydriodic acid, use of liquid paraffin in the preparation of, 1073.
Hydroacridylbenzoic acid, 1183.
Hydrobenzoïn bibenzoate, 1164.
Hydroberberine and its derivatives, 339, 340.
Hydrobromic acid, nitro-, action of, on organic compounds, 1315.
—— —— preparation of, 1091.
—— —— use of liquid paraffin in the preparation of, 1073.
Hydrobutylacridine, 1183.
Hydrocarbons, aromatic, coefficients of expansion and specific volume of additive compounds of, 1252.
—— —— oxidation of substitution-products of, 456, 457.
—— —— oxidation of substitution-products of, experiments with naphthalene-derivatives, 319.
—— conversion of, into aldehydes by the action of chromyl dichloride, 312.
—— from American petroleum and their derivatives, 1106.
—— liquid, from compressed petroleum gas, 879.
—— of the acetylene series, action of, on mercuric oxide and its salts, 719.
—— presence of hydrogen peroxide and ammonium nitrite, and absence of ozone in the products of the combustion of, in air, 818.
—— process for preparing, 788.
—— saturated and unsaturated, specific volume of, 8.
Hydrocarbostyril, amido-, 411.
Hydrocellulose, action of phenylhydrazine on, 897.
Hydrochloric acid, production of, 226, 1442.
—— —— purification of, 259.
—— —— temperature of solidification of, 816.
Hydrocinnamic acid, dinitroparamido-, 1350.
Hydrocinnamide, 1344.
Hydrocollidine, platinochloride of, 89.
Hydrocyanic acid, detection of, 371.
—— —— detection of, in chemico-judicial investigations, 222.
—— —— from animals, 348.
Hydroethylquinoline, ethoxy-derivatives of, 1049, 1050.

Hydrofluoric acid and other acids, reciprocal displacements of, 703.
—— —— thermochemical study of, 544.
Hydrogen, compressibility of, 146.
—— direct union of nitrogen with, 152.
—— liquefaction of, 888, 889.
—— peroxide as beer preservative, 1447.
—— —— commercial estimation of the oxygen value of, 1082.
—— —— in medicine, 1082.
—— —— test for, 1073.
—— phosphide, gaseous, reactions of, 155.
—— —— liquid, action of light on, 1237.
—— potassium fluoride in solution, 704.
—— —— tartarate, solubility of, in dilute acids, 812.
—— presence of hydrogen peroxide and ammonium nitrite, and absence of ozone in the products of the combustion of, in air, 818.
—— sulphide, formation of methylene-blue as a reaction for, 109.
—— —— purification of, 215, 638.
—— —— —— by means of hydrochloric acid, 776.
—— —— recovery of, from alkali waste, 1442.
—— —— value of Lenz's method for the purification of, 638.
Hydrometer for demonstrating alterations in weight in chemical changes, 1253.
Hydromethylquinaldines, 184.
Hydronicotine, 464.
Hydroparacoumaric acid, and its derivatives, 1349.
—— —— dinitro-, and its salts, 1350.
Hydrophobia, 914.
Hydropthalaconecarboxylic acid, and its ethyl salt, 1177.
Hydroquinoline, ethoxy-derivatives of, 1049.
Hydrotriethyldaphnetic acid, 1013.
Hydroxyacids, action of hydrobromic acid on the ethereal salts of, 897.
Hydroxyallyldiamines, 578.
Hydroxyallyldiethylamine, chlor-, 578.
Hydroxyallyltetrethyldiamine, and its derivatives, 578.
Hydroxybenzoic acids, ethylene ethers of, 433.
—— —— meta- and para-, action of phosphorus oxychloride on the sodium salts of, 325.
Hydroxybenzyl cyanide, para-, 1175.
Hydroxybromotoluquinone, 175.
γ-Hydroxycarbostyril, nitroso-, preparation of, 78.
Hydroxycinchonic acid, 84.
Hydroxycitronic acid, 939.
Hydroxycumidine, and the action of acetic anhydride on, 1147.
Hydroxydehydracetic acid, 1121.
Hydroxydichloropyridine, 1369.
Hydroxydihydrocarbostyril, 1338.
Hydroxydimethylpurin, 997.
Hydroxydiphenylene ketone and its derivatives, 325.
Hydroxyisobutyramidine hydrochloride, 1292.
Hydroxyisobutyrimido-ether hydrochloride, 1292.
Hydroxylamine derivatives, organic, 51.
—— —— structure of, 1324.
—— salts, action of, on plants, 1210.
Hydroxymaleïc acid, 993.
Hydroxy-β-methylcoumarilic acid, brom-, 1332.
Hydroxy-β-methylcoumarone, brom-, 1332.
Hydroxymethylpurin, 997.
—— dichlor-, 996.
Hydroxymethylpyridine, and its derivatives, 1196.
γ-Hydroxy-α-methylquinoline and its salts, 334.
α-Hydroxy-γ-methylquinoline and its tetrahydride and nitroso-derivative, 1052.
Hydroxymethylquinolines, 757, 1199.
Hydroxynaphthaquinone, phenylhydrazine-derivatives of, 1359.
Hydroxynaphthaquinonehydrazine and its derivatives, 1360.
Hydroxynaphthaquinonimide, 1037.
Hydroxyoleic acid and its salts, 239.
Hydroxyortho- and para-toluquinolines, 1199.
Hydroxyphenylacetic acids, 1175.
Hydroxyphenylglycines and their derivatives, 1144.
α- and β-Hydroxyphthalic acid, 1177.
γ-Hydroxypicolinic acid, and monochloro-, 840.
Hydroxypropylbenzoic acid, amido-, action of acetic anhydride on, 302.
—— —— —— action of nitrous acid and of ethyl chloroformate on, 1022.
—— —— —— and acetamido-, 317.
—— —— nitro-, and its derivatives, 316.
Hydroxypropylcarboxylphenylurethane, 1023.
Hydroxypropylhydroxybenzoic acid, 1022.
β-Hydroxypyridine, 1050, 1369.
Hydroxypyridine and its dibromo-derivative, 1195.
—— from pyridinesulphonic acid, derivatives of, 1370.

Hydroxypyridinecarboxylic acid, preparation of, from hydroxyquinolinic acid, 945.
Hydroxypyridinemonocarboxylic acid and its salts, 1195.
γ-Hydroxyquinaldine, synthesis of, 1198.
Hydroxyquinaldines and their derivatives, 1374.
Hydroxyquinoline, from paraquinolinesulphonic acid, 758.
—— from xanthoquinic acid, 86.
—— methyl hydride, physiological properties of, 474.
Hydroxyquinolines, preparation of, 945.
Hydroxyquinolinic acid, 1195.
—— —— and some of its salts, 85.
Hydroxyquinone, dinitro-, preparation of, 58.
Hydroxyterebic acid, salts of, 459.
Hydroxyvaleric acid, normal, and its salts, 1122.
Hydroxy-xylic acid, 1347.
Hyoscine, 761.
Hypersthene-andesite, 29, 568.
Hypophosphites, elimination of, by the urine, 1058.
Hypophosphomolybdates, 560.
Hypophosphotungstates, 560.

I.

Ice, electrical conductivity of, 1241.
—— physical properties of, 889.
Idocrase, composition of, 828.
—— from Ala and Monzoni, analyses of, 408.
Idunium, a new element, 1265.
Ilex paraguayensis, analysis of, 479.
Ilicic alcohol, 1366.
Ilmenite, conversion of rutile into, 1104.
Imabenzil, 313.
Imido-ethers, action of hydroxylamine on, 739.
—— —— action of phenylhydrazine on, 743, 1323.
—— —— from acetone cyanhydrin and allyl cyanide, 1292.
Incandescent lamps, electrometric measurement of energy radiated from, 881.
—— —— radiation and energy of, 249.
Indazole, 441.
Indian wheat, 355.
Indican, spectroscopic detection of, 198.
Indicator, a new, 1215.
—— showing the neutral point in alkalimetry and acidimetry, 363.
Indicators, litmus, rosolic acid, methyl-orange, phenacetolin, and phenolphthaleïn, as, 691, 869.
Indigo, artificial, production of, from the orthamido-derivatives of acetophenone and phenylacetylene, 237.
—— assaying, 1438.
—— brom- and chlor-, 1027, 1028.
—— decolorising action of ferric salts on, 457.
—— fixing, on cotton, 136.
—— formation of, from orthamidoacetophenone, 1026.
—— tetrachlor-, 1028.
—— valuation of, 507.
Indigo-forming substances in the urine, knowledge of, 1058.
Indigo-group, compounds of the, 73.
Indigo-vats, application of electrolysis in preparing, 942, 1448.
Indigo-white, conversion of, into indigotin, 1449.
Indileucin and its derivatives, 1029.
Indirubin, 76.
—— and its derivatives, 1028.
—— extraction of, from urine, 1059.
Indoanils, 593,
Indogen, 78.
Indogenide of benzaldehyde and of paranitrobenzaldehyde, 75.
β-Indogenide of ethylpseudoisatin, 76.
Indogenide of pyroracemic acid, 76.
Indogenides, 78.
Indogitin, extraction of, from urine, 1059.
Indole, 1030.
—— derivatives, synthesis of, 1180.
—— preparation of, and transformation of scatole into, 458.
Indophenol-like dyes and indophenols, 593.
Indophenols, 743.
—— indophenol-like dyes and, 593.
Indoxyl, action of aldehydes and ketonic acids on, 75.
—— action of isatin and ethylpseudoisatin on, 76.
—— nitrosamine of, 74.
—— and indoxyl-compounds, action of nitrous acid on, 74.
Induction spark, action of, on benzene, toluene, and aniline, 1243.
Indulines, preparation of, 743.
Ingelstromite from Vester-Silfberg, in Dalarne, 409.
Inoculation, Pasteur's protective, cattle plague and, 473.
—— protective, cattle plague and, 96.
Inorganic acids containing molybdenum, 560, 713, 715.
—— —— containing vanadium, 714, 715.

Insulator, benzene as an, 244.
Insulators, electrical resistance of, 245.
Intellectual activity, influence of, on the elimination of phosphoric acid by the urine, 1394.
Inulin in the artichoke, 284.
Invert-sugar, action of alkalis on, 1112.
Invertin and its action on gelatinised starch, 983.
Iodine, detection of, in presence of chlorine and bromine, 492.
—— estimation of, in presence of chlorine and bromine by means of ferric sulphate, 366.
—— estimation of, in urine, 1423.
—— extraction, 1221.
—— in cod-liver oil and other fish oils, 504.
—— reaction of, with carbon compounds at high temperatures, 1311.
—— and chlorine, separation of, in the dry way, 1073.
—— chlorine, and bromine, estimation of, in presence of one another, 694.
Iodoform, fate of, in the organism, 1062.
Iridium for pen-points, 400.
—— fused, analysis of, 400.
—— phosphide, 400.
Irrigation as a preventive of injury from frost, 357.
—— by means of Danube water, 635.
Iron acetate, behaviour of, 39.
—— analyses of, 1231.
—— containing nickel from Sanarka, in the Ural mountains, 401.
—— dephosphorisation of, 520.
—— industry, novelties in, 129, 1083.
—— investigations on the welding of, 786.
—— metallic, action of various substances on, 518.
—— —— reaction to detect the presence of, 1078.
—— meteorites, peculiar concretions in, 975.
—— modern processes for the manufacture of, and the properties and methods of testing these materials, 519.
—— new process for producing a bronze-coloured surface on, 127.
—— occurrence of, in Mexico, 1101.
—— ores, estimation of manganese in, 116.
—— oxide, reduction of, with carbonic oxide, 20.
—— salts, estimation of, by potassium chromate, 1078.
—— so-called burning of, 935.
Iron vessels, nickel-plated, action of organic acids on, 520.
—— volumetric estimation of, 367, 873.
—— white, decomposition of, by heat, 1444.
—— and iron ores, estimation of phosphorus in, 875.
Isatamidobenzamide, 455.
Isatins, substituted, preparation of, and their conversion into substituted indigos, 944.
Isethionic acid, derivatives of, 1126.
Isobutaldehyde, a derivative of, analogous to hydrobenzoin, 37.
—— preparation of, free from acetone, 37.
Isobutyl nitrite, preparation of, by double decomposition, 1110.
Isobutylbenzene, amido-, constitution of, 1009.
—— iodo-, 1009.
Isobutylbenzoic acid, and its salts, 1010.
Isobutylbiguanide, and its compounds, 287.
—— constitution of, 289.
—— sulphates and hydrochlorides of, 288.
Isobutylene, action of chlorine on, 1276.
—— chloro-, 1276.
Isobutyl-isopropylethylene glycol, 833.
Isobutylnaphthalene, 1185.
Isobutylorthamidotoluenes, isomeric, 899.
Isobutylorthotoluic acid, 899.
Isobutylphenyl cyanide, 1010.
Isobutylphenylthiocarbimide, 1010, 1011.
Isobutyltoluene, 900.
Isobutyric acid, chlor-, 1301.
—— anhydride, boiling point and specific gravity of, 1129.
Isocamphoroxime, 1190.
Isocrotyl chloride, 1276.
Isocymidine, nitro-, 47.
Isodinaphthyl, form of, from amyl chloride and naphthalene, 1358.
Isodiphenylene, new reaction of, 1181.
Isohydrobenzoïn bibenzoate, 1164.
Isologous compounds, specific volumes of, 12.
Isomannide, and its derivatives, 1111.
Isomerism, influence of, on etherification, 726.
Isonicotinic acid, 1194.
Isonitroso-acids, 42.
Isonitroso-compounds, 581.
—— —— various, action of reducing agents on, 1120.
Isopentylarbutin, 432.
Isophthalamidine, and its salts, 1158.
Isophthalimido-ether, and its hydrochloride, 1157.

Isophthalimido-methyl ether, and its hydrochloride, 1157.
Isophthalimido-thioethyl ether, and its hydrochloride, 1158.
Isophthalonitrile, derivatives of, 1157.
Isopicramic acid, an, and its derivatives, 308.
Isopropylacetone, isonitroso-, 581.
Isopropylnitrophenylacetamide, 1353.
Isopropylnitrophenyllactic acid, β-lactone of, 1351.
Isopropylnitrostyrene, 1353.
α-Isopropylpiperidine, 1386.
Isopropylpyridines, 1048.
Isopropylsuccinic acid, and its salts, 423.
—— —— identity of, with pimelic acid from camphoric acid, 296.
Isopropylsuccinimide, 423.
Isosaccharic acid and its salts, 725.
Isotributylene, 167.

J.

Jadeite from Thibet, 407.
Jamaica dogwood, piscidin, the active principle of, 332.
"Jaune solide," 1450.
Joule's law, 881.
Juglone, 1365.

K.

Kainite as potato manure, 108.
Kairin, 1049.
—— physiological properties of, 474.
Kairoline, physiological properties of, 474.
Kairolinmetacarboxylic acid, 1197.
Kaolin, occurrence of, in North Sweden, 273.
Kelp, estimation of iodine in, 505.
Kelyphite, 972.
Kephir, 1086, 1235.
Keratin, do bones contain it? 1398.
Kersantite vein of the Upper Harz, 409.
Kersantites of Southern Thuringia and the Frankenwald, 1273.
Ketones, action of aldehydes on, 445.
—— heats of combustion of, 547.
—— phenylhydrazine, a reagent for, 1150.
Ketonic acids, action of aldehydes on, 445.
—— —— action of phenol on, 55.
Ketonic chlorine-atoms, replacement of, by hydrogen, 1039.
Kola, chemical investigations on, 863.
—— bitter, 864.
Krakatoa volcanic ashes, analysis of, 974, 975.
Krugite as manure for potatoes, 926.
—— influence of, on the percentage of starch in potatoes, 1401.
Kynuric acid, and its salts, 750.
—— —— synthesis of, 751.

L.

Labradorite from St. Paul Island, solubility of, 971.
Lactamine, 725.
Lactarius piperatus, constituents of, 480.
Lactation, influence of pilocarpine and atropine on, 1396.
Lactic acid, optically active, 296.
—— —— trichlor-, preparation of glyoxal derivatives from, 1298.
β-Lactone of metanitrophenyllactic acid, 1174.
—— of paranitrophenyllactic acid, 604.
Lactones, 744.
β-Lactones, aromatic, substituted, 603, 1172.
Lactose, preparation of, from milk-sugar, 980.
—— and arabinose, non-identity of, 1287.
Lactosin, a new carbohydrate, 980.
Lamprophyry, 1273.
Lanoline, 784.
Lanthanum, extraction of, from cerite, 557.
"Lapidolyd," 1087.
Larch fungus, constituents of, 353.
Lard-cream, 536.
Laserpitin, and its derivatives, 182.
Latent heat of vaporisation of liquids, comparison of, in relation to their molecular weight, 551.
Laubenheimer's reaction, 1038.
Laudanine, 616.
Laurene, an isomeride of, 173.
Laurene, Fittig's, 43.
Laurus persea, a sugar from, 1285.
Lauryl chloride, 1125.
Lauth's violet, 595, 1156.
Lavatera arborea, 100.
Law of smallest volumes, 12.
—— thermic substitution constants, 883.
—— thermo-chemical moduli or constants of substitution, 702.
Lazerin, 183.
Lazerol, 183.
Lead acetate, action of carbonic anhydride on, 990.
—— detection and estimation of, in presence of iron, 367.

Lead, detection of bismuth in, 640.
—— electrolytic refining of, 934.
—— estimation of, as lead dioxide by means of the electric current, 777.
—— —— in tinplate, 1078.
—— monoxide, yellow and red, 824.
—— native, in Idaho, 563.
—— oxychlorides and oxybromides, heats of formation of, 384.
Lead-chamber deposit from Japanese sulphuric acid, 392.
Leaven, known in France as *levain de chef*, 532.
Leaves, composition of, 862.
—— respiration of, in the dark, 857.
—— withering of, 918.
Lecithin, 1388.
—— synthesis of, 280.
Lecture apparatus, quantitative, some convenient, 658.
—— experiment, formation of acetylene, 419.
—— experiments, 258, 419, 552, 658.
Leguminose straws, certain, digestibility of, 182
Lemon-juice, production of ether by the action of *Aspergillus glaucus* on, 855.
Lepidote from India, estimation of alkalis in, 27.
Leucine and analogous compounds, action of methyl iodide on, 425.
—— optical rotatory power of, 1115.
Leucite, new case of metamorphism of, 272.
Leucodibromoquinonephenolimide, 594.
Leucomalachite-green, preparation of, 1019.
"*Levain de chef*," 532.
Levulinic acid, action of bromine on, 1297.
Liebig memorial statue at Munich, 880.
Light, chemical action of, 381, 1237.
—— effects of, on the respiration of oxygen by, 916.
—— electrochemical energy of, 382.
—— influence of, on plants, 1206.
—— methods of studying the influence of, on the respiration of plants, 1066.
—— polarised, action of cuprammonium solutions of cellulose on, 577.
—— use of nitrogen iodide to determine the chemical and mechanical equivalent of, 153.
Lighting, artificial, influence of, on the atmosphere of dwellings, 122.
Lignose (wood cellulose), manufacture of, 1451.
Lime, chloride of, 820.
—— -dialogite, 410.
—— osmose process, Dubrunfaut's, 941.
Lime-waste of sugar factories, manurial value of. 925.
Line spectra of boron and silicon, 242.
Linseed, properties of, and behaviour of, in the animal system, 852.
Liquid, new, of high specific gravity, refraction equivalent, &c., 145.
Liquids, molecular volume of, 386.
—— specific volumes of, 147.
—— comparison of the latent heat of vaporisation of, in relation to their molecular weight, 551.
—— constants of capillarity of, at their boiling point, 808.
—— determinations of the density of, by means of the sp. gr. bottle, 213.
—— mean depression coefficient of, 811.
—— mixed, of constant boiling point, 1247.
—— solids and, and gases, a new relation between, 256.
—— sterilisation of, by means of Papin's digester, 864.
—— thermal effect of mixing, 1244.
Lithia, chloride of, 820.
Lithiophillite, analyses of, 26.
Lithium oxide, heat of formation of, 1247.
Litmus as an indicator, 691, 869.
Locust-bean, the shells of, as a condiment, 631.
Löllingite and other minerals from Colorado, 826.
Low temperatures, production of, 383, 656, 1248.
—— —— very, production of, by means of methane, 1218.
Lupine seeds, composition of, 1106.
—— straw, composition of, 1406.
Lupines, composition of, 1405.
—— feeding cattle on, 1211.
—— poisonous matter of, 915.
—— water culture of, 1400.
Lupinindine, 1387.
Lupinine, and the action of acetic chloride and anhydride on, 1387.
Lupinus luteus, the liquid alkaloïd from, 1387.
Luteïn, 196.
Luteo- and roseo-salts, relation between, 1093.
Lutidine from coal-tar, 910.
β-Lutidine hexhydride, 1047.
Lupitz method of cultivation, 105.

M.

Magmas, fused, action of, on various minerals, 401.

Magnesium ammonium bromide and iodide, 263.
—— bromide and iodide, 262.
—— iron sulphate, native, 269.
—— potassium bromide and iodide, 262.
—— preparation of, 1231.
—— sulphite, use of, in sugar factories, 939.
—— verification of the atomic weight of, 815.
Magnetic intensity, absolute, new method of directly measuring, 1243.
Magnetism of organic bodies, 1243.
Maize as food for horses, 355.
—— comparative growth of, in mineral and organic solutions, 1208.
—— cut for fodder, experiments with, at Grignon, 1883, 1070.
—— for milch cows, fermenting, 355.
—— function of silica in the growth of, 201, 669.
—— germinated, amount of easily digestible albuminoïds in, 772.
—— manuring experiments with, 635.
—— the sum of mean temperatures in relation to the cultivation of corn and, 672.
—— use of, in brewing, 527.
Maize-starch, manufacture of, 528.
Malachite-green, orthonitro-, 1315.
Maleïc acid, dibromo-, 1117.
—— and fumaric acids, isomerism of, 1301.
—— bromide, monobromo-, 1305.
Maleïmide, dibromo-, 1116.
—— dichloro-, and the action of phosphorus pentachloride on, 1115, 1116.
—— mono- and di-chloro-, 293.
Malic acid, condensation-product of, 1124.
Malonamide, dibromo-, 1124.
—— preparation of, 728.
Malonanilic acid and some of its salts, 729.
Malonanilide, 728.
Malondianilide, 729.
Malonic acid, action of aldehydes on, 445.
—— —— and its derivatives, 728, 729, 1123.
—— —— and its ethyl salt, action of benzaldehyde on, 444.
—— —— and its ethyl salt, action of fatty aldehydes on, 422.
Malonparatoluidic acid, 1023.
Malontribromanilide, symmetrical, 1123.
Malonyldibenzamic acid, 906.
Malt and barley, analyses of, 233.
—— barley, and peas, comparative feeding value of, 206.
Malt, behaviour of tannin in hops towards the albuminoids in, 527.
—— combings, utilisation of, in the manufacture of pressed yeast, 790.
—— -extract, analyses of, 529.
—— —— by different waters, 1445.
—— —— estimation of, 1439.
—— nitrogenous combinations in, 790, 1446.
Maltose, action of cupric hydroxide on, 1112.
—— and its octacetic derivative, 171.
—— assimilation of, 1392.
—— physiological functions of, 345.
Mandelamide, 65.
Mandelic acid, active, conversion of, into inactive, 318.
Manganese chloro-silicate, 562.
—— detection of, in commercial zinc-dross and in calamine, 640.
—— detection of, in presence of zinc, by electrolysis, 368.
—— estimation of, in iron ores, 116.
—— extraction of, from its ores, 1233.
—— iodosilicate, 563
—— minerals from Vester-Silfberg, in Dalarne, 409.
—— ores. analyses of, 24.
—— oxides, 397.
—— presence of, in wines and other vegetable and animal products, 879.
—— use of air saturated with bromine in the precipitation of, 640.
—— verification of the atomic weight of, 814.
—— volumetric estimation of, 220, 499.
—— estimation of, especially in iron and steel, 116.
Manganese-garnet, artificial production of, 410.
Manganese-hedinbergite, 410
Manganese-iron-olivine, artificial crystals of, 410.
Manganic acetate, 398.
—— acid, sulphur-derivatives of, 1269.
—— arsenate, 399.
—— hydroxide, action of aluminium sulphite on, 700.
—— phosphate, 399.
—— sodium pyrophosphate, 399
Mannite hexylene, derivatives of, 33.
Mannitol, action of, on sodium pyroborate, 279.
—— dichlorhydrin, 1111.
—— formation of, from dextrose and lævulose, 720
—— new derivatives from, 36, 573.
—— oxidation of, 720.
—— preparation of, from dextrose or lævulose, 574.
—— presence of, in the Anana, 629.

Mannitol, second anhydride of, 573, 1111.
Manure, action of sulphuric acid as, 775.
—— disinfected, injurious effects of, 697.
—— estimation of total nitrogen in, 639.
—— farmyard, 1070.
—— —— aërobic fermentation of, 1412.
—— —— loss of nitrogen during the fermentation of, 1413.
—— —— preparation of, 1412.
—— —— production and cost of, 867.
—— fermentation of, 773, 1412.
—— mineral, effect of, on maize, potatoes, and oats, 1401.
—— preparation of, from furnace slag, 212.
—— salt and herring offal as, 866.
—— stable, cause of the high temperatures observed in, 924.
—— —— cost of production of, 637.
Manures, artificial influence of, on the physical properties of soil, 210.
—— estimation of ammonia as nitrogen in, 638.
—— estimation of phosphoric acid in, 217.
—— for beets, sodium nitrate and ammonium sulphate as, 491.
—— inferior, 490.
—— loss of nitrogen during the fermentation of, 1070, 1413.
—— some, volume-weight of, 1213.
—— various nitrogenous, value of, 488.
Manurial experiments at Reims, 1419.
Manuring experiments, 636.
—— —— at Kiel, 211.
—— —— at Peterhof, 636.
—— —— in Posen in 1882, 361.
—— grain, report on experiments on, 1213.
—— systematic, 634.
—— theory of, 486.
—— with sea-mud and peat compost, 867.
Marbles, cipolin, of primary formations, manganese in, 716.
Marine animals, influence of fresh-water on, and influence of the salts of sea-water on fresh-water animals, and the causes of the death of fresh-water animals in sea-water and of marine animals in fresh-water, 620, 621.
Markasite from the Appel mine and from Bleischarley, analyses of, 969.
Marshy land, manuring of, 363.
Mascate pea, 1068.
Mashing temperature, 789.
Maté, 354.
—— and analysis of, 479.
Matico-camphor, 611.
Mean temperatures, the sum of, in relation to the cultivation of corn and maize, 672.
Meat, time required for digestion of, 470.
Meconic acid, action of hydroxylamine on, 993, 1302.
Meionite, artificial production of, 564.
Melanophlogite, 1104.
Melilite, artificial production of, 564.
Melinoïntrisulphonic acid and its salts, 590, 1185.
Melissic acid, 1281.
Melitose from cotton-seed, 1286.
Mellissyl-mellisate, 173.
Mellite, specific heat of, 1244.
Melon-juice, alcohol from, 233.
Melting points of haloid salts in relation to the contraction occurring during their formation from their elements, 709.
—— —— of nitrates, 384.
—— —— of salts, 3.
Menthol, oxidation of, by potassium permanganate, 755.
Menthyl chloride, 167.
Mercaptans, 1328.
Mercapturic acid, formation of, in the organism, and its detection in the urine, 1395.
Mercuric acetate, heat of formation of, 706.
—— cyanide and silver nitrate, reaction between, in presence of ammonia, 168.
—— oxalate, heat of formation of, 706.
—— oxide and its salts, action of the hydrocarbons of the acetylene series on, 719.
—— oxybromides, heat of formation of, 707.
—— salts, action of acetylene hydrocarbons on, 572.
—— sulphide, action of potassium sulphide on, 893, 961.
Mercury diethyl, oxidation of, with potassium permanganate, 1135.
—— diphenyl, action of potassium permanganate on: a correction, 1135.
—— ditolyl, action of potassium permanganate on, 1135.
—— fulminate, experiments on, 419.
—— galvanometer, 940.
—— oxychlorides, thermochemistry of, 884.
—— spontaneous oxidation of, 263.
—— thermometers, use of, with particular reference to the determination of melting and boiling points, 656.

Mercury vapour, pressure of, at ordinary temperatures, 385.
—— volumetric estimation of, 695.
Mesitylene, formation of the benzoyl-derivatives of, 1000.
—— glycerol, preparation of, 57.
—— preparation of, 588.
Mesotartaric acid, salts of, 1124.
Mesoxalic acid, salts of, 1124.
Metabenzhydrilbenzoic acid, and its salts, 428.
Metabenzoyl-benzoic acid, and its reduction products, 427.
Metabenzylbenzoic acid, and its salts, 428.
Metabenzyl-toluene, and its reduction-products, 427.
—— dinitro-, 427.
Metacetoxylide, nitration of, 1013.
Metaethylpropylbenzene, 173.
Metahæmoglobin, 911.
Metahydroxycoumarin, 1346.
Metahydroxydiphenylamine, and its derivatives, 591.
Metahydroxyorthomethoxycinnamic acid, 1165.
Metaisobutyltoluene, and its derivatives, 300.
—— synthesis of, 301.
Metaisocymene, and its monosulphonic acids, preparation of, 43.
—— nitro-, action of dilute nitric acid on, 46.
β-Metaisocymenesulphonic acid, 1355.
Meta-isocymidine, and its derivatives, 46.
Metaisocyminylcarbamide, 47.
Metaisocyminylcarbylamine, 47.
Metaisocyminylethylthiocarbamide, 47.
Metaisocyminylurethane, 47.
Metaisopropylmethylbenzene, 43, 299.
Metallic elements, spark-spectra emitted by, under varying conditions, 801.
—— pyrophosphates, action of ammonium sulphide on, 218.
—— radicle, containing Pt and Sn, 822.
—— solutions, reduction of, by means of gases, &c., 393.
—— sulphides, action of copper chlorides on, 962.
—— vapours, infra-red radiation spectra of, 1237.
Metallurgy, application of electricity in, 785.
—— novelties in, 514, 1084, 1230.
Metallylthiamidobenzoic acid, 907.
Metals, change of volume on melting, 7.
—— comparative poisonous action of, on bacteria, 351.
—— density of, in the liquid state, 708.
Metals, extraction of, by electricity, 541, 934, 1229.
—— —— from certain ores, &c., 1230.
—— spectroscopic examination of vapours evolved on heating, at atmospheric pressure, 801.
Metamethylcinnamic acid, and its salts, 1163.
Metamethylmandelic acid, 1162.
Metamethylmandelonitrile, 1162.
Metaorthodimethoxycinnamic acid, 1166.
Metaparatolylenedithiocarbamide, and its derivatives, 50.
Metaparatolylenethiocarbamide, 49.
Metaphenyl tolyl ketone, 429.
Metaphenylenediamine, trinitro-, 1004.
Metaphenylenedithiocarbamide, diallyl-derivative of, 50.
Metaphenylthiamidobenzoic acid, 907.
Meta-saccharin, from milk-sugar, 283.
Metasaccharinic acid, salts of, 284.
Metasulphoparatolylazoparacresol, and its salts, 901.
Metatoluene-β-methylcoumarin, 67.
Metatoluylaldehyde, orthonitro- and dinitro-, 1163.
Metatoluylamidoacetic acid, and its salts, 1163.
Metatoluylanilidoacetic acid, 1163.
Metatoluylanilidoacetonitrile, and its amide, 1162.
Metatoluylenediamine, and its salts, 1007.
Metatoluylphenylketone, and its reduction products, 427.
—— dinitro-, 428.
Metatolyloxamides, 1142.
Metatritolylstibine, 1136.
Metavoltine, 1103.
Metaxylene derivatives, 1313.
—— dibromo-, 1313.
—— glycol, 1313.
Metaxylidine, nitration of, 1013.
Metaxylideneaniline, 1162.
Metaxylidenephenylhydrazine, 1162.
Metazophenetoil, 1147.
Metazoxybenzanilide, 301.
Meteoric dust, 165.
—— iron from Georgia, 30.
—— —— Pallas, 416.
Meteorite, Alfianello, and analyses of, 276, 415, 976.
—— Nogoya, 977.
—— of Sewrjukowo, 417.
—— the Cranbourne, 416.
Meteorites, Bishopville and Waterville, 976.
—— classification of, 975.
—— iron, peculiar concretions in, 975.
—— Rowton and Middlesbrough, analyses of, 977.

Metethylthiamidobenzoic acid, 907.
Methane, chloro- and bromo-derivatives of, comparison of, 718.
—— dibromodinitro-, 277.
—— —— chlorine-derivatives of, 1107.
—— dichlorodinitro-, 1108.
—— liquid, properties of, and its use as a refrigerator, 1275.
Methenyldiphenylazidine, 1323.
Methenylisotoluylendiamine, and its bromo-derivative, 1143.
Methocodeine, and its derivatives, 614.
Methoxy-β-methylhydrocoumaric anhydride, 1332.
Methoxytoluenesulphonic acid, 454.
Methyl acetate, action of acids on, 581.
—— alcohol, decomposition of, by the silent discharge, 542.
—— —— purification of, 1279.
—— chloroform, monobromo-, 978.
—— coumalinate, 1124.
—— dimethyl-β-methylumbellate, 1331.
—— formate, decomposition of, by the silent discharge, 543.
—— iodide, formation of, from iodoform, 896.
—— isopropyl ketone, action of hydroxylamine on, 611.
—— monochlorallyl carbinol, 1118.
—— monochlorodibromopropyl-carbinyl chloride, 1118.
—— nitrate, action of ammonia gas on, 577.
—— nitrosophenolcarboxylate, 1003.
—— phenylcinnamate, and its bromine-derivative, 1348.
—— propyl carbinol, 1280.
—— telluride, preparation of, 663.
—— trichloropropyl carbinol, and its derivatives, 1118.
Methyl-indigo, 237.
Methyl-orange as an indicator, 691, 869.
Methyl-violet, 606.
—— —— crystalline bases of, 595.
Methylacridine, action of methyl iodide on, 1356.
Methylamidoazobenzene, and its acetyl-derivative, 1149.
Methylamido-α-caproic acid and its derivatives, 664.
Methylammoniochelidonic acid, 1196.
Methylarbutin, separation of, from arbutin, 432.
—— synthesis of, 439.
Methylated spirit, purification of, 1085.
Methylbenzylglyoxime, diacetyl-derivative of, 52.
-Methylbromumbelliferone dibromide, 1331.
Methylcinnolinecarboxylic acid, 1022.
-Methylcoumarin, and its derivatives, 67.
Methylcumazonic acid, and its derivatives, 303.
Methyldicarbocollidylium dihydride, and the action of acids on it, 1046.
Methyldioxyquinizine, isonitroso-, 1379.
Methyldiphenylaminazyline, 180.
Methyldiphenylaminesulphone, 596.
Methyldiphenylcarbamide, 1321.
Methyldiphenylphthalide, 321.
Methyldiphenylthiocarbamide, 1320.
Methylene bromide, 718.
—— iodide, formation of, from iodoform, 896.
—— oxysulphide, 170.
Methylene-blue, 595, 740.
—— —— and allied colouring matters, 595, 1156.
—— —— formation of, as a reaction for hydrogen sulphide, 109.
—— —— synthesis of, 306.
Methylene-white, 740.
Methylenediphenyl oxide, 324, 325.
Methylethylaniline, 1005.
Methylethylbromaniline, 1006.
Methylethylglyoxime, diacetyl-derivative of, 52.
Methylethyloxyquinizine, 1380.
Methylethylquinol, 1138.
Methylglyoxime, diacetyl-derivative of, 52.
Methylhydroparacoumaric acid, dinitro-, 1350.
Methylhydroquinaldine, 183.
Methylhydroxypyridine, and its derivatives, 841.
Methylhydroxytoluoquinoxaline, 1053.
Methylindole, synthesis of, 1181.
Methylindolecarboxylic acid, synthesis of, 1181.
Methylisobutylquinol, 1139.
Methylisopropylacetoxime, 611.
Methylisopropylethylene glycol, 833.
Methylmorphimethine, and its derivatives, 614.
α- and β-Methylnaphthalene, and their derivatives, 1183, 1184.
Methylnonylacetoxime, 1115.
Methyloxyquinizinacetic acid, 1380.
Methyloxyquinizine, isonitroso-, 1378.
Methylparathymolcarboxylic acid, 56.
Methylparathymotic aldehyde, 56.
Methylphenylacridine-ammonium hydroxide, constitution of, 1357.
Methylphenylanthracene, 322.
Methylphenylanthranol, 322.
Methylphenylcarbamide, unsymmetrical, 1321.
Methylphenylethylalkine, and its derivatives, 1011.
Methylphenylhydrazinepyroracemic acid, 53.
Methylphenyloxanthranol, 322.

Methylphenylpropylalkine, 1011.
Methylphenylthiocarbamide, unsymmetrical, 1321.
Methylphthalimide, and its derivatives, 1019.
Methylphthalopseudocumidamide, 1319.
Methylpiperidine, 760.
—— and some of its salts, synthesis of, 1054.
Methylpiperyl-azone and tetrazone-derivatives, 468.
Methylpropylacetic acid, 1120.
Methylpropylbenzene, 44.
Methylpropylglyoxime, 52.
Methylpropylquinol, 1138.
Methylpseudisatin, synthesis of, 1181.
Methylpseudolutidostyrene, and its derivatives, 1046.
Methylpurin, derivatives of, 996.
—— diethoxychloro-, 996.
—— trichloro-, 996.
Methylquinaldines, and their derivatives, 184.
α-Methylquinoline, and its derivatives, 756.
Methylquinolinecarboxylic acid, 1376.
α-Methylquinolinemonosulphonic acids, 1198, 1199.
γ-Methyl - α - quinolinesulphonic acid, 1052.
Methylsalicylaldehyde, nitro-, and its derivatives, 1164.
Methylsulphonic chloride, trichloro-, action of ammonia on, 1126.
Methylthiophene, 586.
Methyltriacetonine, and its derivatives, 1290.
Methyltrichloroquinoline, 1023.
Methyltriphenylmethylamine, and its iodine-compound, 1033, 1034.
Methyltropidine, and some of its derivatives, 761.
β-Methylumbelliferone, and its derivatives, 66, 1331.
—— dibromide methyl ether, 1332.
—— nitro- and amido-derivatives of, 1332.
Methyluric acids, 1308.
Metoxyacrylic acid, 1301.
Metoxalyldibenzamic acid, and diamide of, 906.
Mica, green, in the quartzites of Ouro Preto (Brazil), 408.
—— diorites of Southern Thuringia and the Frankenwald, 1273.
Microclase, 970.
Micro-organisms in soils, 486.
Milk, a physical property of, 941.
—— American, 533.
—— blue, and ropy, 942.
—— cow's, composition of the ash of, 1397.
—— cow's, digestion of, and the substance which increases its digestibility, 192.
—— —— effect of exhausted beetroot pulp on, 317.
—— —— in Holland, composition of, 1306.
—— excretion, influence of feeding with cotton-cake meal on, 623.
—— human, analyses of, 1396.
—— influence of cotton-seed cake on the secretion of, 669.
—— influence of movement on the secretion of, 1205.
—— notes on, 236.
—— from cows of different breeds, percentage of fat in, 94.
—— of lime, density of, 712.
—— on the casein in, 762.
—— physiology of the formation of, 914.
—— researches on, 1219.
—— secretion, 93.
—— thickening of, 941.
—— time required for digestion of, 470.
—— volumetric method for the estimation of fat in, 372.
Milk-analysis, researches on, 1219.
Milk-sugar, a new saccharin from, 283.
—— —— action of alkalis on, 1112.
—— —— action of cupric hydroxide on, 1112.
—— —— birotation of, 1112.
—— —— relation between the solubility and rotation of, and rate of transition of its biroration into normal rotation, 36.
Millet, analysis of, 630.
Mineral acids, liquid, process for converting into a solid form by the addition of kieselguhr, 783.
—— fuel, composition of, 521.
—— new, from Barbin, near Nantes, 408.
—— oils, fractional distillation of, in a current of steam, 936.
—— probably new, from Colorado, 826.
—— water at Brucourt, analysis of, 895.
—— —— Borhegyer, composition of, 978.
—— —— from Aruba, 978.
—— white, a, process for preparing, 136.
Minerals, a new liquid suitable for the separation of, 145.
—— action of fused magmas on, 401.
—— combustible, analyses of, 780.
—— from Berks Co., Pa, 663.
—— from Brazil, 564.
—— from Lehigh Co., 661.
—— isomorphous, which are not chemically analogous, 1096.

Minerals, Italian, chemico-mineralogical studies on, 270.
—— new, from the Tyrol, 1098.
—— of the cryolite-group recently found in Colorado, 21.
—— subsequent alteration of, by the action of water, 1273.
Minette, presence of phosphorus in, 412.
Minium, native, in Idaho, 563.
Minjak-Lagam balsam, constituents of, 354.
Mispickel from Auerbach, 1100.
—— from Queropulca, in Peru, 1100.
—— radiated, from Orawitza, 1099.
Molasses, production of sugar from, by Steffen's and Scheibler's processes, 1236.
—— recovery of sugar from, by means of lime, 939.
—— refining of, by means of concentrated acetic acid, 790.
—— separation of sugar from, 1447.
Molecular calcium compounds, 892.
—— volume of liquid substances, 386.
—— volumes of salt solutions, 658.
—— weight of the amines, 257.
—— —— and velocity of evaporation of liquids, relation between, 551, 950.
—— weights, scale of, 804.
Molybdates, action of hydrogen peroxide on, 965.
Molybdenum compounds, reduction of, 559.
—— estimation of, 965, 1429.
—— sulphide, reduction of, 965.
—— sulphur compounds of, 160, 1267, 1268.
Molybdic acid, nitro-, solution, concentrated, preparation of, 638.
Monamines, aromatic, action of perthiocyanic acid on, 1140.
—— secondary, action of phthalic anhydride on, 418.
Monethyl oxalate, 296.
Monobenzoylpiperylhydrazine, 467.
Monomethyluric acid, 996.
Monophenylmalonamide, 728.
Monostearin, preparation of, 280.
Monostearyldiglycerol, 282.
Monostearylglycerolphosphoric acid, ? 282.
Mordants, contributions to the chemistry of, 794.
Morin, oxidation and reduction of, 816.
—— preparation and derivatives of, 1180.
Morphine and some of its derivatives, 613.
—— estimation of, in opium, 1217.
—— oxidation of, 85.
—— separation of, in toxicology, 373.
Morphothebaïne and its derivatives, 1201.
Mortuary vault, antiseptic experiments in, 878.
Moss as cattle litter, 105.
Mucic acid, antimony derivatives of, 424.
—— —— preparation of, from milk-sugar and lactose, 980.
Mucobromic acid, action of alkalis on, 731.
Muscarine, 1056.
Muscles, influence of ptomaïne hydrochloride on, 618.
Must, estimation of dry substance in, 1432.
—— influence of temperature on the fermenation of, 617.
Mustard, analysis of, 878.
—— white, as fodder, 864.
Myosin, basicity of, 1388.
Myostroine, 1388.
Myricyl alcohol from Carnauba wax, 1281.
Myristoxime, 1115.
Myristyl chloride, 1125.

N.

α- and β-Naphtha-γ-hydroxyquinaldine, synthesis of, 1198.
β-Naphthaldehyde, 1184.
Naphthalene, amidobromo-, 843.
—— bromonitro , 842.
—— derivatives, 80, 751, 812, 1185.
—— —— synthesis of, 907.
—— dibromo-, and its tetrabromide, 842.
—— dibromonitro-, 812.
—— dihydride, diisonitroso-, 1359.
—— dinitro-, preparation of, from dinitro-β-naphthylamine, 1036.
—— hydrides of, 608.
—— nitroso-amido-, 1035.
—— oxidation of derivatives of, 319.
—— tetrabromide, α-nitro-, 842.
α- and β-Naphthaquinaldine and their salts, 1375.
Naphthaquinone, dibromo-, 842.
β-Naphthaquinone, action of hydroxylamine hydrochloride on, 735.
—— nitro-, action of aniline and toluidine on, 1038.
—— —— derivatives of, 1186.
—— tetrabromo-, 1186.
β-Naphthaquinoneanilide, nitro-, 1038, 1186.
α-Naphthaquinonedimethylanilinimide or α-naphthol-blue, 595.
Naphthaquinonimide, amido-, 1037.
—— —— bromine-derivatives from, 1037.

β-Naphthaquinotoluides, nitro-, 1038.
β-Naphthaquinotoluidines, nitro-, 1038.
Naphthenes, 1276.
β-Naphthoic acid, 1185.
Naphthoic acid, derivatives of, 1360.
α- and β-Naphthoic acids, amides of, 1362.
—— —— and their derivatives, 81.
Naphthoic acids, chloro-, 1361.
—— —— nitro-, and their salts, 1360.
Naphthol, γ-nitro-, 752.
—— nitro-, action of ammonia on the ethers of, 1036.
—— oximido-, and diimido-, 1037.
α-Naphthol, α-nitroso-, 1327.
—— β-nitroso-, and the action of hydroxylamine hydrochloride on, 735.
α- and β-Naphthol, derivatives of, 79.
β-Naphthol, condensation-product of, with benzaldehyde, 1185.
—— dinitro- and its derivatives, 1035.
—— nitroso-, action of ammonia on, 1035.
—— pentabromo-, and the action of bromine on, 1185.
β-Naphtholazobenzene, bromine-derivatives of, 326.
α-Naphthol-blue, preparation of, 594.
β-Naphtholdisulphonic acid, action of tetrazodiphenyl on, 1036.
β-Naphtholmonosulphonic acid, preparation of, 238.
Naphthols, nitroso-, action of alcoholic potash on, 1035.
—— orthonitroso-, action of hydroxylamine hydrochloride on, 1359.
β-Naphthomethyl chloride and bromide, 1184.
α-Naphthonitrile, monochloro-, 1361.
α- and β-Naphthonitrile, nitro- 80.
β-Naphtho-oxymethylquinizine, 1154.
α- and β-Naphthyl phenyl ketone, 609.
β-Naphthylamine, dinitro-, 1036.
Naphthylamine, nitro-, 1036.
β-Naphthylaminemonosulphonic acid, preparation of, 238.
Naphthylamines, β- and γ-nitro, and their derivatives, 751.
Naphthylenes or naphthines, 1276.
β-Naphthyl-β-imidobutyric acid, synthesis of, 1198.
Nepheline rock from Ziegenhals, near Wohnfeld, analysis of, 276.
—— —— from the Vogelsberg, 275.
Nerves, influence of ptomaine hydrochloride on, 618.
Nesslerising, coloured tubes for, 1072.
Nets, methods used by fishermen for "barking" and in other ways preserving, 800.
Neuridine, 1202.
Neurine, 342.
Neurine, commercial, 1202.
—— distearylglycerolphosphate and its derivatives, 282.
—— physiological action of, 1056.
Nickel alkali-proof vessels, 1071.
—— atomic weight of, 256.
—— metallurgy of, 129.
—— separation of cobalt from, 498.
Nickel-plated iron vessels, action of organic acids on, 520.
Nickelous chloride, antiseptic action of, 1410.
Nitranilic acid, preparation of, 58.
Nitrates, melting points of. 384.
—— rapid estimation of, 1074.
—— reduction of, by ferments, 350.
Nitre, loss of, in the manufacture of sulphuric acid, 1222.
Nitric acid, ammonium ferrous sulphate as a reagent for, 493.
—— —— detection of, in presence of other acids capable of interfering with its reactions, 365.
—— —— estimation of, 871.
—— —— in soils and subsoils at Rothamsted, 357.
—— —— paratoluidine sulphate as a test for, 365.
—— —— testing for, in vegetable tissues, 1074.
—— —— volumetric estimation of, 366.
—— and nitrous acids, estimation of, separately or together, 366.
—— oxide, product of the action of bromine on, 1257.
Nitrifying action, comparative, of certain salts, 924, 1417.
Nitrile of anhydrobenzodiamidobenzene, 741.
Nitriles, action of hydroxylamine on, 734.
—— conversion of primary amines into, 1288.
—— from aromatic amines, 734.
—— preparation of, 1314.
—— transformation of, in the organism, 1061.
—— ethereal, limit of the formation of, by double decomposition, 1110.
Nitrogen, absorption of, by leguminous plants, 1401.
—— ammoniacal, in soils, estimation of, 1423.
—— apparatus, Dumas', 1072.
—— boiling point of, under atmospheric pressure, 817.
—— combined terrestrial, origin of, 104.
—— compounds, new group of, 725.
—— copper iodide, 154.
—— critical temperature and pressure of; relation between its boiling point and the pressure, 1257.

Nitrogen, detection of, in organic compounds, 1072.
—— electrochemical researches on, 383.
—— elimination of, in the free state, from the animal body, 1391.
—— estimation, examination of H. Grouven's method of, 1215.
—— estimation of, by combustion with calcium hydroxide, 1422.
—— —— in nitro-, azo-, and diazo-compounds, 364.
—— in bone-meal, 359.
—— in organic substances, a new method of estimating, 364.
—— in the soils of experimental fields at Rothamsted, determinations of, and bearing of the results on the question of the sources of the nitrogen of our crops, 682.
—— iodide and the action of sunlight on, 818.
—— iodides, 152, 818.
—— loss of, by organic matters during putrefaction, 1214, 1417.
—— —— during the fermentation of farmyard manure, 1413, 1416.
—— solidification of, 553.
—— and hydrogen, direct union of, 152.
—— and oxygen, in presence of chlorine, action of the silent discharge on, 710.
Nitrogenous matter in the soil, some of the changes which it experiences, 490.
Nitrous acid, combined, volumetric estimation of, 493.
—— —— new volumetric method for the estimation of, 870.
—— and nitric acids, estimation of, separately or together, 366.
—— anhydride, liquid, 15.
Nitrosyl bromide, 1258.
Nonane, and monochloro-, from American petroleum, 1106.
Nonoic acids from different sources, 295.
Nonylene, 1107.
Nonylic alcohol, 1107.
Nucin, 1365.
Nuclein, 90.
Nucleus, chemistry of the, 97.
Nutrition, influence of potassium bromide on, 850.
Nux-vomica, effect of alcohol of various strengths on, 946.
—— —— tincture of, 946.
Nymphæa alba, constituents and properties of, 108.

O.

Oak-bark, two acids in, 1439.
—— —— tannin, behaviour of tannin and, towards various reagents, 1355.
"Oak-red," 321.
Oats, experiments with, at Grignon, in 1883, 1069.
—— importance of silicic acid in the culture of, 1211.
—— influence of thick and thin sowing and of the manuring on the yield of, 768.
—— irritant properties of, 914.
—— manuring, with nitrogen and phosphates, 925.
Oceanic deposits, solid and gaseous constituents of, 31.
Ochre colours, process for preparing, 784.
Octacetylquercetin, 847.
—— and tribrom-, 1365.
Octadecylene bromide, 1108.
—— preparation of, 571.
Octadecylidene, 1108.
Octane from American petroleum, 1106.
Octodecyl alcohol, 1280.
Octohydroacridine and its derivatives, 608.
Octoic acid, 461.
Octylamine, action of bromine in alkaline solution on, 1114.
Octylene from diisopropylglycol, 38.
Œnanthaldoxime and its ethyl salt, 581.
Oil of birch, 459.
—— hops obtained from commercial lupulin, 459.
Oils, drying, acceleration of the oxidation of, 532.
—— lubricating, behaviour of, with glacial acetic acid, 1078.
Olefines, higher, preparation of, 571.
Oleocutic acid, 859.
Olive oil, examination of, 931.
Olivine of the melilite-basalt of Hochbohl, 829.
Opium, estimation of morphine in, 1217.
Optically inactive compounds, decomposition of, 1303.
"Orantia," 236.
Orantin, 910.
Orcinol, action of acetaldehyde and of chloral hydrate on, 598.
—— mononitroso-, 1341.
—— dyes, 1341.
Orcylaldehyde, 1346.
Ores which are good conductors of electricity, 786.
Organic bases, a new group of, 302.
—— —— hydrocyanides of, 338.

Organic bodies, magnetism of, 1243.
—— matter in water, estimation of, 369.
Organisms, lower, action of oxygen on the activity of, 1399.
Orsat's apparatus for the estimation of oxygen, improved form of, 695.
Orthacetotoluide, nitration of, 1012.
Orthazoethylbenzene, and its reduction, 903.
Orthazophenol, trichlor-, 1015.
Orthazotoluene, 903.
Orthazoxybenzanilide, 1327.
Orthobenzylamidoacetophenone and its nitroso-derivatives, 1021.
Orthoclase, alteration of, into albite, 273.
—— from Mt. Blanc, analysis of, 403.
Orthocresol, amido-, 902.
—— nitro-, and its derivatives, 1007.
—— nitroso-, 1003, 1327.
—— amido-, 1003.
—— trinitro-, 1007.
Orthodiazocinnamic acid, hydrochloride and nitrate of, 441.
Orthoethylamido-acetophenone, 1021.
Orthoethylphenol, 174.
Orthohydrazinanisoïl and its derivatives, 440.
Orthohydrazinecinnamic anhydride, 441.
Orthohydrazobenzoic acid, 1312.
Orthohydroxybenzyleneamidobenzamide, 455.
Orthohydroxyhydroethylquinoline, 1049.
Orthohydroxymandelic acid, 1022.
Orthohydroxyphenylacetic acid and its derivatives, 1021.
Orthohydroxyphenylglyoxylic acid, 1021.
Orthohydroxyquinoline and its derivatives, 1199, 1370.
Orthometatolidine, 903.
Orthomethoxycinnamic acid, derivatives of, 1165.
Orthomethoxytoluquinoline, 1199.
Orthomethylparapropylcoumarin, 1316.
Orthophenylenediamine, action of ferric chloride on, 1322.
—— preparation of, 49.
Orthophenylenethiocarbamide, 49.
Orthoquinolinesulphonic acid, oxidation of, 1049.
Orthotolidine, action of nitrous acid on, 903.
Orthotolu-dimethyloxyquinizine, 1153.
Orthotolueneazometatoluene, 903.
Orthotoluene-γ-hydroxyquinaldine, synthesis of, 1198.
Orthotoluic acids, nitro-, 745.
Orthotoluidine, nitration of, 1012.
—— nitro-, of melting point of 107°, and its derivatives, 1006.
Orthotoludine, paratoluidine, and aniline, separation of, 46.
Orthotolunitrile from formorthotoluide, 734.
Orthotolu-oxymethylquinizine, 1153.
Orthotoluquinolinemonosulphonic acids, 1199.
Orthotolyl-β-imidobutyric acid, synthesis of, 1198.
Orthotolyl-α- and β-naphthylamine, 80.
Orthotolyloxamides, 1112.
Orthotolylparamethylimesatin, 48.
Orthotolylphthalimide, 453.
Orthoxylene derivatives, 898, 1313.
—— glycol, 1000.
Orthoxylidine, [1 : 2 : 4], and its derivatives, 737.
Orthoxyphenylacetic acid, lactone of, 1022.
Orthoxylyl cyanide, 898.
Orthoxylylene bromide and the action of ethyl sodomalonate on it, 752.
—— diethyl ether, 1313.
—— iodide, 1314.
—— sulphide, 1313.
Orthoxylylenedianilide, 1313.
Oxalamido-acids, 906.
Oxalethylisoamyline, 986.
Oxalic acid, dry, use of, in the formation of condensation-products, 1019.
—— —— effect of light on the decomposition of, by ferric chloride, 381.
Oxalines, oxidation of, by means of hydroxyl, 986.
Oxalisoamylisoamyline, 986.
Oxalisobutylisoamyline, 986.
Oxallyldiethylamine, 577.
Oxalmethylisoamyline, 986.
Oxalpropylisoamyline, 986.
Oxides, action of sulphur on, 959.
Oxyaurin, 591.
Oxy-azobenzene, metadichloro-, 903.
Oxybutyric acid, chlor-, 1301.
—— —— amido-, 1301.
Oxydimethylpurin, dichlor-, 997.
—— diethoxy-, 997.
—— ethoxychlor-, 997.
Oxy-β-dimethyluric acid, 1309.
Oxygen, action of, on the activity of the lower organisms, 1399.
—— active, 14.
—— apparatus for preparing quickly, 1254.
—— atomic weight of, 659.
—— boiling point of, under atmospheric pressure, 817.
—— constant production of, by the action of sunlight on *Protococcus pluvialis*, 201.
—— determination of the rate of consumption of, in the tissues by means of the spectroscope, 1391.

Oxygen, improved form of Orsat's apparatus for the estimation of, 695.
—— liquid, coefficient of expansion of, 816.
—— —— critical temperature and pressure of, 148, 149.
—— —— density of, 14, 388, 553, 816.
—— —— ebullition of, 553.
—— and carbon, heat of combination of, 141.
—— and nitrogen in presence of chlorine, action of the silent discharge on, 710.
Oxyhydrogen mixture, supposed recombination of, in the dark, 1092.
Oxyisoamylamine, and the action of phosphorus pentoxide on it, 1190.
Oxyisobutyric acid, chlor-, 1301.
Oxylepidine, tribrom-, 1383.
Oxymethylene, 293.
Oxymethylquinizine, 1153.
Oxymorphine and its derivatives, 616.
Oxypyride, 85.
Oxypyridine, dibrom-, and its salts, 1370.
Oxyquinoterpene, 1191.
Oxysulphides, organic, action of chlorine on, 1127.
Oxythiacetone, 580.
Oxythiomolybdates, 1268.
Oxytolylic acid, products of the reduction and oxidation of, 841.
Oxytrinicotine, 464.
Oxytropine, an, 761.
Ozone, some reactions of, 259.

P.

Pachnolite, 265, 716.
—— from Colorado, 21.
Pallas meteoric iron, 416.
Palm-cake and palm-meal, 631.
Palm-meal, palm-cake and, 631.
Palm-oil residue as fodder, 355.
Palmityl chloride, 1125.
Panclastite, 1452.
Pancreatic ferment, changes which proteïd matters undergo by the action of, 1056.
Papaverine, 186.
Paper, incombustible, 379.
Parabutyltoluene and its derivatives, 301.
Paracetotoluide, nitration of, 1012.
Paracresol, amido-, and its ethenyl-derivative, 901.
Paracresol-chloral, 187.
Paracresyl benzyl ether, nitro-derivatives of, 1337.
—— laurate, 1125.
—— myristate, 1125.
—— palmitate, 1125.
Paracresyl phosphate, 1338.
—— stearate, 1126.
Paracyanoquinoline, 1051.
Paradioxybenzophenone, oxime of, 1182.
Paradipropylbenzenesulphonamide, 457.
Paradipropylbenzenesulphonic acid, 457.
Paradipropylsulphonamide, oxidation of, 457.
Parethoxycarbanil, 1159.
Parethoxyphenylurethane and some of its derivatives, 1159.
Paraffin, liquid, as a reagent for the presence of water in alcohol, ether, and chloroform, and its use in the preparation of hydrobromic and hydriodic acids, and of the alkyl iodides, 1073.
—— —— of the German Pharmacopœia, 1073.
Paraffin-shale from Servia, 879.
Paraffins, action of benzaldehyde on the mononitro-derivatives of, 313.
—— and their derivatives, some, 166.
—— substituted derivatives of, proposed division of, into two distinct types, 730.
Paraguay tea, notes on and analysis of, 354, 479.
Parahydroxybenzaldehyde, action of zinc chloride on, 1164.
Parahydroxybenzide, and its derivatives, 416.
Parahydroxybenzoic acid, dry distillation of, 446.
—— —— para- and dipara-hydroxybenzoyl, 447.
Parahydroxybenzonitrile, 417.
Parahydroxybenzoylparahydroxybenzoic acid, 417.
Parahydroxybenzylsulphonic acid, 69.
Parahydroxydiphenylamine, and its derivatives, 592.
Parahydroxytoluquinoline, 1199.
Paraisopropylorthonitrophenyl-β-bromopropionic acid, 1352.
Paraisopropylorthonitrophenyllactic acid, and its salts, 1353.
Paraldehyde, physiological action of, 199.
Paraldol, action of heat on, 579.
Paramethoxyphenylacetic acid, 1176.
Paramethoxytoluquinoline, 1199.
Paramethylimesatin, 48.
Paramethylindophenin, 48.
Paramethylisatin, 48.
Paramethylisatinimide, 48.
Paramethylisatinmetabromoparatolylimide, 48.
Paramethylisatinorthotolylimide, 48.
Paramethylisatin-paratolylimide, 47.
Paramethylisatinphenylimide, 48.
Paramethylnitroso-oxindole, 48.
Paramethylquinophthalone, 335.

Paraphenetoïl-azoparacresol, 1147.
Paraphenetoïl-azoresorcinol, 1147.
Paraphenoxybenzoic acid, 447.
Paraphenylenediamine, nitration of, 738.
Paraphenylene-diamines, preparation of, 49.
Paraphenylenedithiocarbamide, derivatives of, 50.
Paraphenylpyridine, and its salts, 1194.
Paraphenylpyridinetetracarboxylic acid, and its salts, 1193.
Paraquinolinecarboxylic acid, 1052.
Paraquinolinesulphonic acid and its homologues, 1051.
—— —— and its salts, 757.
Parasulphophenylazoparacresol, and its salts, 901.
Parasulphophenylazorthocresol, 902.
Parathymotic acid, preparation of, 56.
—— alcohol, 56.
—— aldehyde, 56.
Paratolueneazoacetone, 1342.
Paratoluidine, azophenine of, 743.
—— nitration of, 1012.
—— orthotoluidine, and aniline, separation of, 46.
—— sulphate as a test for nitric acid, 365.
Paratolumethyloxyquinizine, 1154.
Paratolunitrile from formoparatoluide, 734.
Paratoluquinolinemonosulphonic acid, 1199.
Paratolylazoparacresol, and its acetic and benzoic derivatives, 901.
Paratolylethylthiourethane, orthonitro-, 307.
Paratolyl-γ-hydroxyquinaldine, synthesis of, 1198.
Paratolyl-β-imidobutyric acid, synthesis of, 1198.
Paratolyl-α- and β-naphthylamine, 80.
Paratolyloxamides, 1141.
Paratolylparamethylimesatin, metabromo-, 48.
—— preparation of, 47.
Paratolylphenylthiocarbamide, orthonitro-, 307.
Paratolylpropaldehyde, and its derivatives, 1342.
Paratritolylstibine oxide and hydroxide, 1136.
Paratolylthiocarbamide, orthonitro-, 307.
Paratolylthiocarbimide, orthonitro-, 307.
Paraxylenol, bromo-, 1329.
Paraxylic acid, monobromo-, and its salts, 1347.
Parazoaniline, 666, 1016.
Parazobenzyldisulphonic acid, 69.
Parazoethylbenzene, and its reduction 904.
Parazoxyacetanilide, 301.
Parazoxyaniline, and its derivatives, 301.
Parazoxybenzanilide, 666.
Parenchyma, living, osmotic functions of, 1403.
Parvoline, and its derivatives, 172.
—— oxidation of, 173.
"Patent block composition," Harris Hewit's, 1088.
Pathological liquid, a, composition of, 1060.
Patina, imitation of, 1414.
Pea, white, grey, and sand, cultivation of, 770.
Peas, barley, and malt, comparative feeding value of, 206.
—— comparative growth of, in mineral and organic solutions, 1208.
Peat compost, manuring with, 867.
—— litter, analysis of, 925.
—— —— and straw litter, comparison of, 1418.
Peaty waters, self-purification of, 781.
Pectose, 860.
Pentamethylparaleucaniline, 607.
Pepsin, commercial, digestive power of, 471.
Peptone, from proteïd matters by the action of pancreatic ferment, 1057.
—— gelatin, 344.
Peptonisation, studies on, 1390.
Perfumes, extraction of, 378.
Periodic law, history of, 958.
Peronospora viticola, 1406.
Perowskite, artificial production of, 565.
—— from Rympfischwäng near Zermatt, analysis of, 402.
Persite, a sugar analogous to mannitol, 1285.
—— nitro-, 1285.
Perspiration, chemistry of, 189.
Perthiocyanogen, fixing of, in printing, 796.
Perthiomolybdates, 1268.
Petroleum, American, hydrocarbons from, and their derivatives, 1106.
—— Caucasian, 1276.
—— determination of the flashing point of, 1431.
—— Galician, 166.
—— gas, compressed, liquid hydrocarbons from, 879.
—— investigation of, 500.
—— lamps, researches on, 936.
—— Russian, researches on, 936.
—— testing, 369.
—— —— in tropical climates with Abel's apparatus, 877.
Petroleums, physical properties of, 277.
Peziza aurantia and *P. convexula*, orange-red colouring matter of, 847.

Phellandrium aquaticum, 331.
Phellanthrene, 331.
Phenacetolin as an indicator, 691, 869.
Phenaceturic acid, 1061.
Phenanthraquinone, derivatives of, 328.
—— hydrocyanide, saponification of, 329.
—— Laubenheimer's colour reaction for, 1038.
—— monisonitroso- and dioximide-derivatives of, 62.
—— nitro-, 82.
Phenanthrone and its monochlorinated derivative, 82.
—— dichloro-, reduction of, 81.
Phenethyl compounds, 1000.
Phenetoïl, amido-, action of monochloracetic acid on, 1144.
—— hydrochloride, tetramido-, 1161.
—— nitro-, experiments on the preparation of, 433.
—— trinitro-amido-, 1161.
Phenol, action of an alternating current on, 1136.
—— —— on ketonic acids, 55.
—— —— quinonechlorimide on, 593.
—— bromodinitro-, 55.
—— colouring matters, 1340.
—— diorthonitroparamido-, and its salts, 308.
—— estimation of, in commercial carbolic acid, 503.
—— in the stem, leaves, and cones of *Pinus sylvestris*, 863.
—— methyl ethers of, 589.
—— monobromo-, a fourth, 55.
—— nitroso-, ethereal salts of, 1003.
—— ortho- and para-amido-, action of monochloracetic acid on, 1144.
—— paranitro-, action of the nitrate of orthodiazobenzoic acid on, 1014.
—— triamido-, and some of its derivatives, 309.
—— trinitro-, detection and estimation of, 221.
Phenol-blue, preparation of, 594.
Phenolphthaleïn, as an indicator, 691, 869.
—— as indicator in the estimation of carbonic anhydride in mixtures of gases, 1072.
Phenols, action of aldehydes on, 597, 598.
—— —— aromatic hydroxy-acids on, 310.
—— —— diazobenzene on, 1146.
—— —— phosphorus trisulphide on, 54.
—— bromo-, 900.
—— compounds of, with ethylacetoacetate, 1331.
—— condensation of aromatic aldehydes with, 590.
Phenols, high-boiling, contained in coal-tar, 1003.
—— nitro-, ethylene ethers of, 433.
—— nitroso-, 735, 1137, 1327.
Phenolsulphonic acids, amido-, and their relationship to Liebermann's colouring matters, 1354.
Phenolsulphuric acid, preparation of, from urine, 1353.
Phenomalonic acid, trichloro-, and its bromine-derivative, 1122.
Phenosafranine, 538.
Phenoxyacetic acid, derivatives of, 1170.
—— —— orthonitro-, action of reducing agents on, 1170.
Phenoxymucobromic acid, 731.
Phenyl benzyl ethers, paranitro-, 1005.
—— cyanate, preparation of, 1002.
—— ethers of phosphoric acid, nitration of, 1337.
—— —— para-, and ortho-nitro-, of dinitrophenol and of picric acid, 1328.
—— laurate, 1125.
—— mercaptan, preparation of, 1328.
—— methyl glycols, two isomeric, 1003.
—— myristate, 1125.
—— palmitate, 1125.
—— para- and ortho-nitrophenyl oxide, α-dinitro- and trinitro-, 1328.
—— parahydroxybenzoate, 448.
—— paranitrobenzyl ethers, 1005.
—— phenylparahydroxybenzoate, 447.
—— phosphate, mononitro-, 1337.
—— stearate, 1126.
—— thienyl acetoxime, 1168.
—— —— ketone, 1168.
Phenylacetaldehyde, action of nitric acid on, 1020.
—— derivatives of, 1020.
Phenylacetamidine, and its derivatives, 1134.
Phenylacetic acid, isonitroso-, ethers of, 581.
—— —— orthoparadinitro-, 178.
Phenylacetimido-acetate, 1134.
Phenylacetimido-ethyl-ether, and its hydrochloride, 1134.
Phenylacetonitrile, transformation of, in the organism, 1061.
Phenyl-β-acetylalanine, orthonitro-, lactam of, 305.
Phenylacridine, and its derivatives, 1356.
—— diamido-, 749.
—— from chrysaniline, 749.
Phenyl-β-alanine, orthonitro-, and its derivatives, 304.
—— —— lactam of, 305.
—— paranitro-, and its derivatives 1172.

Phenylamidoazobenzenepolysulphonic acids, preparation of, 237.
Phenylammoniochelidonic acid, 1196.
Phenyl-α-anilidocrotonamide, 1315.
Phenyl-α-anilidocrotonic acid, 1315.
Phenyl-α-anilidocrotononitrile, 1315.
Phenyl-β-anilidopropionic acid, paranitro-, 1173.
Phenylarabinosazone, 1287.
Phenylazocresols, reduction of, 1146.
Phenylazocumenol, and reduction of, 1147.
Phenylazoindoxyl, 74.
Phenylazometacresol, 902.
Phenylazoparacresol, and its acetic and benzoic derivatives, 736, 900.
Phenylazoparacresolsulphonic acid, 901.
Phenylazorthocresol, and its acetic and benzoic derivatives, 736, 902.
Phenylbenzo-β-naphthacridine, 1359.
Phenylbromacetic acid, action of, on ethyl acetoacetate, 746.
Phenylbromopropionic acid, metanitro-, 1175.
Phenyl-β-bromopropionic acid, and its derivatives, 603.
—— —— orthonitro-, and its derivatives, 65.
Phenylbutyrolactone, action of halogen acids and of gaseous ammonia on, 744.
Phenylcinnamic acid, derivatives of, 1348.
Phenylcumazonic acid, 304.
Phenylcyanamide, preparation of, 1157.
Phenyldiethylalkaline, 1011.
Phenyldipropylphenylguanidine, 1008.
Phenyldisazometacresol, 902.
Phenyldisazomethoxybenzene, 902.
Phenyldisazoresorcinol, 1147.
Phenyldisazorthocresol, 902.
Phenylenediimidobutyric acid, synthesis of, 1198.
Phenylenedithiocarbamides, 49, 50.
Phenylenorthodiacetic acid, 898.
Phenylethylparatolylthiocarbamide, 1321.
Phenylgalactosazone, 1287.
Phenolglucoside, tetracetyl-, 439.
Phenylglycidic acid, 604.
Phenylglyoxime, 52.
α-Phenylhydrazidoisobutyric anhydride, 1153.
α-Phenylhydrazidoisobutyrimide, 1153.
α-Phenylhydrazidoisobutyronitrile, 1152.
α-Phenylhydrazidopropionic acid, and its salts, 1152.
α-Phenylhydrazidopropionitrile, and its amides, 1152.
Phenylhydrazine, action of ethyl acetoacetate on, 302.
Phenylhydrazine, action of ethyl diacetosuccinate on, 1381.
—— —— —— succinosuccinate on, 1154, 1380.
—— —— on cyanhydrins, 1152.
—— —— on imido-ethers, 713, 1323.
—— —— substituted acetoacetates on, 1380.
—— compounds of, with ketonic and aldehydic acids, 1151.
—— derivatives of hydroxynaphthaquinone, 1359.
—— preparation of, 597.
—— reactions of the salts of, 897.
—— reagent for aldehydes and ketones, 1150.
Phenylhydrazineglyoxylic acid, 1151.
Phenylhydrazinemesoxalic acid, 1151.
Phenylhydrazinepropionic acid, 53.
Phenylhydrazinepyroracemic acid, 1151.
—— —— and its ethyl-derivative, 52.
Phenylhydroxyacetimido-ether and amidine, 65.
Phenylhydroxyamidine, and its hydrochloride, 65.
Phenyl-α-hydroxycrotonic acid, and its methyl and ethyl salts, 1344.
Phenyl-α-hydroxycrotononitrile, 1344.
Phenyl-β-imidobutyric acid, action of nitrous acid on, 1368.
—— —— synthesis of, 1198.
Phenylindolecarboxylic acid, synthesis of, 1181.
Phenylisocrotonic acid, action of nitric acid on, 906.
Phenylisopropyl ethylene glycol, 833.
Phenyl-β-lactanilide, paranitro-, 1173.
Phenyllactic acid, metanitro-, and β-lactone of, 1174, 1175.
—— —— paranitro-, β-lactone of, 604.
Phenyl-β-lactic acid, nitro-, etherification of the three isomeric, 1351.
—— —— orthonitro-, 58, 66.
—— —— paranitro-, and its ethyl- and methyl-derivatives, 604.
Phenyllactic aldehyde, orthonitro-, 58.
Phenyl-β-lactone, orthonitro-, 65.
Phenylmelilotic acid, synthesis of, 176.
Phenylmethyl-β-naphthylthiocarbamide, 1321.
Phenylmethylparatolylthiocarbamide, 1321.
Phenyl-β-naphthacridine, 1357, 1358.
Phenyl-α-naphthylacetoxime, 1182.
Phenyl-α and β-naphthylamine, 80.
Phenylnitroethylene, 313, 906.
Phenylnitropropylene, 313.
Phenylorthonitroparatolylthiocarbamide, metanitro-, 307.
Phenyloxyacrylic acid, Erlenmeyer and Glaser's, 605.

Phenylparaconic acid, constitution of, 906.
Phenylparacoumaric acid, synthesis of, 176.
Phenylparamethylimesatin, 48.
Phenylparaoxyphenylthiocarbamide, metanitro-, 307.
Phenylparatolylthiocarbamide, metanitro-, 307.
Phenylquinoneimide, monochlorodianilide, 431.
Phenylsulphhydantoic acid, 907.
Phenylsulphhydantoin, 907.
Phenylsulphometanitro- and amidoparatoluide, 51.
Phenylsulphorthonitro- and amidoanilide, 51.
Phenylthienylmethane, 1001.
Phenylthiocarbamide, compounds of, with metallic salts, 1018.
—— metanitro-, and its derivatives, 306.
β-Phenyltribromopropionic acid, 603.
β-Phenylumbelliferone, 67.
Phonolites of Elfdalen, 276.
—— of Hegau, chemical composition of, 568.
Phlobaphen, 321.
Phloroglucinocarboxylic acid, 1335.
Phloroglucinol, derivatives of, and their relation to daphnetin and æsculetin, 1335.
—— di- and tri-ethyl ether, 1336.
Phlorol, chemical nature of, 174.
Phlorolcarboxylic acid, 174.
Phosphate from the Rata Island, analysis of, 360.
—— of lime, basic, as an addition to cattle fodder, 194.
Phosphates, acid, of the alkaline earths, decomposition of, in presence of water, 556.
—— dissolved and undissolved, comparison of, 774.
—— insoluble, 213.
—— native, commercial assay of, 1075.
—— retrograde, Gladding's process for the estimation of, 639.
Phosphines, action of zinc-ethyl on, 985.
Phosphoric acid, biological function of, 1392.
—— —— estimation of, 871.
—— —— —— as magnesium pyrophosphate, 493.
—— —— —— in arable soils, 871.
—— —— —— in manures, 217.
—— —— —— in superphosphates, 1424.
—— —— —— oxalic acid method as compared with the molybdic method, 929.
Phosphoric acid in rocks and soils, assimilability of, 868.
—— —— manufacture of, 260.
—— —— reverted, 1424.
—— —— —— application of ammonium citrate for the estimation of, 1075.
—— —— —— examination of, at various periods, 744.
—— —— volumetric estimation of, 110.
—— anhydride, three modifications of, 1258.
Phosphorites, origin of, in limestone districts, 1272.
Phosphoroso-molybdates, 561.
Phosphorous anhydride, action of sunlight on, 156.
Phosphorus, estimation of, in iron and in iron-ores, 875.
—— moist air, and carbonic oxide, 660, 711.
—— origin and distribution of, in coal and cannel coal, 1270.
—— oxychloride, preparation of, 155.
—— —— preparation of, from phosphates, 392.
—— —— heat of formation of, 250.
—— sulphides, 1259.
—— trisulphide, sulphur salts derived from, 555.
—— white, 154.
Phospho-vanadio-molybdates, 713.
Phospho-vanadio-tungstates, 714.
Phospho-vanadio-vanadico-tungstates, 715.
Photographic films, expedients for rendering them sensitive to green, yellow, and red rays, 1081.
Photosantonic acid, specific rotatory power of, 464.
Phthalacene, 1176.
Phthalacene-derivatives, 1180.
Phthalacenic acid, 1190.
Phthalaconecarboxylic acid, and its derivatives, 1176.
Phthalic acid, dibromo-, and its anhydride, 842.
—— —— monobromo-, and its anhydride, 843.
—— —— tribromo-, and its salts, 1186.
—— anhydride, action of, on secondary monamines, 448.
—— —— condensation-products from, 1176.
—— —— tribromo-, 1186.
—— chloride, constitution of, 1187.
—— glycol, 1000.
—— metaisocymidide, and its nitro-compound, 47.
Phthalide, dibromo-, 842.
Phthalopseudocumidamide, 1319.
Phthalopseudocumide, 1318.

Phthalopseudocumidic acid, and its salts, 1319.
Phthalyl chloride, constitution of, 1024.
Phyllites of the Tyrolean Alps, 274.
Phylloxera, 99, 355, 481.
—— suggestions for the destruction of, 920.
Physiological action, connection between chemical constitution and, 348.
Picolinecarboxylic acid, and its derivatives, 758.
Picolinic acid, 1201.
Picric acid, detection and estimation of, 221.
Picrotoxin, 845, 846.
Picrotoxininbenzoic anhydride, 845.
Pigeons, feeding experiments on, 473.
Pigments, urine-, &c., some unusual, 194.
Piles, dry, conversion of liquid batteries, into, 1240.
Pilocarpine, action of bromine on, 468.
—— influence of, on lactation, 1396.
Pimaric acid, and the hydrocarbon from, 1364.
Pimelic acid, and its salts, 423.
—— —— from camphoric acid, identity of isopropylsuccinic acid with, 296.
Pinite from Auvergne, 403.
Pinnoite, a new borate from Stassfurt, 1271.
Pinus sylvestris, phenol in the stem, leaves, and cones of, 863.
Piperethylalkine bromide, and its derivatives, 760.
Piperidine, 945.
—— and its homologues, synthesis of, 1054.
—— bases, conversion of pyridine bases into, 760.
—— —— synthesis of, 1195.
—— synthesis of, 760, 1202.
Piperilene-phthalamic acid, 452.
Piperpropylalkine, and its derivatives, 1054.
Piperylenamine-phthalein, and its dibromide, 452, 453.
Piperylhydrazine, and its derivatives, 467.
Piperylsemicarbazide, 468.
Piperylthiocarbazide, 468.
Piperylthiosemicarbazide, 468.
Piscidin, the active principle of Jamaica dogwood, 332.
Pisum arvense, cultivation of, 769.
Pit-water, analysis of, 782.
Pitchblende from Norway, 1101.
Pitchstone-porphyrite, 413.
Pith parenchyma, 861.
Plagioclase and scapolite minerals, chemical resemblance between, 567.
Plant, chemical processes in the, 670.
Plant development, influence of light and heat on, 855.
—— growth, effect of altitude on, 627.
—— -life, poisonous action of ammonium thiocyanate on, 768.
—— sap, easily oxidisable substances in, 918.
Plants, absorption of nitrogenous food-stuffs by, 1401.
—— action of hydroxylamine salts on, 1210.
—— —— rain, dew, and watering on, 766.
—— ash of leaves of, grown in the earth under water-culture, 98.
—— assimilation of carbon by, 202.
—— behaviour of zinc salts in the soil, and with, 856, 1407, 1408.
—— chemical phenomena of the respiration of, 1403.
—— chemistry of, 765.
—— concentrated nutritive fluid for, 1205.
—— contributions to the doctrine of thermic constants in, 1067.
—— contributions to the histochemistry of, 847.
—— cultivated, influence of climate, of condition, and extent of soil on the stem production of, 624.
—— distribution of water in heliotropically inclined parts of, 352.
—— effect of depth of sowing on the germination and growth of, 1404.
—— effects of light on the respiration of oxygen by, 916.
—— effect of mowing and feeding-off, on the production of side shoots, 625.
—— —— variations in the quantity of oxygen on the growth of, 625.
—— —— water holding sodium chloride and zinc sulphate in solution on, 856.
—— functions of tannin in, 628.
—— glycogen in, 354.
—— higher, development of starch-transforming ferments in the cells of, 917, 1063.
—— —— formation of diastatic ferments in the cells of, 1402.
—— influence of constant temperatures in the soil on, 916.
—— —— light and heat on, 1206.
—— —— radiant heat on the growing parts of, 626.
—— —— water on the growth of, 1401.
—— leguminous, absorption of nitrogen by, 1401.
—— lime and magnesia in, 917.
—— means of protecting, against frost, 1067.
—— methods of studying the influence of light on the respiration of, 1066.

Plants, poisonous effects of arsenic and lead on, 1407.
—— structure and functions of the epidermic system of, 1066.
—— transpiration in, in the tropics, 1403.
—— water, constituents and properties of some, 108.
Plasmolysis, 1065.
"Plastering," influence of, on the composition of wine, 646.
Plastin, 90.
Platinum, absorption of gases by, 702.
—— phosphides, 400.
—— vessels, action of lithium carbonate on, 1071.
Poison of Batrachians, 764.
Polarised light, action of solutions of cellulose on, 833.
Polyoxides, constitution of, 1260.
Polyporus officinalis, constituents of, 353.
Polysulphides, constitution of, 1260.
Porphyrite, Tuedian, from Stichill, analysis of, 413.
Porphyrites, Cheviot, 413.
Porphyritic obsidian, analysis of, 28.
Portland cement, detection of adulteration in, 876.
Potable waters, analysis of, 1431.
—— —— prothistological examination of, 369.
—— —— titration of organic matter in, by means of permanganate, 409.
Potash, examination of, 928.
—— manuring with, 774.
—— quantitative separation of, from ferric oxide, alumina, lime, and magnesia in silicates, 110.
—— soda felspar, triclinic (microclase), 970.
—— volumetric estimation of, 695.
Potassium alcoholate, heat of solution of, 4.
—— arsenite and arsenate, behaviour of, with indicators, 869, 870.
—— bromate, testing of, 218.
—— bromide, influence of, on nutrition, 850.
—— ferricyanide, reduction of, by potassium cyanide, 35.
—— ferrocyanide, estimation of, 501.
—— —— production, 501.
—— fluorides, heat of formation of, 5.
—— glyoxal-hydrogen sulphite, preparation and heat of formation of, 989.
—— hydrogen carbonate, estimation of, in presence of normal carbonate, 869.
—— hydroxide, preparation of, 15.
—— iodide, commercial, assay of, 366.
—— permanganate, action of, on certain sulphur-compounds, 151.
Potassium seleniocyanate, action of iodine on, 1109.
—— succinate, normal and acid, water of crystallisation of, 584.
—— sulphide, action of cupric sulphide and of mercuric sulphide on, 963, 964.
Potato starch, preparation of, 134.
—— waste, three processes for obtaining the albuminoïd matter from, 948.
Potatoes, change in the composition of, by ripening, 1400.
—— cultivation of, 101, 483, 1411.
—— preservation of, 101.
—— effect of drying the seed tubers on the yield of, 624.
—— —— potassium and sodium nitrates on the growth of, 361.
—— heaping, 772.
—— influence of krugite on the percentage of starch in, 1401.
—— influence of manuring on the composition of, 102.
—— krugite as a manure for, 926, 1401.
—— manuring, 101, 102, 635, 865, 866.
—— —— of, with bone-meal, 637.
—— with lime as a manure, 1419.
—— and sweet potatoes, 208.
Poudrette, preparation of, 489.
Pre-Cambrian rocks, supposed, of St. David's, 411.
Prehnite from Cornwall, Lebanon Co., Pa., 266.
Pressure, influence of, on the temperature of volatilisation of solids, 252.
Printing, fixing perthiocyanogen in, 796.
Propaldehyde, action of ammonia on, 172.
Propargyl iodide, and triiodide, 970.
Propenylbenzoic acid, amido-, action of nitrous acid on, 1022.
—— —— and its derivatives, 317.
—— —— nitro-salts of, 317.
Propeptone, 1388.
— from proteïd matters by the action of pancreatic ferment, 1057.
Propinine thiocyanate, and its derivatives, 664.
Propionamidine hydrochloride and platinochloride, 723.
Propionic acid, chlorotribromo-, decomposition of, by alkaline hydroxides, 663.
—— —— αβ dibromo-, action of, on ethyl malonate, 991.
—— —— tetrabromo-, and its salts, 664.
Propionic acids, substituted, 663.
Propionitrile, transformation of, in the organism, 1061.
Propionylcodeïne, and its derivatives, 614.
Propyl glycol, action of aldehyde on, 85.

Propyl nitrite, preparation of, by double decomposition, 1110.
Propylaniline, 1376.
Propylbenzoic acid, 1009.
Propylcarbamide, dibromo-, and its derivatives, 732.
Propyleneacetal, 35.
Propylenecarbamide, bromo-, and its derivatives, 733.
Propyleneglycolcarboxylic acid, 1301.
Propyleneoxycarboxylic acid, and its derivatives, 1301.
Propylethylquinoline, 1376.
Propylidene-acetic acid, 423.
Propylidene-diacetic acid, 423.
Propylnaphthalene, preparation of, 1357.
Propylphenyl cyanide, 1009.
Propylphenylamine, derivatives of, 1007.
Propylphenylcarbamide, 1008.
Propylphenylthiocarbamide, 1008.
Propylphenylthiocarbimide, 1008.
Propylpiperidines, 1196.
γ-Propyl-pyridine, 759.
Propylpyridines, 1196.
Prosopite, 22, 266.
—— from Colorado, 22.
Protalbumose, 1389.
Proteïn-compounds, changes which they undergo by the action of pancreatic ferment, 1056.
—— vegetable, solubility of, in water containing hydrochloric acid, 1390.
Protococcus pluvialis, constant production of oxygen by the action of sunlight on, 201.
Protoplasm, aldehydic nature of, 202.
Prout's hypothesis, 550.
Pseudacetopyrroline, 289, 291, 1044.
—— action of bromine on, 289, 291.
Pseudacetyl-α-carbopyrrolic acid, and its methyl salt, 1045.
Pseudobutylene bromide, dichloro-, 295.
Pseudocumidine, derivatives of, 1318.
Pseudoindoxyl, 73.
—— isonitroso-, 74.
Pseudoisatin, 73.
Pseudoisatin-α-ethyloxime, 74.
Pseudoisatin-α-oxime, 74.
Pseudomorphine, and its derivatives, 616.
Pseudotriacetonalkamine, 1290.
Pseudotriacetonine, 1291.
Pseudotropine, and some of its derivatives, 761.
Pteris aquilina, analysis of, and of its ash, 207.
Ptomaïne hydrochloride, influence of, on nerves and muscles, 618.
Ptomaïnes, 342, 343, 469, 617, 618, 1056.
Ptomaïnes, so-called, in relation to toxicological researches, 342, 469.
Pulvic acid, constitutional formula of, 841.
Pulvinic acid, products of the reduction and of oxidation of, 841.
Purpurin, oxidation of, 1040.
Purpurogallin, 175.
Putrefaction, influence of high pressures on, 1399.
—— loss of nitrogen by organic matter during, 1214, 1417.
Pyridic hydrides, synthesis of, 1047.
Pyridine, action of phthalic anhydride on, 335.
—— bases, action of alcoholic iodides on, 612, 759.
—— —— action of boiling water on the platinochlorides of, 612.
—— —— from coal-tar, 611.
—— —— process for preparing dyestuffs from, 798.
—— —— reaction for, 1438.
—— —— synthesis of, 1195.
—— compounds, 914.
—— constitution of, 1193.
—— derivatives, 1048, 1195, 1368.
—— —— and condensation of, 758.
—— dibromo-, 1195.
—— di- and tri-chloro-, 1195, 1369.
—— propiodide, action of heat on, 1195.
—— and benzene, relation between, 758.
γ-Pyridinecarboxylic acid, 1194.
—— —— from γ-isopropylpyridine, 1048.
Pyridinedicarboxylic acid, 173, 758, 1018.
—— —— and some of its salts, 758.
Pyridinedisulphonic acid, and its salts, 1195.
—— —— formation of, from piperidine, 945.
Pyridinemonocarboxylic acid, 337.
—— —— copper salt of, 758.
Pyridines, methylated, condensation-products of, 335.
Pyrites, cobalt-, nickel- and iron-, 1098.
—— estimation of sulphur in, 492.
—— residues, zinc from, 788.
—— Spanish, and Massachusetts, composition of, 230.
Pyrocoll, 176.
—— derivatives of, 292.
—— perchloro-, action of phosphorus pentachloride on, 176.
—— perchloro-octochloride or perchloride of, 292.
—— synthesis of, 585, 725.

Pyrocoll, tetrabromo-, 292.
Pyrocressol, so-called, 79.
Pyrodithiomolybdates, 1268.
Pyroelectricity of blende, sodium chlorate, and boracite, 3
Pyrogallol, derivatives of, and their relation to daphnetin and æsculetin, 1335.
—— electrolysis of, 175.
—— new reaction for, 1078.
Pyroligneous acid, occurrence of valero- from, lactone in, 1118.
—— —— of the German Pharmacopœia, 371.
—— —— removal of furfuraldehyde from, 1304.
Pyromeconic acid, action of hydroxylamine on, 1302.
Pyrometer, Boulier's, 543.
Pyromucic acid, bromo-derivatives of, 1305.
—— —— substitution-derivatives of, 1305.
Pyrophthalone, and its derivatives, 335.
Pyrophyllite in anthracite, 273.
Pyroracemic acid, hydrazines of, 52.
—— —— indogenide of, 76.
Pyrostilpnite from St. Andreasberg, 403.
Pyrosulphuric chloride, heat of formation of, 250.
Pyrotartaric acid, action of aniline on, 1006.
—— —— new method of formation of, and a new reaction for, 1123.
—— chloride, reduction of, 297.
Pyrotartrylfluorescein, 1019.
Pyrotritartaric acid, action of bromine on, 993.
Pyroxene, cupriferous variety of, 272.
—— relation between the optical properties and chemical composition of, 971.
—— synthesis of, 1105.
Pyrroline, action of acetic anhydride and benzoic anhydride on, 1014.
—— action of alkaline hypochlorites and hypobromites on, 1367.
—— blue colouring matter from, 740.
—— derivatives, synthesis of, 1368.
—— dyestuffs, 1015.
—— group, 586.
—— series, decomposition-products of, 1045.
—— tetrachloro-, and the synthesis of, 292, 293.
Pyruvic acid, uvitonic acid from, 759.
—— ureïdes, 957.

Q.

Quartz, estimation of, in siliceous rocks and soils, 872.
Quartz-trachyte covered with a deposit from the Echinus Geyser, pebble of, 28.
Quassic acid, 1193.
Quasside, 1192.
Quassin and its constitution, 1192.
—— preparation of, 908.
Quercetin and its derivatives, 846.
—— derivatives of, 1365.
Quinaldic acid, and its salts, 185.
Quinaldine, and its derivatives, 756.
—— bases, 183, 1373.
—— dichloro-, 1028.
—— formation of, 1373.
—— homologues of, 1375.
—— methiodide, 181.
—— nitro- and amido-derivatives of, 1373.
—— preparation of, 183, 337.
—— preparation of, on the large scale, 337.
Quinaldinecarboxylic acids, and their salts, 1200.
Quinaldinosulphonic acids, 1373.
Quinaldines, preparation of, 757.
Quinidine, constitution of, 86.
Quinine, action of aromatic aldehydes on, 466.
—— —— of benzyl chloride on, 465.
—— and the formation of an anhydride from, 1381.
—— chloride, 1383.
—— compound of, with chloral, 186.
—— constitution of, 86.
—— ethylcyanide, 338.
—— mono- and di-chloracetate of, 465.
—— oxidation-products of, 1383.
—— phenolsulphonate, 339.
—— sulphate, assay of, 1080.
Quininic acid, 86.
Quinisatic acid, and its salts, 79.
Quinisatin, 78, 1029.
Quinisatoxim, 1029.
Quinizine-derivatives, constitution of, 1377.
Quinol, action of aniline on, 591.
—— —— phosphorus pentachloride on, 429.
—— mixed ethers of, 1138.
—— monochloro-, 429.
Quinoline, and its derivatives, 756.
—— bases formed by the addition of haloïd ethereal salts to, 1050.
—— bases, process for preparing dyestuffs from, 798.
—— compounds, 941.
—— derivatives of, 1018.
—— —— method for the synthesis of, 1050.

Saltpetre (potassium nitrate), deposit of, at Cochabamba, Bolivia, 1271.
Salts, certain, comparative nitrifying action of, 1417.
—— containing water, dissociation of, and relation of the dissociation to the molecular volume of the combined water, 952.
—— curves of solubility of, 807.
—— decomposition of, by water, 807.
—— dehydrating action of, 1251.
—— densities of solutions of, 251.
—— heat of hydration of, 803.
—— hydrated, electrolysis of, 654.
—— melting points of, 3.
—— neutral, relative absorption of, in the human stomach, 193.
—— of ammonium, the amines, the alkali metals, and the alkaline earths, physiological action of, 348.
—— of bivalent metals, freezing points of solutions of, 808.
—— of the alkali metals, freezing points of solution of, 701.
—— solubility of, 887.
—— —— in water at high temperatures, 254.
—— various, comparative nitrifying effect of, 924.
—— water of crystallisation of, 806.
Samarskite, analysis of, 111.
—— from Berthier Co., Quebec, 894.
Sanitation of large towns and value of the refuse matter from them, 642.
Santonous acid, products of the decomposition of, 327.
Saponetin, 334.
Saponin, and its acetyl-derivatives, 463.
—— from *Saponaria officinalis*, 332.
—— position of, in the roots of certain plants, 847.
—— products of decomposition of, 334.
Sarcosine, 994.
—— anhydride, and its salts, 994.
—— formation of urea from, 1394.
Sarcosine-mesouric acid, 1129.
—— bromo-, 1128.
Sarcosine-uric acid, 1128.
"Scab," in potatoes, 1419.
Scales of temperature and molecular weights, 804.
Scapolite and plagioclase minerals, chemical resemblance between, 567.
—— group, 566.
Scatole, synthesis of, 458.
—— transformation of, into indole, 458.
Schists, crystalline, of Kaiserberg, in Styria, 412.
Schreibersite, in the Cranbourne meteorite, 417.
Schweizer's solution, 957.
Scovillite, a new phosphate of didymium, yttrium, and other rare earths from Salisbury, Conn., 26.
Scovillite, and rhabdophane, identity of, 827.
Sea-mud, 106.
—— —— manuring with, 867.
Sea-water, influence of the salts of, on fresh-water animals, 620.
—— physical properties of, 889.
—— solid and gaseous constituents of, 31.
Secondary amines, action of sulphonic chloride on, 285.
Seed tubers, effect of drying, on the yield of potatoes, 624.
Seeds, effect of drying on the germination of, 629.
—— of forest trees, mineral constituents of, 353.
—— of Leguminosæ, occurrence of citric acid in, 1301.
—— of various sizes, plants from, 352.
—— ratio of nitrogen to phosphoric acid in, 1404.
—— relation between chemical metamorphosis and transformation of forces during the germination of, 1207.
—— valuation of, 200.
Selenium minerals, from Cacheuta, 406.
Separators (cream), comparison of, 1417.
Serradella at various ages, composition and digestibility of, 206.
Sesame seed, properties of, and behaviour of, in the animal system, 852.
Sèvres blue, manufacture of, 641.
Sewage, methods used for the disposal of, 612.
—— use of carbolic acid in the disinfection of, 697.
—— utilisation of, 1418.
Sewage-contaminated rivers, self-purification of, 932.
Sewer slime, manurial value of, 107.
Sheep, urine of, 1201.
Shellac, refining of, 380.
Silage, 864.
—— changes which take place in the conversion of hay into, 772.
—— composition of, 770.
Silent discharge, action of, on oxygen and nitrogen in presence of chlorine, 710.
—— —— compounds obtained by means of gas batteries and, 1242.
Silesian farm without cattle, 636.
Silfbergite, 409.
Silica, artificial pseudomorphism of, 895.
—— estimation of, in ores, 493.
—— function of, in the vegetation of maize, 201.

Silica, importance of, in the culture of oats, 1211.
—— soluble, preparation of, 958.
—— vitreous and ordinary amorphous, 1258.
Silicates, artificial production of, 564.
—— quantitative separation of potash and soda from ferric oxide, alumina, lime, and magnesia in, 110.
Silicon fluoride and hydride, spectra of, 649.
—— —— heat of formation of, 1246.
—— —— temperature of solidification of, 817.
—— line spectra of, 242.
Silken goods, process for finishing, with amber, 799.
Silkworms, development and nutrition of, 1202.
—— in their different stages, analyses of, 668.
—— Japanese (*Bombyx mori*), development and nutrition of, 667.
Silver chloride, action of light on, 1238.
—— —— bromide, and iodide, action of bromine and iodine on, 393, 556.
—— —— displacement of chlorine by bromine in, 1245.
—— compounds, with, S, As, and P, 156.
—— cyanide, detection of, 118.
—— —— reactions with, 118.
—— electrochemical equivalent of, 1089.
—— extraction of, from ores by means of sodium thiosulphate, 1084.
—— ferricyanide, reactions with, 118.
—— ferrocyanide, reactions with, 118.
—— iodide, dimorphism of, 16.
—— —— relation between the pressure and the temperature of transformation of, 1260.
—— nitrate and ammonia, 261.
—— —— reaction between mercuric cyanide and, in presence of ammonia, 168.
—— nitrite and ammonia, 157.
—— nitrocyanide, 168.
—— permeability of, to oxygen, 961.
—— toughening, in the melting crucible, 1445.
Sinapic acid, and its salts, 1387.
Sinapine, investigations on. I. Sinapic acid, 1387.
Skim-milk, estimation of the fat in, 1435.
—— —— utilisation of, 534.
Skrivanoff's cell (pocket form), 881.
Slag, basic, crystalline appearance of, 1085.
—— process for the recovery of, 1226.
Slags, formation and use of, 1226.
Slags, phosphatic, utilisation of, 783, 1228.
Sleepers, solution for the preservation of, 1233.
Smaltine from Schneeberg, 1100.
Soap analysis, 223.
Soap varnishes, 618.
"Soda caustique," Renz's, 1088.
—— industry, notes on, 643, 1412.
—— quantitative separation of, from ferric oxide, alumina, lime, and magnesia in silicates, 110.
Soda-lime, preparation of, 639.
Sodium, a new microchemical test for, 366.
—— alcoholate, heat of dissolution of, 4.
—— alcoholates and sodium salts of organic acids, action of carbonic oxide on mixtures of, 38.
—— —— heats of formation and dissolution of, 112.
—— arsenite and arsenate, behaviour of, with indicators, 869, 870.
—— bicarbonate, preparation of, 712.
—— calcium carbonate from the crude soda solution of Leblanc's process, 1412.
—— carbonate, artificial, history of the preparation of, from common salt, 16.
—— chlorate, pyroelectricity of, 3.
—— chloride as a manure, 926.
—— —— electrolysis of, 541.
—— —— —— and its industrial applications, 248.
—— fluorides, heat of formation of, 546.
—— hydrogen carbonate, estimation of, in presence of normal carbonate, 869.
—— hydroxide, estimation of small proportions of, in presence of large quantities of carbonates, 869.
—— —— preparation of, 15.
—— malonic ether, action of ethyl-α-bromisovalerate on, 123.
—— mercaptide, action of sulphur on, 1282.
—— nitrite, commercial, 514.
—— nitrosophenol, preparation of, 1003.
—— polysulphides, 1260.
—— stannate, analysis of, 498.
—— sulphate, formation of, in bricks, 127.
—— —— heat of dissolution of, 4.
—— —— maximum solubility of, 556.
—— sulphates, normal and acid, heats of solution of, 803.
—— thiosulphate, dimorphism of, 819.
Soil, arable, assimilation of the organic matter of, 208.

Soil, behaviour of zinc salts with plants and in the, 1408.
—— chemical changes in, 633.
—— effect of water holding sodium chloride and zinc sulphate in solution on, 856.
—— influence of a crop and shelter on the physical properties of, 922.
—— influence of artificial manures on the physical properties of, 210.
—— influence of the amount of, on the development of roots of various plants, 626.
—— of barley plots, nitrogen in, 687.
—— of bean plots, nitrogen in, 687.
—— of clover plots, nitrogen in, 687.
—— of root plots, nitrogen in, 687.
—— sandy, manuring with kainite and bone-meal, 868.
—— some of the changes which the nitrogenous matter in, experiences, 490.
—— temperature in relation to the air temperature, 357.
—— which had been removed from its original position and subsequently replaced, fertility of, 773.
Soils, analysis of, 921.
—— arable, estimation of phosphoric acid in, 871.
—— assimilability of the phosphoric acid in, 868.
—— at Rothamsted, nitric acid in, 357.
—— certain, in Japan, examination of, 680.
—— chemical study of, 677.
—— different, rich in humus, and their behaviour with water, 632.
—— heavy, raw, how to bring, into cultivation, 1412.
—— micro-organisms in, 486.
—— of experimental fields at Rothamsted, determinations of nitrogen in, and bearing of the results on the question of the sources of nitrogen of our crops, 682.
—— of experimental mixed herbage plots, nitrogen in, 690.
—— of experimental wheat plots, nitrogen in, 685.
—— of *Melilotus leucantha* and white clover plots, nitrogen in, 688.
—— phosphates in, 1424.
—— thermal conductivity of, 923.
—— use of gypsum and its mode of action as a dressing for, 1418.
Soja bean, notes on, 918.
Solar rays, influence of, on the temperature of trees, 917.
—— temperature, approximate estimation of, 241.
Solid bodies, perfect elasticity of, 255.
—— substances, solubility of, in water at various temperatures, 1090.
Solids and liquids and gases, a new relation between, 256.
—— determination of the density of, by means of the sp. gr. bottle, 213.
—— influence of pressure on the temperature of volatilisation of, 252.
Soluble substances in dilute solutions and water, attraction between, 1065.
Solution, nature of, 253.
—— thermal effect of, 1244.
Solutions, dilute, electrical conductivity of, 1241.
Solvents, general law of freezing of, 952.
Sorbin, action of cupric hydroxide on, 1112.
Sorgho-sugar making in America, 699.
Sorghum halepense, cultivation of, 921.
Sowing, effect of depth of, on the germination and growth of plants, 1401.
Spark-spectra emitted by metallic elements under varying conditions, 801.
Sparteine and its derivatives, 337.
Spathiopyrite and saflorite, identity of, 405.
Specific gravities of several organic compounds at temperatures near their melting points, 1089.
—— —— of normal salt solutions, 144.
—— heat of mellite, 1214.
—— volumes of saturated and unsaturated alkyl salts and hydrocarbons, 8.
—— —— of some double chlorides, 956.
—— —— of liquids, 147, 1252.
Spectra, infra-red, 1.
—— —— —— radiation, of metallic vapours, 1237.
—— of silicon fluoride and hydride, 619.
—— ultra-violet spark, emitted by metallic elements, and their combinations under varying conditions, photographic investigations of, 137.
Spessartite, artificial production of, 410.
Sphene, artificial production of, 565.
Spheroidal state, 957.
Spice, champion, 865.
Spices, examination of, 642.
Spirit, artichokes a source of, 526.
—— preparation of, 132.
Spyrogyra, albumin in, 313.
Splenic fever, inoculation against, with Pasteur's protective lymph, 914.
Spodumene from Dakota, 23.
Sprouting of grain, chemical changes induced by, 200.
Stables, Stassfurt salts as absorbents in, 491.

Standard soap solution, 1072.
Stannate of soda, analysis of, 498.
Stanno-platinic compounds, 823.
Stannous salts, estimation of, by potassium chromate, 1078.
—— selenide, action of hydrochloric acid on, 19.
—— sulphide, action of hydrochloric acid on, 18.
—— telluride, action of hydrochloric acid on, 19.
Starch, action of acetic anhydride and acetic chloride on, 420.
—— —— dilute acetic acid on, 284.
—— —— dilute hydrochloric acid on, 721.
—— behaviour of, in the presence of inorganic and organic acids, 36, 574.
—— behaviour of, towards gases, 1250.
—— estimation of, in food, 930.
—— iodine reaction of, 576.
—— manufacture of, 1234.
—— —— from maize, 528.
—— potato, preparation of, 134.
—— relation of red colouring matter of the phanerogams to the migration of, 1402.
—— soluble, 36.
—— varieties detected by the swelling process, 370.
Starch-grains, chemical nature of, 575.
Starch-paste and swollen starch, difference between, 576.
Starch-sugar, occurrence of, in a commercial raspberry-juice, 778.
Starches, &c., estimation of moisture in, 927.
Stature, influence of, on the interchange of matter and energy, 1393.
Stearic acid, amido-, 89.
Stearocutic acid, 859.
Stearoxime, 1115.
Stearyl chloride, 1126.
Steel, analyses of, 1231.
—— castings, evolution of gas from, 787.
—— modern processes for the manufacture of, and the properties and methods of testing these materials, 519.
—— new method of estimating carbon in, 1427.
—— so-called burning of, 935.
Stephanite, crystal of, from Wheal Newton, 405.
Sterile soil from California, 486.
Stibnite from Japan, 22.
Stomach, human, alteration of cane-sugar in, 91.
—— —— relative absorption of neutral salts in, 193.
Stone, artificial, preparation of, 379.
—— fruit, ratio of flesh to stone in, 477.
Stonework, process for preserving and colouring, 880.
Stony concretions in animals, 348.
Stratiotes aloides, constituents and properties of, and its use as a manure, 108.
Straw, aërobic and anaërobic fermentation of, 1412, 1413.
—— effect of high farming on the amount of nutritious matter in, 772.
Straw-litter and peat-litter, composition of, 1418.
Strontia process, recovery of sugar by, 133.
Strontia-sugar, production of, from molasses, by Scheibler's process, 1236.
Strontium compounds, recovery of, 394.
—— hydroxide, preparation of, 712, 1224.
—— monosaccharate, table of the solubility of, in water at different temperatures, 134.
—— oxysulphide, 1263.
—— separation of, from calcium, 497, 1077.
—— sulphate, process for working up, 1225.
—— —— solubility of, in acids, 813.
Strychnic acid, 188.
Strychnine, a product of the action of potassium permanganate on, 188.
—— behaviour of, in the animal organism, 188.
—— conversion of brucine into, 88.
—— ethylcyanide, 338.
—— solubility of, and preparation of some of its salts, 187.
Styphnic acid, derivatives of, 1004.
Styrene dibromide, orthonitro-, 66.
—— dibromo-, action of bromine-vapour on, 603.
—— orthonitro-, action of sulphuric acid on, 66.
—— paranitro-, and its dibromide, 604.
Styrolene, metanitro-, and its dibromide, 1175.
—— orthonitrochloro-, and orthamidochloro-, 1030.
Suberin, 860.
Sublimates, apparatus for obtaining, 364.
Subsoils at Rothamsted, nitric acid in, 357.
Succinic acid, di-isonitroso-, and its salts, 584.
—— chloride, action of phosphorus pentachloride on, 40.
Succinimide, derivatives of, 1115.
Succirubra bark, natural and renewed, analysis of, 919.

Sugar, action of carbonic anhydride on calcareous solutions of, 419.
—— analysis, 502, 503.
—— distribution of, in beet, and the position in the beet of the mean amount of sugar, 766.
—— *estimation of, in beetroot*, 642.
—— —— in pure aqueous solutions, 1219.
—— examination of, 1219.
—— factories, use of magnesium sulphite and ferric chloride in, 939.
—— improvements in the manufacture of, 1235.
—— recovery of, by the strontia process, 133.
—— refinery, working of, 791.
—— refining of, by means of concentrated acetic acid, 790.
—— separation of, from molasses, 133, 527, 1447.
—— sorgho-, making in America, 699.
—— Steffen's process for obtaining, from molasses, 1235.
Sugar-cane, researches on, 1212.
Sugars, action of cupric hydroxide on, 1111.
—— some reactions of, 778.
Sunflower-seed cake as fodder for milch cows, 483.
Sunlight, action of, on water and oil colours used in dyeing and printing, 700.
Sulphamineparapropylbenzoic acid and some of its salts, 456, 457.
α- and β-Sulphaminephthalic acid, derivatives of, 320.
Sulphanilazocumenol, potassium salt of, 1147.
Sulphides, conversion of, into sulphates, 1092.
—— formed by pressure, influence of repeated compression on the amount of, 959.
Sulphonic acids, amido-, aromatic, acetyl-derivatives of, 1024.
—— derivatives, action of chlorine on, 1127.
Sulphoparahydroxybenzoic acid and its salts, 446.
α- and β-Sulphophthalic acid and its salts, 320.
Sulphorthotolylazometacresol, 902.
Sulphur, action of, on oxides, 959.
—— atomic refraction of, 149.
—— compounds, certain, action of potassium permanganate on, 151.
—— —— volatile organic, analysis of, 1215.
—— crystallisation of, 889, 1254.
—— estimation of, in organic compounds, 500.
Sulphur, estimation of, in pyrites, 492.
—— experiments to combine sulphur with, 1255.
—— from the fumaroles of Montecito in the Island of Ischia, 1099.
—— *octohedral*, *solidification of*, 390.
—— oxychlorides, heat of formation of, 250.
—— red, 391.
—— salts derived from phosphorus trisulphide, 555.
—— Schaffner and Helbig's process for the recovery of, 228.
—— superfused, duration of the solidification of, 553.
—— —— solidification of, 389.
Sulphuric acid, action of, as a manure, 775.
—— —— as a manure, 926.
—— —— density of, 1256.
—— —— dilute, electrolysis of, 654.
—— —— estimation of, in presence of organic matter, 109.
—— —— formation of, in the lead chambers, 698.
—— —— Japanese, lead-chamber deposit from, 392.
—— —— loss of nitre in the manufacture of, 1222.
—— —— manufacture of, 126.
—— —— —— free from arsenic and selenium, 126.
—— —— —— from pyrites in America, 1082.
—— —— —— in America, 230.
Sulphurous acid and its salts, titration of, 776.
—— anhydride, compounds of, 1256.
—— —— in the air of Lille, 710.
—— chloride, conversion of, into disulphur dichloride, 1255.
Superphosphate as manure, 867.
Superphosphates, a cause of the differences noticed in the estimation of, 639.
—— action of, on the soil, 1071.
—— analysis of, 1426.
—— estimation of phosphoric acid in, 1424.
—— influence of, on the quality of the yield, 360.
—— retrogression of, 1214.
—— use of, 925.
Syenite, Biellese, presence of yttrium in the sphene of, 158.
Sylvic acid, and the hydrocarbon from it, 1364.
Synthetical mineralogical studies, 565.
Syntonin, 1388.
Syssiderite of Atacama, analysis of the rocky portion of, 414.

Syssiderite of Lodran, geological history of, 417.

T.

Tachylyte of the Western Isles of Scotland, 570.
Talc, alteration of, into anthophyllite, 272.
—— pseudomorphous after magnetite, 273.
Tannic acid, oakbark, 321.
Tannin, acetylisation of, 1178.
—— action of air on solutions of, 1438.
—— and oak-bark tannin, behaviour of, towards various reagents, 1355.
—— estimation of, 696, 1438.
—— extracts, examination of, 931.
—— function of, in plants, 628, 1209.
—— hemlock-, and some of its derivatives, 1025.
—— in hops, behaviour of, towards the albuminoïds in malt, 527.
—— oak-bark-, 1439.
Tannins, bark, and some of their derivatives, 1025.
Tartar emetic, substitute for, in dyeing, 796.
Tartaric acid, estimation of, 372.
—— —— from erythrol, attempt to obtain, by electrolytic oxidation, 297.
—— —— trustworthiness of Berthelot and Fleurier's method for the estimation of, 371.
—— glucoside, synthesis of, 1304.
Tartronamide, 1124.
Tartonic acid, derivatives of, 1123.
—— —— from glycerol, attempt to obtain, by electrolytic oxidation, 297.
Tellurium, reactions of, 663.
Tellurous anhydride, compounds of, with acids, 1256.
Temperature, effect of, on the electromotive force and resistance of batteries, 243.
—— influence of, on the rate of certain reactions, 1295.
—— radiation, and energy, relation between, 249.
—— regulator, 656, 883.
—— scale of, 804.
Temperatures, constant, in the soil, influence of, on plants, 916.
Tephroite, 972.
Terebic acid, and some of its derivatives, 459.
Terebilic acid, chloro-, and some of its salts, 460.
—— —— derivatives of, 459.
Terephthalaldoxime, and its ethyl- and acetyl-derivatives, 581.
Terephthalamidine, and its salts, 1158.
Terephthalic acid from isobutylbenzoic acid, 1010.
Terephthalonitrile, derivatives of, 1157.
Terpene, from isoamylamine, synthesis of, 1190.
Tertiary alcoholic iodides, some reactions of, 167.
—— amyl compounds, vapour-density of, 1119.
Tetracetamidodihydroxyphenylquinol, 309.
Tetracetamidodihydroxyphenylquinone, 309.
Tetracetylphenolglucoside, 439.
Tetradecylene bromide, 1108.
—— preparation of, 571.
Tetradecylidene, 1108.
Tetrahydrazoresorufin, 1334.
Tetrahydroanthracenecarboxylic acid, 330.
Tetrahydronaphthalenedicarboxylic acid ($\beta\beta$), synthesis of, 907, 908.
Tetrahydronaphthalenesulphonic acids, 608.
Tetrahydroquinaldine, and its derivatives, 183.
Tetrahydroquinolinemetacarboxylic acid, 1197.
Tetrahydrorthohydroxyquinaldine, and its derivatives, 1374.
Tetrahydrorthomethoxyquinaldine, 1374.
Tetrahydroxamylidene - phosphonium iodide, 1119.
Tetrahydroxethylidene - phosphonium iodide, 1119.
Tetrahydroxybenzene, nitramido-, 58.
Tetramethoxydiamidodiphenyl, and its derivatives, 1330.
Tetramethylallylalkine, 1114.
Tetramethylamidobenzene, 1320.
Tetramethylammonium cyanide, and double salts of silver cyanide with, 286.
—— —— and its salts, 338.
Tetramethylbenzene, 44.
—— and thiocarbimide and thiocarbamide of, 1320.
Tetramethylbenzidine, and its derivatives, 747.
Tetramethyldiamidodiphenylamine, oxidation of, 597.
Tetramethyldiamidotriphenylmethane, orthonitro-, 1315.
Tetramethyldiethylparaphenylammonium iodide, 178.
Tetramethylphenylene-safranine, 589.
Tetramethylpiperidine, moniodo-, 1290.
Tetramethylsulphonamide, 285, 286.
Tetramethylthionaniline, and its salts, 1141.
Tetramethyluric acid, 1310.

Tetraphenylethane, 1034.
—— unsymmetrical, 326.
Tetrethylallylalkine, 1111.
Tetrethyldiamidotriphenylmethane, orthonitro-, and its amido- and colour-base, 1316.
Tetrethylsafranine, 539.
Tetric acid, and its homologues, 41.
Tetronerythrin, 196.
Teucrin, action of nitric acid on, 332.
Thallium dihydrogen pyrophosphate, 397.
Thapsia resin, 460.
Thapsic acid, and its salts, 461.
Thebaïne, and its derivatives, 1201.
Thenardite, and preparation of the artificial variety, 969
Thermic substitution constants, law of, 883.
Thienyl, 586.
Thioaldehyde, oxidation of, 294.
Thiocarbamidazobenzene, 1149.
Thiocarbamide, compounds of, with metallic salts, 1017.
Thiocarbimides, action of, on amido-acids, 907.
Thiocarbonates, volumetric estimation of carbon bisulphide in, 1077.
Thiocyanates, estimation of, 501.
Thiodilactylic acids, 1298.
Thiodiphenylamine, and its derivatives, 595, 1156.
Thioeosin, 1025.
Thiofluoresceïn, 1025.
Thiohydracrylic acid, 1299.
Thioisophthalamide, 1157.
Thiolactic acids, and their salts, 1298.
Thiomolybdates, 161, 1268.
Thiophene, artificial formation of, and its derivatives, 15.
—— chloro-, and iodo-derivatives of, 1130, 1131.
—— condensation-products of, with aldehydes, methylal, and benzyl alcohol, 1000.
—— derivatives, nitration of, 1314.
—— group, 45, 586, 1130.
—— homologues of, 586, 1131.
—— iodonitro- and dibromodinitro-, 1314.
—— series, isomerism in, 1131.
—— simple condensation-products of, 586.
Thiophenecarboxylic acid, 46.
Thiophenenitrile, 46.
Thiophenesulphonic acids, 45, 1133.
—— —— derivatives of, 1130, 1133.
Thiophenic acid, 46.
Thiophthalic anhydride, 1025.
Thiosulphuric acid, estimation of, 492.
—— —— time of existence of, in aqueous solution, 554.
Thioterephthalamide, 1158.
Thiotolene, and di- and tri- bromo-, 1132.
Thomsenolite, 265, 716.
Thoria, separation of, from the other oxides, 111.
Thorite of Arendal, 406.
Thymodialdehyde, 57.
Thymol, derivatives of, 56.
Thymol-chloral, 187.
Thymoparacrylic acid, and its methyl-derivative and salts, 57.
Thyroïd gland of men and oxen, chemical constituents of, 1060.
Timbers, solution for the preservation of, 1233.
Tin, antimony, and arsenic, qualitative separation of, 777.
—— bromine compounds of, 1265.
—— brucine as a test for, 498.
Tinplate, estimation of lead in, 1078.
Tissues, determination of the rate of consumption of oxygen in, by means of the spectroscope, 1391.
Titanates, artificial production of certain, 564.
Titanic acids, gelatinous modification of, 1093.
—— —— influence of, on the fusibility of refractory earths, 784.
—— oxide, separation of alumina, ferric oxide and, 640.
Titanium, atomic weight of, 395.
—— double fluorides and oxyfluorides of, 264.
—— monosulphide, 1093.
Tobacco fat, 173.
—— manuring of, 362, 490.
—— smoke, wax-like body from, 173.
—— stems from Virginia, analysis of, 90.
Toluene, action of methylene chloride on, 1312.
—— —— the induction spark on, 1243.
—— bromiso-orthodiamido-, 1143.
—— chloronitro-, Wachendorff's, 1133.
—— purest, of commerce, sulphur compound in, 46.
—— tetra- and hexa-hydrides, from resin essences, 844.
Toluenedisulphonic acid, parabromo-, and its derivatives, 70.
Toluene-orthosulphinic acid, paramido-, and its salts, 454.
Toluene-orthosulphonamide, paramido-, and parachloro-, 73.
Toluene-orthothiosulphonic acid, paramido-, 454.
Toluene-parasulphinic acid, orthamido-, and its salts, 454.
Tolueneparasulphonamide, orthamido-, and its derivatives, 72.
—— orthochloro-, 72.

Tolueneparathiosulphonic acid, orthamido-, and its salts, 453.
Tolueneparasulphonic acid, orthochloro-, 73.
Toluenesulphamine, 451, 455.
Toluic acid, nitro-, from nitro-metaisocymene, 46.
Toluidine, nitro-, action of ethylene bromide on, 1142.
—— —— (m. p. 91·5°) prepared from liquid dinitrotoluene, 1316.
Toluidines, action of cyanogen on, 1141.
Toluquinoxaline, and its salts, 1053.
Toluquinoline, derivatives of, 1198, 1199.
Toluquinone, tribromo-, action of potassium hydroxide on, 175.
Toluylaldehydes, and their derivatives, 1161.
Toluylenediamine, 1316.
Tolyldiphenylcarbinolmetacarboxylic acid, 323.
Tolyldiphenylmethane, 322.
Tolyldiphenylmethanecarboxylic acid, 322.
Tolylstibine, and its derivatives, 1135.
Tolylthiobiuret, and its acetyl-derivative, 1140.
Topaz from Maine, U.S., 27.
Trachyte of Gleichenberg, action of water containing carbonic acid on, 569.
—— region of the Rhodope, 414.
Trees, influence of solar rays on the temperature of, 917.
Triacetonealkamine, preparation of, 1290.
Triacetonamine and its homologues, 1290.
Triacetonine, 1290.
—— nitroso-, 1290.
Triacetylformamidil, 723.
Triacetyl-triamidophenol, 309.
Tribenzoylmesitylene, 1000.
Tribenzoylmethane, 64.
Tribromhydrin, crude, a monobromoglycol obtained by the saponification of, 57.
Tricalcium phosphate, preparation of, 892.
Tricaprylamine, 985.
Tricarbopyridinic acid, and its salts, 758.
Triethoxybenzaldehyde, 68.
Triethoxybenzoic acid, 68, 1043.
Triethoxyphenylpropionic acid, 68.
a- and *β*-Triethylæsculetic acid, and their ethyl salts, 68.
Triethyldaphnetic acid, and its ethyl salt, 1042, 1043.
Triethylgallic acid, and its salts, 1335.
Triethylpyrogallocarboxylic acid, 1335.
Trihydroxydimethylpurin, 997, 998.
Trihydroxyoleic acid, and its salts, 239.
Triisobutylphenylguanidine, 1010.
Trimesitinic acid, and its salts, 738.
Trimethylazobenzeneammonium iodide, 1119.
Trimethylene-derivatives, 1154.
Trimethylene-ring, existence of, 992.
Trimethylamine aurochloride, 286, 577.
Trimethylenediamine, and its salts, 1289.
Trimethylenedicarboxylic acid, and its anhydride, 992.
—— —— and its ethyl salt, 832.
—— and vinylmalonic acids, identity of, 992.
Trimethylenediethylalkine, 1115.
Trimethylenemonocarboxylic acid, and its derivatives, 832.
Trimethylenetetracarboxylic acid, and its salts, 1300.
Trimethylenetricarboxylic acid, and its salts, 992, 1300.
Trimethylhydroxethylammonium hydroxide, 1202.
Trimethyl-leucine, periodide of, and the action of silver hydroxide on, 425.
Trimethylpiperidine, iodo-, 1291.
Trimethylpropylphenylammonium iodide, 1006.
Trimethylquinaldine, 1375.
Trimethyluric acid, 1309.
Trimethylvinylammonium hydroxide, 1202.
Trioctylamine, 984.
Trioxymethylene, 170.
Triparacresyl phosphate, 1338.
Triphenyl phosphate, trinitro-, 1338.
Triphenylamidomethane, action of halogens on, 1033.
—— and its derivatives, 1031, 1032.
Triphenylcarbinolcarboxylic acid, 323.
Triphenylethane, 837.
Triphenylethylamine, and its hydrochloride, 1031.
Triphenylguanidine, action of ethoxalyl chloride on, 1150.
Triphenylmethane, amido-derivatives of, 1031.
——violet derivatives of, 606, 749.
Triphenylmethane-anhydrocarboxylic acid, 323.
Triphenylmethanedicarboxylic acid, 323.
Triphenylmethyl bromide, reactions of, 1030.
—— thiocyanate, 1030.
Triphenylmethylamine, 809.
Triphenylmethyl-aniline, 1031, 1033.
—— nitroso-, 1031.
Triphenylmethylaniline-sulphonic acid, 1032.
Triphenylmethyl-benzylamine and its hydrochloride, 1081.

Triphenylmethyl-paratoluidine, nitroso-, 1032.
Triphenylmethyl-toluidines, 1032.
Triphenylphosphine oxide, nitro- and amido-, 1180.
Triphenylthiocarbamide, 1321.
Tripropylphenylguanidine, 1008.
Tritochlorite ? 24.
Tubes, coloured, for Nesslerising, 1072.
Tungsten compounds, reduction of, 559.
—— estimation of, 1429.
—— iron and steel, composition of, 1231.
Tungstoborates, new, 1266.
Turf fibre as cattle litter, 105.
Turkey-red dyeing and printing with alizarin, abridged process for, 1236.
—— —— oil, composition of, and its modes of action, 238, 946.
Turquoise found at Alexandria, 269.
Type metal, analysis of, 1429.

U.

Ulmin, natural and artificial, morphology and chemistry of, 923.
Ultra-violet absorption spectra of albuminoids, 242.
—— spark spectra emitted by metallic elements and their combinations under varying conditions, photographic investigations of, 137.
Ultramarine, in a fine state of division, similarity of the behaviour of, to that of metallic sulphides in the colloidal state, 147.
Umbelliferone, 1174.
Uranium compounds, 825.
—— mineral from Moss, and on the occurrence of uranates generally, 1102.
—— nitrate or acetate from residues, 397.
Urea and inorganic salts, excretion of, with the urine under the influence of an artificially increased temperature, 1394.
—— estimation of, 122, 507.
—— formation of, from sarcosin, 1394.
—— poisonous action of, 1398.
Uric acid, constitution of, 426, 1310.
—— —— derivatives of, 996, 1128, 1308.
Urinary pigment, a, 1059.
Urine, alkaline bismuth solution as a test for glucose in, 1433.
—— detection of mercapturic acid in, 1395.
—— dog's, estimation of chlorides and chlorates in, 1423.
Urine, elimination of hypophosphites by, 1058.
—— estimation of iodine in, 1423.
—— estimation of the total nitrogen in, 1440.
—— excretion of urea and inorganic salts with, under the influence of an artificially increased temperature, 1394.
—— extraction of indogitin and indirubin from, 1059.
—— hemialbumose in, 854.
—— influence of intellectual activity on the elimination of phosphoric acid by, 1394.
—— occurrence of glycerolphosphoric acid in, 1058.
—— of cows and sheep, 1204.
—— partially oxidised sulphur in, 347.
—— proportion of incompletely oxidised phosphorus contained in, 913.
—— source of hippuric acid in, 1057.
—— Volhard's volumetric estimation of chlorides in, 1424.
Urobilin, febrile, 197.
Uroerythrin, 198.
Urohæmatin, and Harley's, 197.
Uromelanin, 1060.
Urorubin, 1059.
Uvitonic acid, formation of, from pyruvic acid, 759.

V.

Valeric acid, α-isonitroso-, 42.
Valero-betaïne, derivatives of, 425.
Valerolactone, occurrence of, in pyroligneous acid, 1118.
Vanadates of the alkali-metals, preparation of, 395.
Vanadic acid, sulphur-derivatives, 1269.
Vanadio-molybdates, 561.
Vanadio-tungstates, 562.
Vanadio-vanadico-molybdates, 714.
Vanadio-vanadico-tungstates, 715.
Vanadium, diffusion of, in the mineral and vegetable kingdoms, 159.
Vanillin and dimethylaniline, condensation-product of, 1316.
—— preparation of, 1343.
Vapour, arising from electrified surfaces of liquids, electrical neutrality of, 243.
Vapour-densities, determination of, by gaseous displacement under low and variable pressures, 886.
Vapour-density apparatus, 956.

Vapours evolved on heating iron, &c., at atmospheric pressures, spectroscopic examination of, 801.

Variolite, at Hausdorf, in Silesia, 408.

Vasculose, 858.

Vaugnerite at Irigny (Rhone), 405.

Vegetable acids, part played by, in causing the turgescence of cells, 1064.

—— extracts, estimation of amides in, 1438.

—— fibres, method of imparting the appearance of silk to, 799.

—— juices and extracts, detection of asparagine and glutamine in, 373.

—— —— —— estimation of ammonia in, 373.

—— organisms, poisonous effects of arsenic, zinc, and lead, on, 1407.

—— tissues, behaviour of, towards gases, 1250.

—— —— constituents of, 858.

—— —— nature of the gases contained in, 670.

Vegetables used as food in Japan, and analyses of them, 674.

"Vegetaline," 1088.

Vegetation, influence of weather on, 856.

Verdigris, adulteration of, 1236.

Vermilion, explanation of the wet process for the manufacture of, 964.

Vesuvian, decomposition-products of, 566.

Vicia faba, occurrence of vicin in, 1405.

Vicia villosa, cultivation of, 769.

Vicin, occurrence of, in broad beans (*Vicia faba*), 1405.

Vine diseases and their remedies, 481.

Vinegar, testing for free sulphuric acid in, 215.

Vines, manuring, 103.

—— sulphuring of, 629.

Vineyards, artificial manures for, 637.

—— manuring of, 1421.

Vinyl bromide and tribromide, action of benzene on, in presence of aluminium chloride, 753, 754.

—— methyl ether, dichloro-, 1282.

Vinyldiacetonalkamine, 1291.

Vinyldiacetonamine, 1291.

Vinyldiacetonine, 1291.

Vinylmalonic acid, and its derivatives, 295.

—— —— and trimethylenedicarboxylic acid, identity of, 992.

Viola-quercitrin, a new glucoside, 1191.

Vitreous humour of the human eye, albuminoids in, 198.

Volcanic ashes from the last eruption of Krakatoa, 415.

Volcanoes of Northern California, Oregon, and Washington, 28.

Volhard's volumetric estimation of the chlorides in urine, 1424.

Voltaite, 1103.

Voltameter, weight, for measuring electric currents, 654.

Voltzine, crystallised, 1101.

Volume, change in, on melting, 1089.

Volumes, law of smallest, 12.

Volumetric analysis, 213.

Vulpic acid, derivatives and constitutional formula of, 841.

W.

Water, absorption of, by flower petals, 1403.

—— absorption spectrum of, 701.

—— analysis, the ammonia process for, 696.

—— attraction between soluble substances in dilute solutions and, 1065.

—— colour of, 259.

—— distilled, electrical conductivity of, 1241.

—— estimation of organic matter in, 369.

—— holding sodium chloride and zinc sulphate in solution, effect of, on the soil and on plants, 856.

—— microscopic examination of, for organic impurities, 221.

—— of a thermal spring in the Island of Pantellaria, analysis of, 1105.

—— of the Danube above Vienna in the year 1878, chemical composition of, 122.

—— of the new mineral springs at Freyersbach, composition of, 1274.

—— plants, constituents and properties of some, 108.

—— solvent action of, on zinc, and effects of drinking water contaminated with zinc, 878.

—— suspended matter in, 117.

Waterproof materials, preparation of, 379.

Waters, peaty, self-purification of, 781.

—— potable, protoistological examination of, 369.

Weeds in soils, 211.

Weight of a body, method of correcting, for the buoyancy of the atmosphere when the volume is unknown, 13.

Wheat, American, composition of, 1404.

—— chaff, digestibility of, and the changes which it undergoes by different methods of preparation, &c., 772.

Wheat, continuous cultivation of, at Woburn, 482.
—— crop, influence of rainfall on, 206.
—— experiments with, at Grignon, 1883, 1068.
—— germinated, chemical examination of, 1087.
—— Indian, 355.
—— manuring experiments with, 103.
—— meal, separation of, from rye meal, 376.
—— starch, elementary composition of, 284.
White iron, decomposition of, by heat, 1441.
—— lead manufacture, 1232.
Wine, analyses of, 645.
—— analysis, 1432.
—— chemistry of, 131, 1445.
—— detection of artificial colouring matters in, 370, 502.
—— —— Bordeaux red in, 370.
—— —— sulphurous anhydride in, 1440.
—— —— the colouring matter of Campechy wood in, 502.
—— estimation of acetic acid in, by distillation with steam, 641.
—— —— alum in, 1077.
—— —— free tartaric acid in, 501.
—— —— magenta and tannin in, 1432.
—— —— sugar in, by Fehling's solution, 502.
—— —— tartaric acid in, 504.
—— —— the dry extract of, 1432.
—— examination, 131, 501.
—— inferior, improvement of, by addition of the husks of superior grapes, 938.
—— plastered, 233, 646.
—— —— potassium tartrate in, and estimation of tartaric acid, 372.
—— reaction of ashes from, 642.
—— red, manufacture in Germany, 130.
—— reduction of extractive matter by clearing of, 938.
—— salicylic acid in, 778.
—— souring of, 646.
—— Tyrolese, 1883 vintage, extractive matter in, 130.
—— yeast, cultivated, 1399.
Wines and other vegetable and animal products, presence of manganese in, 879.
—— clouding and fining of, 233.
—— free from artificial colouring matter, presence of arsenic in, 526.
—— from Anjou, analyses of, 646.
—— of Médéah, analyses of, 1086.
—— from Palestine, &c., analyses of, 646.
Wines from sugar, 1086.
—— Lorraine, examination of, 131.
—— preservation of, 130.
—— testing for free sulphuric acid in, 215.
Winter flax, cultivation of, 921.
Withania coagulans, "rennet" ferment from the seeds of, 535.
Wollastonite, artificial production of, 564, 1262.
—— from Sardinia, 270.
Wood cellulose, manufacture of, 1451.
—— colour mordants for, 379.
—— constituents of, 860.
—— decayed, chemical changes in, 477.
—— elementary composition of certain kinds of, with a calorimetric investigation of their combustibility, 477.
—— products of the dry distillation of, at low temperatures, 788.
Woody fibre as fodder, 864.
—— —— test for, 118.
—— tissues, chemical composition, of 285.
Wool-dust, examination of, 637.
Wool washing works, utilisation of the waste waters from, 783.
Wormseed oil, 1363.
—— —— action of the haloïd acids on, 1363.

X.

Xanthine, bromo-, 467.
Xanthoquinic acid, 86.
Xenotime from Norway, 1101.
Xylene, orthodibromo-, and orthodichloro-, 1000.
—— tetrahydride, from resin essences, 844.
Xylenes, 1000.
—— coal-tar, English and Scotch, 898.
—— three, in coal-tar, analytical estimation of, 1431.
Xylic acid, bromo-, 1347.
Xylide, aceto-, 737.

Y.

Yarns, bleaching, 1234.
Yeast, action of air on, 939.
—— fermentative strength of, in distillery mash, 939.
—— cells, effect of the presence of certain organic substances on the respiratory combustion, 857.
—— influence of alcohol, and sulphuric and salicylic acids on, 476.

Yeast, pressed, preparation of, 132.
—— —— utilisation of malt combings in the manufacture of, 790.
—— sowing, the favourable temperature for, 789.
—— strong, preparation of, 789.
—— testing of, 931.
Yttrium, presence of, in the spenhe of Biellese syenite, 158.

Z.

Zeolites in the dolerites of Chaux-de-Bergonne (Puy-de-Dôme), 829.
—— production of, in the cold, 405.
Zephroite, artificial production of, 161.
Zinc amalgam, position of, in electro-potential series, 382.
—— arseniferous, purification of, 962.
—— atomic weight of, 256.
—— blende from Cornwall, Lebanon Co., Pa., 266.
Zinc, detection and estimation of, in presence of iron, 367.
—— electrolytical deposition of, 933.
—— electro-plating, with nickel, 231.
—— from pyrites residues, 788.
—— from Sagor, 1231.
—— in drinking water, 697.
—— iodide, sp. gr. of, 394.
—— isobutyl, boiling point of, 1117.
—— salts, behaviour of, with plants and in the soil, 1108.
—— solvent action of water on and effects of drinking water contaminated with, 878.
—— verification of the atomic weight of, 815.
Zinc-ethyl, action of, on amines and phosphines, 985.
Zincammonium compounds, manufacture of, and their technical application, 1232.
Zircon, disintegration of, 821.
—— from the itacolumite of Edge Hill, Pa., 270.

ERRATA IN VOL. XLIV.

Page	Line	
733		in the Abstract "**Mononitroresorcinol**," *read* "mononitrosoresorcinol" for "mononitroresorcinol" throughout.
785	15	from bottom, *for* "Freih" *read* "v. d. Pfordten."

ERRATA, VOL. XLVI.

Page	Line				
164	17	from	top,	*for*	"Zephroïte" *read* "Tephroïte."
168	18	„	bottom,	„	"A white, opaque, and silky crystalline precipitate" *read* "A white, opaque and a silky, crystalline precipitate."
257	5	„	„	„	"Trimethylamine" *read* "triethylamine."
781	13	„	top,	„	82·86 *read* 82·85.
